It is now common for internists to encounter patients with human immunodeficiency virus (HIV) infection with hyperlipidemia. Some series estimate that more than half of HIV patients treated with protease inhibitors for 2 years develop dyslipidemia, frequently with a redistribution of fat resembling that in genetic lipodystrophy syndromes (Chapter 396). Newer protease inhibitors appear to have fewer metabolic sequelae than older agents such as ritonavir. In addition to appropriate management of other risk factors, lipid-lowering therapy should be tailored to the ongoing HIV drug regimen. Pravastatin is least likely to interact with protease inhibitors but is less effective at lowering LDL cholesterol. Agents such as simvastatin that are substantially metabolized by the cytochrome P-450 3A4 system should not be used in patients treated with protease inhibitors because of delayed clearance of the statin. PPARα agonists such as fenofibrate can be used to lower triglycerides, but the effects are limited because their clearance is accelerated by protease inhibitor treatment.

Antipsychotics have complex effects on metabolism. Some of the newer agents used to treat schizophrenia promote hyperlipidemia, obesity, and insulin resistance. Although therapeutic decisions should be based on psychiatric responses, substituting for agents with prominent metabolic side effects, such as olanzapine, can improve lipid profiles.

Laboratory Evaluation

After an 8- to 12-hour fast (subjects should be told that it is acceptable to drink water and other calorie-free beverages during this period), total triglycerides, total cholesterol, HDL cholesterol, and LDL cholesterol should be measured. In most clinical laboratories, LDL cholesterol is still calculated using this formula: LDL = total cholesterol − HDL cholesterol − (triglycerides/5). This formula is not valid when triglycerides are greater than 400 mg/dL, however. It is also possible to measure LDL directly,

which is sometimes useful for monitoring the therapeutic effects on LDL alone, and this determination does not require patients to fast. Excessive lipid determinations may not be helpful. Biologic and random variability in cholesterol levels is considerable, and for patients with levels that are 19 mg/dL or more below their goal, serial monitoring is more likely to detect false-positive than true-positive increases over a period of 3 years.

What constitutes "normal" lipid levels is unknown. For triglycerides, the Adult Treatment Panel III of the National Cholesterol Education Program identified a normal triglyceride level as less than 150 mg/dL. Values from 150 to 199 are borderline high, 200 to 499 is considered high, and above 500 is very high. In patients with fasting triglycerides greater than 500 mg/dL, triglycerides are a primary target of therapy in order to decrease the risk of pancreatitis and chylomicronemia syndrome. These individuals are treated with a very low fat diet (usually 15% of calories from fat), an exercise program, a weight-loss regimen in the setting of obesity, glycemic control in the setting of diabetes, and either nicotinic acid or a fibrate drug alone or in combination with fish oils.

Risk Assessment

In 2001 the Adult Treatment Panel III identified therapeutic goals for LDL cholesterol levels based on the 10-year risk of coronary heart disease, and it updated these goals in 2004. High risk, with a greater than 20% probability of a vascular event in 10 years, includes those with coronary heart disease (myocardial infarction, angina of any type, previous coronary artery procedure, known myocardial ischemia) or a coronary heart disease equivalent (diabetes, carotid artery disease, abdominal aortic aneurysm, peripheral vascular disease, multiple risk factors indicating a 10-year risk >20%). For these high-risk patients, the LDL goal is less than 100 mg/dL; less than 70 mg/dL is an optional goal.

Risk factors for coronary heart disease include smoking, hypertension (or treatment for hypertension), family history of premature coronary heart disease (younger than 55 years in males, 65 in females), low HDL (<40), and age (older than 45 in men, 55 in women). For those with two or more risk factors and a calculated 10-year risk for coronary heart disease less than 20%, the LDL goal is less than 130 mg/dL. For those with one or no risk factors, the LDL goal is less than 160 mg/dL.

These recommendations are likely to be modified as new data are incorporated into practice. The most recent updates, as well as 10-year risk calculators that are useful for customizing recommendations for individuals patients, are available at http://www.nhlbi.nih.gov/guidelines/cholesterol.

TREATMENT Rx

General Measures

Intensive Lowering of Low-Density Lipoproteins

Randomized clinical trials support the concept that intensive LDL lowering is appropriate for patients with coronary heart disease and its equivalents. In the Heart Protection Study, those who entered the study with LDL less than 100 mg/dL benefited from further lowering of LDL with simvastatin.[1] In the Pravastatin or Atorvastatin Evaluation and Infection Therapy trial, patients with acute coronary syndrome derived greater benefit with an LDL of 62 mg/dL achieved with atorvastatin than with an LDL of 95 mg/dL achieved with pravastatin.[2] In the Treating to New Targets study, patients with stable coronary heart disease had fewer clinical events with an LDL of 77 mg/dL achieved with 80 mg of atorvastatin than with an LDL of 101 mg/dL achieved with 10 mg of the same drug.[3] Those with metabolic syndrome also accrued benefits in the Treating to New Targets study.[4] In the Incremental Decrease in End Points through Aggressive Lipid-Lowering study, there were fewer secondary end points among patients with stable coronary heart disease with an LDL of 81 mg/dL achieved with 80 mg of atorvastatin compared with an LDL of 104 mg/dL achieved with 20 mg of simvastatin.[5] In healthy individuals with LDL less than 130 mg/dL and C-reactive protein greater than 2 mg/dL, rosuvastatin (20 mg/day) reduced major cardiovascular events by 44% and all-cause mortality by 20%.[6]

Lifestyle Changes

Therapeutic lifestyle changes should be recommended as part of the treatment regimen. These include smoking cessation, weight reduction, exercise on most days of the week, reduced intake of dietary cholesterol to less than 200 mg/day, reduction of saturated fat to less than 7% of total calories, increased soluble fiber intake (to at least 10 g/day), and consumption of plant stanols or sterols (2 g/day).

Medical Therapy

Medications commonly used to treat lipid disorders are listed in Table 213-5.

Statins

Statins are by far the most effective. An analysis of results from 90,000 participants in statin trials suggested that the 5-year incidence of cardiovascular events decreases by about 1% for each 2 mg/dL decrease in LDL. The benefit appears to be independent of a patient's baseline lipid values. Patients at sufficient risk should be treated so that LDL is lowered by 30 to 40%, regardless of initial levels.

Statins are well tolerated. Up to 5% of patients have mildly elevated serum transaminases with therapy, which is usually asymptomatic and resolves

TABLE 213-5 MEDICATIONS USED TO TREAT LIPID DISORDERS

CLASS	SIDE EFFECTS	LIPID EFFECTS	SPECIFIC AGENTS (DOSE)
Statins (HMG-CoA reductase inhibitors)	Mildly increased liver enzymes, myalgias without evidence of muscle disease, constipation, insomnia, rhabdomyolysis (rare)	↓↓LDL, 18-55% ↑HDL, 5-15% ↓TG, 7-30%	Simvastatin (20-80 mg/day) Atorvastatin (10-80 mg/day) Pravastatin (20-80 mg/day) Fluvastatin (20-80 mg/day) Lovastatin (20-80 mg/day) Rosuvastatin (10-40 mg/day)
Nicotinic acid	Flushing, nausea, diarrhea, hyperglycemia, hyperuricemia, hepatotoxicity (rare)	↑↑HDL, 15-35% ↓↓TG, 20-50% ↓LDL, 5-25% ↓Lp(a), variable	Extended-release or crystalline niacin (1-2 g/day)
Fibrates	Mildly increased liver enzymes, dyspepsia, gallstones, hepatotoxicity (rare), rhabdomyolysis (rare)	↓↓TG, 20-90% ↑HDL, 10-20%	Gemfibrozil (1.2 g/day) Fenofibrate (34-200 mg/day)
Cholesterol absorption inhibitor	Hepatitis, abdominal pain, back pain, arthralgias	↓LDL, 18%	Ezetimibe (10 mg/day)
Bile acid sequestrants	Constipation, decreased absorption of some drugs	↓LDL, 15-30% ↑TG, variable ↑HDL, 3-5%	Colesevelam (2.5-3.75 g/day); this agent also approved for lowering glucose in type 2 diabetes Cholestyramine (4-16 g/day) Colestipol (2-16 g/day)
Fish oils	Eructation, dyspepsia	↓TG, variable ↑ LDL, variable	Omega-3-acid ethyl esters (variable)

HDL = high-density lipoprotein; HMG-CoA = 3-hydroxy-3-methylglutaryl coenzyme A; LDL = low-density lipoprotein; Lp(a) = lipoprotein (a); TG = triglyceride.

spontaneously. Therapy should be discontinued if elevations exceed three times the upper limit of normal or if patients have symptoms of liver dysfunction (especially fatigue and weight loss). Rhabdomyolysis is rare and more likely in the setting of concurrent treatment with azole antifungals, erythromycin, cyclosporine, and several other agents. Common side effects include constipation, abdominal pain, and difficulty sleeping. A substantial minority of patients treated with statins develop myalgias without physical findings or laboratory evidence of muscle dysfunction. The cause of this side effect is unknown. Patients with this complaint should be evaluated for hypothyroidism, vitamin D deficiency, rheumatologic disorders, and depression. The problem may be resolved by changing to a different statin or by stopping the medication, allowing symptoms to resolve, and restarting at a much lower dose with gradual increases over weeks.

Given the success of statins, it is not surprising that they are also formulated with other agents. Pravastatin with aspirin, atorvastatin with amlodipine, simvastatin or lovastatin with extended-release niacin, and simvastatin with ezetimibe are available as single pills. Outcome data for these combinations are not available. If both agents are indicated, these combinations can enhance compliance and decrease patients' copayment costs.

Nicotinic Acid

Nicotinic acid is a B complex vitamin required to prevent pellagra. When administered in high doses, it has potent triglyceride-lowering and HDL-elevating effects and a modest LDL-lowering effect. A once-daily extended-release form appears to be safe and effective. The most common side effect is flushing, which frequently diminishes over time. The intensity of flushing can be diminished with aspirin, by taking the medication with a small snack, and by avoiding hot beverages at that time. Nicotinic acid has been used safely with simvastatin in patients with vascular disease to induce atherosclerotic regression.

Fibrates

Fibrates are effective for lowering triglycerides in patients with very high levels who are at risk for pancreatitis, especially those who cannot tolerate niacin. These drugs increase HDL (although not as effectively as niacin) but also tend to increase LDL in patients with high triglycerides. The effects of fibrates in clinical trials have been mixed.[9] Many clinicians use fibrates with statins in high-risk patients with mixed hyperlipidemia, which should be done cautiously because of the increased risk of rhabdomyolysis with this combination. The combination of fenofibrate and simvastatin did not reduce nonfatal myocardial infarction, nonfatal stroke, or fatal cardiovascular events compared with simvastatin alone in patients with type 2 diabetes.[10]

Other Agents

Ezetimibe lowers both LDL and triglycerides, with minimal effects on HDL. It is effective at achieving additional LDL lowering when used in combination with a statin. However, there is currently no evidence that LDL lowering with ezetimibe provides a corresponding reduction in clinical events. In those with coronary disease or a coronary risk equivalent, combining extended-release niacin with statin therapy was superior to combining ezetimibe with statin therapy in terms of decreasing carotid intima-media thickness.[11] There were fewer cardiovascular events in the niacin-statin group.

Bile acid sequestrants have been shown to lower LDL and decrease cardiovascular event rates. They are especially effective when combined with statins. Acceptance by patients is limited because of gastrointestinal side effects. These agents also tend to elevate triglycerides and decrease the absorption of some drugs, an effect that is less of an issue with colesevelam.

Fish oils may be used as an adjunct in the therapy of patients with very high triglycerides. These omega-3 fatty acids, which occur naturally in cold-water fish, may work by activating PPARα. They tend to elevate LDL but may also have beneficial anti-inflammatory properties.

PRIMARY PREVENTION

The results of clinical trials (see Treatment) strongly support lipid lowering for secondary prevention, that is, preventing events in those with known disease. Data are less compelling for primary prevention, that is, preventing events in those without known disease. There is evidence that the use of a statin to lower lipids is effective for primary prevention in at least three groups: patients with multiple risk factors, individuals with type 2 diabetes, and middle-aged and older people with relatively low LDL levels in the setting of elevated C-reactive protein. In the Anglo-Scandinavian Cardiac Outcomes Trial—Lipid-Lowering Arm, subjects with hypertension and at least three other risk factors had fewer events with an LDL of 90 mg/dL achieved with atorvastatin than with an LDL of about 130 mg/dL in control subjects.[12] In the Collaborative Atorvastatin Diabetes Study, people with type 2 diabetes had fewer events with an LDL of about 75 mg/dL achieved with atorvastatin compared with placebo-treated subjects with an LDL of about 119 mg/dL.[13] In the Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin, men over the age of 50 and women over the age of 60 had fewer events and were less likely to die with an LDL of about 55 mg/dL achieved with rosuvastatin compared with placebo-treated subjects with an LDL of about 108 mg/dL.[8]

In short, there does not appear to be a threshold effect of LDL on atherogenesis. In people with established coronary heart disease and those with diabetes, reaching very low LDL cholesterol levels is desirable. The absolute value at which maximal benefit is reached is unknown, and higher doses of statins are associated with more side effects (especially increased serum transaminases), but some analyses assume that an LDL of 40 mg/dL represents no increased risk of vascular disease.

GLYCOGEN STORAGE DISEASES

JOSEPH I. WOLFSDORF AND DAVID A. WEINSTEIN

DEFINITION

Glycogen, a highly branched polymer of glucose, is the storage form of glucose in mammals. The major sites of glycogen deposition are skeletal muscle and liver. Several other tissues and organs, including cardiac and

smooth muscle, kidney, brain, and intestine, are sites of glycogen synthesis, which can be impaired in the glycogen storage diseases (GSDs).

EPIDEMIOLOGY

The overall frequency of the GSDs is approximately 1 per 20,000 to 25,000 births. Fifteen distinct types have been identified, and they are referred to by either the deficient enzyme or a numbering system that reflects the historical sequence of their description. All are uncommon, and some are extremely rare. Six types account for approximately 97% of GSD cases: GSD I (25%), GSD II (15%), GSD III (24%), GSD IV (3%), and GSD VI and IX (30%).

PHYSIOLOGY

Glucose transporter type 2 (GLUT2) predominates in the liver (and pancreatic beta cells) and has a high K_m (≈15 to 20 mmol/L); consequently, the free glucose concentration in hepatocytes increases in direct proportion to the increase in plasma glucose concentration. Glucose is rapidly phosphorylated by glucokinase to form glucose-6-phosphate, which is converted to glucose-1-phosphate, the starting point for glycogen synthesis (Fig. 214-1). Hepatic glycogen synthase catalyzes the formation of α-1,4-linkages, which elongate the chains of glucose molecules. A branching enzyme leads to the formation of α-1,6-linkages at branch points along the chain. The concentration of GLUT4 in the plasma membrane of skeletal muscle increases markedly after exposure to insulin and in response to exercise, resulting in increased glucose transport into skeletal muscle, where it is either oxidized to provide energy for contracting muscle or converted to glycogen.

In the intervals between meals and during the overnight fast, a cascade of enzymatic reactions (including adenylyl cyclase, phosphorylase *b* kinase, and cyclic adenosine monophosphate–dependent protein kinase) activates hepatic glycogen phosphorylase, the rate-limiting enzyme in glycogenolysis, leading to the formation of glucose-6-phosphate. Glucose-6-phosphatase catalyzes the terminal reaction of both glycogenolysis and gluconeogenesis, the hydrolysis of glucose-6-phosphate, thereby allowing glucose to be released from the liver into the systemic circulation. This process is critical for the maintenance of glucose homeostasis. Because muscle lacks glucose-6-phosphatase, it cannot release glucose for systemic use. Muscle glycogen is used to meet the energy requirements of contracting muscle and is a source of lactate, pyruvate, and alanine for gluconeogenesis early in starvation. The rate of glycogenolysis in muscle is most rapid during the first 5 to 10 minutes of exercise. As exercise continues and blood flow to muscle increases, blood-borne substrates (glucose and free fatty acids) become increasingly important sources of energy.

PATHOBIOLOGY

The glycogen storage diseases (GSDs) or glycogenoses comprise several inherited disorders of glycogen synthesis or degradation. All are autosomal recessive with the exception of a subtype of GSD IX that is X-linked. They are caused by mutations in the genes that code for enzymes involved in the synthesis or degradation of glycogen and may involve the liver, skeletal muscle, and the kidney. They are all characterized by an abnormal tissue concentration or structure (or both) of the glycogen molecule. Molecular genetic testing performed on DNA extracted from blood or saliva is used to diagnose all the common forms of GSD.

CLINICAL MANIFESTATIONS

Hepatomegaly and hypoglycemia are the principal clinical manifestations of the hepatic glycogenoses, whereas muscle cramps, exercise intolerance, easy fatigability, and progressive weakness are the major manifestations of the muscle glycogenoses. Features of the most common GSDs are shown in Table 214-1.

TREATMENT

Rx

The goal of treatment of the hepatic forms of GSD is to prevent hypoglycemia and glucose counter-regulation. The specific details of therapy depend primarily on whether normal gluconeogenesis can occur. In GSD I, abnormal glucose-6-phosphatase activity impairs both glycogenolysis and gluconeogenesis. In contrast, gluconeogenesis is intact in the other liver forms of GSD, allowing protein to be used as a substrate for endogenous glucose production.

Treatment of GSD I consists of providing a continuous dietary source of glucose to maintain blood glucose levels at 75 to 90 mg/dL before meals and overnight. Glucose concentrations must be maintained above 70 mg/dL to prevent counter-regulation, which causes the shunting of glucose-6-phosphate into alternative pathways, resulting in hyperlactacidemia, hyperuricemia, and hypertriglyceridemia. In infants, continuous glucose can be provided by frequent feeds during the day and continuous intragastric feeds at night via a nasogastric or gastrostomy tube. Beginning at 6 to 12 months of age, uncooked cornstarch (UCS), which is slowly digested and absorbed into

TABLE 214-1 PRINCIPAL FEATURES OF THE COMMON GLYCOGEN STORAGE DISEASES

TYPE*	DEFECTIVE ENZYME	CHARACTERISTIC CLINICAL FEATURES	HIGH-RISK POPULATIONS	THERAPY
0	Hepatic glycogen synthase	Liver small or normal in size, fasting ketotic hypoglycemia, postprandial hyperglycemia and hyperlactatemia	French Canadian Italian	UCS, especially at bedtime, with high-protein diet
Ia (Von Gierke's disease)	Glucose-6-phosphatase	Hepatomegaly, failure to thrive, growth retardation, severe hypoglycemia, lactic acidosis, hyperuricemia, hyperlipidemia	Ashkenazi Jew Mexican Chinese Japanese	UCS during the day and at night or continuous overnight intragastric feeding
Ib	Glucose-6-phosphate transporter	Same as type Ia; also neutropenia, recurrent bacterial infections, inflammatory bowel disease	Native American Iranian Jew	UCS as for type Ia; granulocyte colony-stimulating factor
II (Pompe's disease)	Lysosomal acid maltase (α-glucosidase)	Infantile form: severe generalized hypotonia, muscle weakness, hypertrophic cardiomyopathy leading to cardiorespiratory failure usually by age 1 yr Juvenile and adult forms: skeletal myopathy with slowly progressive muscle weakness; markedly increased serum creatine kinase	None	Intravenous enzyme replacement with recombinant human α-glucosidase
III (Cori's or Forbes' disease)	Debranching enzyme	Hepatomegaly, moderate to severe ketotic hypoglycemia, muscle weakness and wasting, hypertrophic cardiomyopathy (IIIa); increased transaminases without muscle involvement (IIIb)	Faroe Islander First Nation (Canada) Inhabitants of Indian subcontinent	High-protein diet with low-dose UCS supplementation
IV (Andersen's disease)	Glycogen branching enzyme	Clinically heterogeneous; typical presentation is liver disease in early childhood progressing to lethal cirrhosis; less common neuromuscular presentation is divided into four groups by age at onset: perinatal, congenital, childhood, adult	None	No specific treatment; liver transplantation has resulted in decreased glycogen storage in heart and skeletal muscle
V (McArdle's disease)	Muscle glycogen phosphorylase	Symptoms usually begin in adolescence or early adulthood with exercise intolerance, fatigue, myalgia, muscle cramps, muscle swelling; transient myoglobinuria due to rhabdomyolysis may occur after exercise; severe myoglobinuria may lead to acute renal failure; later in adult life, persistent and progressive muscle weakness and atrophy with fatty replacement occurs; increased serum creatine kinase	None	High-protein diet (50% carbohydrate, 25-30% protein); oral sucrose before sustained aerobic exercise may be beneficial
VI (Hers' disease)	Hepatic glycogen phosphorylase	Hepatomegaly; growth retardation; moderate ketotic hypoglycemia; increased serum transaminases, cholesterol, and triglycerides	Mennonite	UCS dosed to prevent hypoglycemia and ketosis
VII (Tarui's disease)	Muscle phosphofructokinase	Presents in childhood with fatigue, muscle cramps, exercise intolerance; rhabdomyolysis and myoglobinuria with strenuous exertion; increased serum creatine kinase; may have mild hemolytic anemia and mild hyperbilirubinemia; hyperuricemia	None	No specific treatment; avoid strenuous exercise
IX	Phosphorylase *b* kinase	Hepatomegaly, mild ketotic hypoglycemia, growth retardation, increased serum transaminases, hypercholesterolemia, hypertriglyceridemia; may be X-linked or autosomal recessive	Mayan	UCS dosed to prevent hypoglycemia and ketosis

*GSD types X-XIV are very rare disorders and are not presented here due to limited cases and lack of formal recommendations.
UCS = uncooked cornstarch.

the circulation as glucose, can be used as an alternative method of providing glucose. Initially, UCS is given every 3 hours. As children age, and guided by the results of periodic blood glucose and lactate monitoring, the interval between feeds is eventually increased to 4 to 6 hours. Galactose and fructose must be restricted because they cannot be converted to glucose, and large quantities may exacerbate the biochemical derangements. Optimal care usually ameliorates the biochemical abnormalities; however, if optimal dietary management does not lower serum uric acid and triglycerides to acceptable levels, treatment with allopurinol and gemfibrozil, respectively, is indicated. Neutropenia (Chapter 170) in GSD Ib responds well to low-dose granulocyte colony-stimulating factor therapy; however, untoward effects of therapy are common. The recommended starting dose (2.5 μg/kg/day) is therefore lower than in other conditions, and the lowest possible dose that prevents infection is used. An enterocolitis that resembles Crohn's disease (Chapter 143) occurs almost universally in GSD Ib, and mesalamine (Pentasa) is first-line therapy because small intestinal disease predominates.

Patients with the other forms of GSD utilize a high-protein diet (2 to 3 g/kg) supplemented with complex carbohydrates and UCS, which is typically administered every 6 to 8 hours to maintain glucose concentrations above 75 mg/dL. Because β-oxidation of fatty acids can occur in these forms of GSD, ketosis can develop rapidly, and UCS doses are titrated to maintain normal blood ketone concentrations (<0.3 mmol/L). Strict avoidance of fructose and sucrose is unnecessary; however, consumption of concentrated sweets is discouraged to avoid excessive storage of glycogen. This is particularly important in GSD III, because excessive glycogen storage has been associated with worsening of the associated hypertrophic cardiomyopathy.

Treatment of the muscle glycogenoses is shown in Table 214-1.

Management of Complications

Despite improvements in care, long-term complications are common in GSD I and III. Hepatic adenomas develop in the majority of patients with GSD I during adolescence or early adulthood; the tumors may gradually enlarge, undergo malignant transformation, or hemorrhage into the peritoneal cavity. Nephrocalcinosis and nephrolithiasis, caused by hypocitraturia, are also common and can be prevented by the use of oral citrate supplementation. Maintenance of optimal metabolic control can prevent renal tubular dysfunction, focal segmental glomerulosclerosis, gout, and osteoporosis.

In GSD III, hypertrophic cardiomyopathy develops in the majority of patients during mid-childhood. Hepatic adenomas develop in 25% of patients; cirrhosis and hepatocellular cancer are rare. Most patients with GSD III do not have myopathic symptoms during childhood or early adulthood. Progressive myopathy develops in most people in the third or fourth decade of life.

Short stature and osteoporosis are the only common complications in GSD 0, VI, and IX, but these can be prevented by maintenance of optimal metabolic control.

215 THE LYSOSOMAL STORAGE DISEASES

DONNA M. KRASNEWICH AND ELLEN SIDRANSKY

The lysosomal storage diseases encompass a group of more than 45 different inherited disorders, all sharing a defect in lysosomal function. Lysosomes are acidic, membrane-bound organelles present in the cytoplasm that contain enzymes that degrade macromolecules. These disorders ensue when one or more of the hydrolytic enzymes are deficient or when essential lysosomal transporters, receptors, cofactors, or protective proteins are defective or lacking. Typically, complex macromolecules, including glycolipids, mucopolysaccharides, and glycoproteins, are delivered to the lysosome, where they undergo sequential modification by a series of hydrolases. An enzymatic deficiency becomes clinically important when macromolecules accumulate owing to inadequate degradation. Different categories of defects resulting in lysosomal dysfunction are encountered in the lysosomal storage disorders, and examples of each type are listed in Table 215-1.

Although most lysosomal storage disorders are quite rare, as a group their frequency is estimated to be 1 per 7000 to 8000 live births. This is an underestimate, because milder or attenuated forms of these disorders are often not identified. All the disorders have an autosomal recessive pattern of inheritance, with the exception of Fabry's disease and Hunter's disease (mucopolysaccharidosis [MPS] II), which are X-linked. As a whole, these disorders are characterized by a vast spectrum of manifestations, often causing them to evade diagnosis. Many were traditionally classified into infantile, juvenile, and adult types, based on the patient's age at the onset of manifestations, but atypical presentations complicate these distinctions. Among the factors contributing to this phenotypic diversity are the amount of residual enzyme activity, cellular localization of the enzyme, genotype, and the genetic background of the affected individual, as well as other genetic, environmental, or epigenetic influences.

With the advent of new therapies for some of the lysosomal storage disorders, establishing the diagnosis early is paramount. Suggestive clinical findings include coarse facial features; organomegaly; progressive loss of developmental skills; specific eye findings, including corneal clouding or a cherry red spot (of the macula); and skeletal abnormalities, notably dysostosis multiplex. Disorders associated with each of these findings are listed in Table 215-2. There should be a greater index of suspicion whenever these features occur in concert, the findings are progressive, or the patient appears dissimilar to other family members.

The diagnostic work-up includes a careful history, with analysis of the family pedigree and assessment of developmental milestones in childhood and adolescence. A family history of consanguinity, other affected siblings, or early deaths can aid in making the diagnosis. Ethnicity can be a helpful clue because some of the lysosomal disorders occur with increased incidence in specific populations, such as Ashkenazi Jews (Gaucher's disease type 1, Tay-Sachs disease, mucolipidosis type IV) and Scandinavians (mannosidosis, aspartylglucosaminuria, Salla's disease, Gaucher's disease type 3). On physical examination, special attention should be paid to head circumference, facial appearance, enlargement of the tongue, hepatosplenomegaly, skeletal manifestations (including kyphosis), broadening of the long bones, and stiffness of the joints. Skin evaluation may reveal angiokeratoma, especially around the umbilicus and in skin creases. The eye evaluation should include a funduscopic and slit lamp examination, as well as an assessment for atypical eye movements, which may be pathognomonic for disorders such as neuronopathic Gaucher's disease and Niemann-Pick type C. A careful neurologic and cognitive evaluation can be quite fruitful because some of the later presentations include dementia or psychiatric manifestations. Moreover, regression of milestones can provide an early diagnostic clue. Preliminary diagnostic studies include urine for thin-layer chromatography, a blood smear for vacuolated white blood cells, skeletal x-rays, and an ophthalmologic examination.

For the most part, the diagnosis of a specific lysosomal storage disorder is made by assaying enzymatic activity in a blood sample or fibroblast cell line. A lysosomal panel, evaluating the activity of multiple lysosomal enzymes from the same sample, should be the first-tier test. If a lysosomal storage disorder is still suspected, a tissue biopsy, most often of the bone marrow or liver, can be considered, although this is rarely indicated. Most of the genes encoding for the lysosomal enzymes have been identified, and mutation analysis is available. However, in most cases there is vast genotypic

TABLE 215-1 CLASSIFICATION OF LYSOSOMAL STORAGE DISORDERS BASED ON THE TYPE OF DEFECT*

SPHINGOLIPIDOSES
Fabry's disease (α-galactosidase)
Farber's disease (ceramidase)
GM_1 gangliosidosis/Landing's disease (β-galactosidase)
GM_2 gangliosidosis/Tay-Sachs disease (β-hexosaminidase A)
Sandhoff's disease (α-hexosaminidases A and B)
Gaucher's disease (glucocerebrosidase)
Niemann-Pick disease types A and B (sphingomyelinase)
Metachromatic leukodystrophy (arylsulfatase A)
Krabbe's disease (β-galactocerebrosidase)
LIPID STORAGE DISORDERS
Wolman's disease (acid lipase)
Neuronal ceroid-lipofuscinosis (adult)/Kufs' disease/Parry's disease (CLN4, heterogeneous)
MUCOPOLYSACCHARIDOSES
Type I/Hurler's disease (α-L-iduronidase)
Type II/Hunter's disease (iduronate-2-sulfatase)
Type III/Sanfilippo's disease (four different enzymes in the degradation of heparan sulfate defining types A-D)
Type VI/Maroteaux-Lamy disease (*N*-acetylgalactosamine-4-sulfatase)
Type VII/Sly's disease (α-glucuronidase)
OLIGOSACCHARIDOSES
Aspartylglucosaminuria (aspartylglucosaminase)
Fucosidosis (α-fucosidase)
α-Mannosidosis (α-mannosidase)
Schindler's disease (α-*N*-acetylgalactosaminidase)
Sialidosis I (sialidase)
Sialidosis II/mucolipidosis I (sialidase)
MUCOLIPIDOSES
Mucolipidosis II/I-cell disease (*N*-acetylglucosaminylphosphotransferase)
Mucolipidosis III/pseudo-Hurler (*N*-acetylglucosaminylphosphotransferase)
Mucolipidosis IV(*MCOLN1* mutation)
LYSOSOMAL GLYCOGEN STORAGE DISORDER
Glycogenosis type II/Pompe's disease (α-1,4-glucosidase)
LYSOSOMAL TRANSPORT DISORDERS
Sialic acid storage disease/Salla's disease (sialin/SLC17A5)
Cystinosis (cystine transporter)
Niemann-Pick disease type C (intracellular cholesterol transport)
MULTIPLE ENZYME DEFICIENCIES
Galactosialidosis (β-galactosidase and sialidase)
Multiple sulfatase deficiency/Austin's disease (sulfatases)

*Full chapters describing each of these disorders are available in Scriver CR, Sly WS, Childs B, Beaudet AL. *The Metabolic and Molecular Bases of Inherited Disease,* 8th ed. New York: McGraw-Hill Professional; 2001.

TABLE 215-2 MANIFESTATIONS OF LYSOSOMAL STORAGE DISORDERS

FINDING	DISORDERS
Hepatosplenomegaly	GM_1 gangliosidosis, Niemann-Pick disease, Gaucher's disease, Wolman's disease, fucosidosis, Pompe's disease, mannosidosis, multiple sulfatase deficiency, sialidosis, galactosialidosis, several mucopolysaccharidoses, cystinosis
Coarse facies	GM_1 gangliosidosis, fucosidosis, Pompe's disease, mannosidosis, multiple sulfatase deficiency, I-cell disease, several mucopolysaccharidoses, mucolipidosis II, sialic acid storage disease, aspartylglucosaminuria
Skeletal findings	GM_1 gangliosidosis, Gaucher's disease, fucosidosis, mannosidosis, sialidosis, galactosialidosis, several mucopolysaccharidoses, I-cell disease, mucolipidosis III
Cherry red spot	Infantile forms of GM_1 gangliosidosis, Sandoff's disease, Tay-Sachs disease, Niemann-Pick disease, sialidosis, galactosialidosis, I-cell disease
Corneal clouding	GM_1 gangliosidosis, several mucopolysaccharidoses, mannosidosis, I-cell disease, mucolipidosis III and IV, multiple sulfatase deficiency, galactosialidosis
Cognitive impairment	GM_1 gangliosidosis, Sandoff's disease, Tay-Sachs disease, Niemann-Pick disease, Gaucher's disease type 2, Wolman's disease, fucosidosis, mannosidosis, multiple sulfatase deficiency, sialidosis, galactosialidosis, several mucopolysaccharidoses, sialic acid storage disease, aspartylglucosaminuria, I-cell disease, mucolipidosis III and IV, Krabbe's disease, metachromatic leukodystrophy, neuronal ceroid-lipofuscinosis
Hematologic:	
Foam cells	GM_1 gangliosidosis, Niemann-Pick disease, Gaucher's disease, acid lipase deficiency, fucosidosis
Granulated/vacuolated WBCs	Several mucopolysaccharidoses, sialidosis, galactosialidosis, neuronal ceroid-lipofuscinosis, Niemann-Pick disease, Wolman's disease, fucosidosis, mannosidosis, aspartylglucosaminuria, I-cell disease, mucolipidosis III, multiple sulfatase deficiency
Psychiatric or behavioral manifestations	Several mucopolysaccharidoses (especially Sanfilippo), sialidosis, galactosialidosis, Fabry's disease, mannosidosis, neuronal ceroid-lipofuscinosis, metachromatic leukodystrophy, Tay-Sachs disease, Niemann-Pick disease type C
Newborn presentations	Gaucher's disease type 2; GM_1 gangliosidosis; Krabbe's disease; Niemann-Pick disease types A and C; mucopolysaccharidosis I, IVA, and VII; Pompe's disease; sialidosis types I and II; mucolipidosis I and II; Schindler's disease; Wolman's disease; infantile sialic acid storage disease; sialuria; Salla's disease; galactosialidosis; multiple sulfatase deficiency; prosaposin deficiency

WBC = white blood cell.

heterogeneity, and mutation screening is useful only when a mutation has already been identified in a specific family.

Improved care and new therapeutic modalities have transformed the natural history of several of these disorders. With patients' increased longevity, diseases that were once encountered only by pediatricians have now made their way to the offices of internists. Moreover, many of the classic complications are now avoided by early therapeutic interventions such as enzyme replacement therapy. However, in some instances, prolonged longevity has unmasked unanticipated clinical manifestations. Physicians' increased awareness of the range of manifestations and presentations of lysosomal disorders may lessen the long delays in diagnosis that patients frequently describe. Lysosomal disorders encountered in adult patients are discussed here, with a focus on Gaucher's disease and Fabry's disease. A brief discussion of specific disorders frequently diagnosed during adulthood, as well as childhood-onset lysosomal disorders that persist through adulthood, is included.

GAUCHER'S DISEASE

Gaucher's disease, the autosomal recessively inherited deficiency of the lysosomal enzyme glucocerebrosidase, is a disorder primarily of the reticuloendothelial system. Lysosomes within macrophages become engorged with the substrate glucocerebroside, giving rise to the characteristic Gaucher cells, with a wrinkled-paper appearance resulting from intracytoplasmic substrate deposition. The accumulated glycolipid glucosylceramide derives from the degradation of senescent leukocytes or erythrocyte membranes. Clinically, Gaucher's disease has been divided into three types, based on the absence or presence and the rate of progression of neurologic involvement. Type 1, the non-neuronopathic form, is the most common type and can manifest at any age. Type 2, the acute neuronopathic form, presents before or shortly after birth and has a rapid and progressive course. Type 3 is the subacute neuronopathic form. The spectrum of manifestations encountered in this disorder ranges from asymptomatic octogenarians to infants that succumb in utero, and some patients defy classification into one of the three types. It is a panethnic disorder, although type 1 Gaucher's disease is more frequent among Ashkenazi Jews, where the carrier frequency is about 1 in 16; in contrast, the approximate carrier frequency in the general population is 1 in 100.

The gene encoding glucocerebrosidase *(GBA)* is located on chromosome 1q21, and more than 300 different mutations have been found in patients. Several mutations are encountered with increased frequency in type 1 Gaucher's disease; for example, among Ashkenazi Jews, mutation N370S is the most common allele. However, the mutations identified do not adequately account for the range of manifestations encountered.

In recent years, an association between Gaucher's disease and parkinsonism (Chapter 416) has been reported. Both patients with Gaucher's disease and carriers of mutations in *GBA* have a higher incidence of Parkinson's disease and Lewy body disorders. Studies in cohorts of patients with Parkinson's disease around the world demonstrate that they have a greater than five-fold increased frequency of *GBA* mutations, rendering this the most common genetic risk factor for parkinsonism identified to date.

CLINICAL MANIFESTATIONS

Commonly encountered symptoms in all types of Gaucher's disease include easy bruisability, hepatomegaly, splenomegaly, chronic fatigue, and bone pain or pathologic fractures. Laboratory findings include anemia, thrombocytopenia, and elevations of ferritin, acid phosphatase, angiotensin-converting enzyme, and, at times, liver enzymes. Painless splenomegaly is the most common presentation in patients with type 1 Gaucher's disease, and the spleen can be massively enlarged. Occasional patients have pulmonary involvement or pulmonary hypertension. Bone involvement is a significant cause of morbidity and can manifest with extreme bone pain or pathologic fractures. Most patients have radiologic evidence of skeletal involvement, including the classic Erlenmeyer flask deformity of the distal end of the femur and osteopenia (Fig. 215-1A). Pathologic fractures, especially of the hip or spine; lytic bone lesions; and osteoporosis may occur. Painful bone crises, episodes of bony infarcts, can last for weeks and may require aggressive pain management.

Type 2 disease, which is rare, is characterized by a rapid neurodegenerative course with extensive visceral involvement; death usually occurs within the first 2 years of life. The disease is diagnosed prenatally or in infancy and is associated with increased tone, strabismus, and organomegaly. Failure to thrive and stridor from laryngospasm are typical. Progressive psychomotor degeneration leads to death, usually secondary to an intercurrent respiratory infection and respiratory compromise.

Type 3 disease is clinically variable and is often noted in infancy or childhood. In addition to organomegaly and bone involvement, patients have abnormal horizontal eye movements, and some develop myoclonic epilepsy or neurodegenerative manifestations. A subgroup of patients has cardiac calcifications, hydrocephalus, and other atypical manifestations, and all carry the mutation D409H in the *GBA* gene.

DIAGNOSIS

Gaucher's disease should be considered in the differential diagnosis of patients of all ages with unexplained organomegaly, easy bruisability, or bone pain. The diagnosis can be made by demonstration of deficient glucocerebrosidase activity in leukocytes or cultured cells. In some populations, particularly Ashkenazi Jews, mutation analysis can be diagnostic, and mutation N370S accounts for about 70% of mutant alleles. However, the presence of a highly homologous pseudogene sequence nearby can complicate molecular analyses. Bone marrow and liver biopsies show pathologic changes

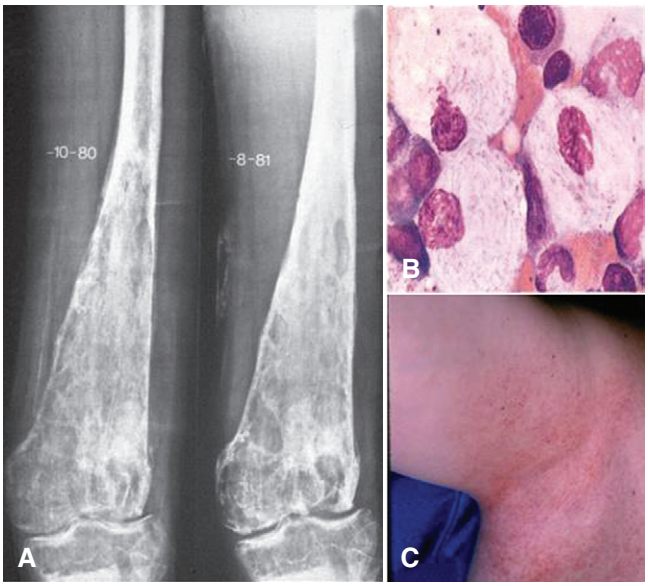

FIGURE 215-1. **A,** Radiographic image showing the Erlenmeyer flask deformity seen in Gaucher's disease. There is cortical thinning and widening of the medullary cavity of the metaphysis and adjacent diaphysis. **B,** Gaucher cells—reticuloendothelial cells storing abnormal amounts of lipid. **C,** Angiokeratomas, the nonblanching punctuate skin lesion seen in Fabry's disease.

(Fig. 215-1B) but are not indicated for diagnosis. Carrier identification is best achieved by DNA testing when the mutant allele is known. Prenatal diagnosis is possible by determining the enzymatic activity or specific mutations in chorionic villi or cultured amniotic fluid cells.

TREATMENT Rx

Enzyme replacement with recombinant glucocerebrosidase is available for the treatment of symptomatic patients with type 1 disease. Studies show that anemia, thrombocytopenia, and organomegaly are reversed within 12 to 36 months using enzyme doses between 30 and 120 IU/kg given monthly. The treatment is ongoing, administered intravenously, and extremely expensive. Several companies are now testing different forms of recombinantly produced enzyme. The enzyme does not cross the blood-brain barrier and does not alter the neurologic progression of patients with neuronopathic forms of Gaucher's disease, but it can still be useful in alleviating visceral manifestations. Efforts are also under way to develop alternative therapies, including substrate reduction therapy, chemical chaperones, and gene therapy. One oral form of substrate reduction therapy, an iminosugar derivative, has been approved and is efficacious for some of the systemic manifestations of type 1 Gaucher's disease. Useful supportive therapies include bisphosphonates for osteoporosis, orthopedic surgery for bone fractures, and palliative therapy and hydration for bone crises. Total or partial splenectomy, once commonly performed in patients with Gaucher's disease, is now rarely indicated. Bone marrow transplantation (Chapter 181) has improved systemic but not neurologic manifestations.

FABRY'S DISEASE

Fabry's disease, an X-linked inherited deficiency of the lysosomal enzyme α-galactosidase A, has intermediate penetrance in females and is considered a systemic vascular disorder. This defect in the hydrolytic cleavage of the terminal molecule of galactose from glycolipids causes lysosomal accumulation of globotriaosylceramide and galabiosylceramide in many cell types. Lysosomal inclusions or lipid deposits can be seen in vascular cells, including both endothelial and smooth muscle cells; cardiac cells, including endocardial cells, cardiomyocytes, and cardiac valves; kidney epithelial cells, including tubular and glomerular cells and podocytes; and nerve cells, including dorsal root ganglia and some central nervous system neurons. Clinically, angiokeratomas—nonblanching, punctate, blue-black skin lesions—debilitating pain, and corneal opacities can occur in early childhood and may lead to the diagnosis. If the diagnosis is missed, the disease can result in progressive renal and cardiac deterioration. Patients have a propensity to develop ischemic stroke, sometimes in their 20s but more commonly in the fourth and fifth decades of life. As with many metabolic disorders, there is a spectrum of presentations that can mimic more common disorders, and many patients are undiagnosed. The disease incidence is about 1 in 117,000 live male births. Evidence suggests that 50% of females with Fabry's disease are asymptomatic or are not identified.

The gene encoding α-galactosidase A, *GLA*, is located on Xq22.1. More than 431 mutations have been described, including missense/nonsense mutations, small deletions, large deletions, splice defects, and complex rearrangements. Most affected individuals may have 2 to 25% residual activity, but the most severe form of Fabry's disease has been correlated with complete absence of α-galactosidase A activity.

CLINICAL MANIFESTATIONS

Fabry's disease typically presents in childhood with episodes of extremity pain. Angiokeratomas develop in adolescence, followed by progressive renal and cardiac deterioration. Adults may experience ischemic strokes, initially occurring between their 20s and 50s. Acroparesthesia, or a "Fabry crisis," occurs in the majority of patients and is characterized by excruciating, burning pain that may be either continuous or episodic. The pain typically affects the feet first, followed by the hands, and may be triggered by exercise, stress, and extremes in environmental temperatures. Abdominal or flank pain, simulating renal colic, may occur.

Angiokeratomas (Fig. 215-1C) are often the first sign of Fabry's disease and are accompanied by hypohidrosis. These classic skin lesions increase in number and size over time and are typically most dense between the umbilicus and the knees; however, they may occur anywhere, including the buccal mucosa. Ophthalmologic findings include conjunctival and retinal tortuosity and corneal opacities (cornea verticillata). Characteristic lenticular lesions are observed during slit lamp examination and are present in affected males and 70% of female heterozygotes. Progressive hearing loss is also common.

Renal involvement manifests as progressive proteinuria with birefringent "Maltese crosses" in the urinary sediment. Declining glomerular filtration rates lead to end-stage renal disease in the second to fourth decades. Hyperfiltration precedes the decline in renal function. Cardiovascular findings may include decreased exercise capacity, hypertension, progressive hypertrophic cardiomyopathy, conduction defects and arrhythmias, and valvular disease (insufficiency or stenosis). Abnormal electrocardiograms and echocardiography are common. Affected individuals have an estimated twenty-fold increased risk of ischemic stroke and transient ischemic attacks compared with the general population. Asymptomatic lesions of the brain, typically in white matter, are often seen on magnetic resonance imaging.

The intermediate penetrance of this X-linked disorder is reflected in the fact that 70% of females carrying the mutation have symptoms. Affected or carrier females have more variable and less severe symptoms with a later onset, but they may develop progressive renal disease, cardiac symptoms, and stroke.

DIAGNOSIS

Fabry's disease should be considered in individuals with angiokeratoma, acroparesthesia, and corneal lesions, as well as in patients with cryptogenic strokes, idiopathic cardiomyopathy, or renal disease. However, the identical corneal abnormalities can result from the use of chloroquine or amiodarone, and exposure to silicone dust can result in similar renal findings. Angiokeratoma should be differentiated from Fordyce's disease, benign angiokeratomas of the scrotum, and angiokeratoma circumscriptum. Angiokeratomas are also seen in mannosidosis, fucosidosis, sialidosis, and β-galactosidase and β-hexosaminidase deficiency. A presumed diagnosis can be confirmed by low α-galactosidase activity in peripheral white blood cells or cultured skin fibroblasts. Levels below 20% of normal should be considered diagnostic, and levels 35% of normal should be considered suspicious. *GLA* mutation analysis is available and is critical for confirmation in heterozygote females because random X chromosome inactivation may lead to only slightly reduced or normal enzyme activity.

TREATMENT Rx

Symptomatic treatment of the clinical manifestations of Fabry's disease should follow standard medical care. Antiplatelet agents such as clopidogrel and aspirin or long-acting dipyridamole should be used for the prevention of strokes in individuals with Fabry's disease. The use of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers is appropriate to manage hypertension and preserve renal function. Renal transplantation is effective in individuals with end-stage renal disease. Neuropathic pain can be treated with

relatively low doses of antiepileptic medications, antidepressants, topical anesthetics, or pain relievers.

Enzyme replacement therapy has been available since 2001, and evidence continues to be gathered about its efficacy in modifying the natural course of the disease. Enzyme replacement therapy appears to slow the decline in renal function, but there is no evidence thus far that it can change the progression of cardiac disease; nor has a reduction of stroke risk been demonstrated. Treatments targeted at chaperoning the enzyme to the lysosome to enhance enzymatic degradation are in development.

OTHER LYSOSOMAL DISORDERS FREQUENTLY ENCOUNTERED IN ADULTS

Metachromatic leukodystrophy, the deficiency of arylsulfatase A, results in the accumulation of sulfatides in the central and peripheral nervous systems, leading to demyelination of axons and peripheral nerves. It presents with a spectrum of manifestations, divided into childhood and adult variants. In both, gait disturbance and cognitive regression are seen. The adult form is associated with behavioral disturbances and dementia, often mistakenly resulting in a diagnosis of psychosis. Metachromatic leukodystrophy is a recognized underlying cause of psychiatric illness in adults, and prominent features include auditory hallucinations, bizarre delusions, behavioral changes, personality changes, disinhibition and disorganization in daily life, and catatonic posturing. The diagnosis can be especially difficult in these individuals. Other neurologic signs such as dysarthria and spasticity present later as the disease progresses. The diagnosis is made initially by demonstrating low arylsulfatase A activity. However, because there can be a pseudodeficiency, it must be confirmed by molecular diagnosis or the demonstration of the excretion of sulfatides in urine.

Tay-Sachs disease, caused by β-hexosaminidase A deficiency, is characterized by an excessive accumulation of the fatty acid derivative ganglioside GM_2 in neurons. There are three clinical variants, based on the age of onset: type 1—infantile acute, type 2—subacute (2 to 18 years), and type 3—late onset. The main features of the disease are neurologic and cognitive deterioration, as well as blindness, the macular "cherry red spot," and deafness. In patients with late-onset GM_2 gangliosidosis, psychiatric signs can manifest years before the appearance of motor signs. The most common psychiatric signs include acute psychosis, mania, and depression without psychosis. Either recurrent progressive psychosis, consistent with schizophrenia-hebephrenia, or major depression followed by psychotic features may occur. Dysarthria and progressive speech loss are also common. The disorder is diagnosed by measuring β-hexosaminidase A activity in the serum or white blood cells in the presence of normal or elevated activity of the β-hexosaminidase B (HEX B) isoenzyme. In pregnant women or those taking oral contraceptives, the test should be performed only in leukocytes.

Niemann-Pick disease type C has a spectrum of features, ranging from a rapidly progressive, fatal neonatal phenotype to an adult-onset chronic, neurodegenerative course. Progressive ataxia, vertical supranuclear ophthalmoplegia, dystonia, and dementia are variable. Hepatosplenomegaly is frequently encountered. The disorder results from an error in cellular trafficking of exogenous cholesterol, leading to lysosomal accumulation of unesterified cholesterol. The diagnosis is made by demonstrating impaired cholesterol esterification in cultured fibroblasts or by molecular genetic testing for mutations. Glycosphingolipids and cholesterol accumulate in different tissues such as the liver, spleen, bone marrow, and brain. In adults, psychiatric manifestations consistent with acute psychosis, paranoid delusions or schizophrenia with delusions, hallucinations, disorganized behavior, and aggressiveness are observed.

Aspartylglucosaminuria, a disorder more common in Finland than elsewhere in the world, is an autosomal recessive defect in glycoprotein degradation characterized by a slow or progressive delay in psychomotor development. Delayed speech and motor defects are often accompanied by repeated upper respiratory infections. Patients typically achieve the developmental competency of a 5- to 6-year-old child at around puberty; subsequently, they may experience progressive deterioration, resulting in the severe cognitive impairment seen in adulthood. The characteristic coarse facial features, thick calvaria, and osteoporosis result from mild connective tissue transformation. About 20% of patients experience seizures during the later stages of the disease, resulting primarily from abnormalities in the differentiation between gray and white matter and delayed myelination. The diagnosis is made by the detection of elevated urine oligosaccharides and deficient aspartylglucosaminidase activity in leukocytes.

The neuronal ceroid-lipofuscinoses are divided into four major groups—infantile, classic late infantile, juvenile, and adult—reflecting the age of symptom onset and the appearance of storage material on electron microscopy. Although generally inherited in an autosomal recessive fashion, the adult type can be inherited as a dominant allele. These diseases are characterized clinically by visual impairment leading to blindness, gait abnormalities, seizures, dementia, and early death. They are a genetically heterogeneous group of progressive, hereditary neurodegenerative diseases with a variable onset. To date, approximately 160 mutations causing neuronal ceroid-lipofuscinoses have been found in eight human genes, complicating genetic analysis. Symptoms result from deficiencies in palmitoyl-protein thioesterase 1 and tripeptidyl-peptidase 1. The diagnosis is based on diminished enzyme activity and molecular genetic testing and, in some cases, on clinical findings and electron microscopy of biopsied tissues. Accumulation of autofluorescent ceroid lipopigments is seen in the brain and other tissues. Adult patients may exhibit behavioral disturbances and cognitive decline, and parkinsonian features may be prominent.

Pompe's disease is discussed in Chapters 214 and 429.

The mucopolysaccharidoses are a group of disorders resulting from defective lysosomal degradation of glycosaminoglycans. These chronic, progressive storage disorders show clinical manifestations that vary by type. Findings include coarse facial features, dysostosis multiplex, organomegaly, and neurologic manifestations with regression. All types are inherited in an autosomal recessive pattern except for MPS II/Hunter, which is X-linked. The mucopolysaccharidoses were once typically thought of as pediatric disorders, but with the advent of enzyme replacement therapy and the recognition of milder forms, more patients are reaching adulthood. Classically, patients with MPS type IS/Scheie, II/Hunter, III/Sanfilippo, IV/Morquio, and VI/Maroteaux-Lamy may have life expectancies beyond the pediatric years. Patients with MPS IS may present with normal to short stature, normal intelligence, degenerative joint disease, corneal opacities, and cardiac valve lesions. Patients with MPS II/Hunter share the symptoms of MPS I/Hurler, except that airway involvement may be more significant in individuals with Hunter's syndrome, and the corneas are clear. Patients with MPS III/Sanfilippo have primarily central nervous system manifestations, with mild somatic involvement. They have progressive speech impairment, with the development of severe behavioral and sleep disturbances. Later they have unrelenting loss of skills and deterioration into a vegetative state, with death in the third decade. Individuals with MPS IV have severe skeletal dysplasia, with normal intelligence in type A and a degenerative course in type B. Trials exploring enzyme replacement therapy are ongoing for MPS IS, MPS II, and MPS IV. Medical management is type specific. Generally, attention should focus on airway involvement resulting from progressive storage in the soft tissue of the upper airway and the need to optimize joint mobility and function by physical therapy. Patients with MPS I, II, and VI should be monitored for the development of cervical myelopathy due to dural thickening, which may lead to loss of endurance before ascending paralysis becomes apparent.

Cystinosis is a lysosomal storage disorder with three clinical phenotypes: the most common infantile or nephropathic form, an intermediate or juvenile-onset form, and a benign form typically seen in adults and affecting primarily the eyes. Lysosomal cystine accumulation results from mutations in the gene *CTNS*, which codes for cystinosin, a lysosomal carrier protein. Individuals with the nephropathic form have lysosomal cystine accumulation leading to multiorgan system involvement, including progressive renal disease, corneal crystals, and effects on the thyroid, gonads, pancreas, muscle, and central nervous system. The adult form has only corneal crystals. Treatment is supportive and should include cysteamine, which is an oral medication that decreases cystine accumulation.

216 HOMOCYSTINURIA AND HYPERHOMOCYSTEINEMIA

BRUCE A. BARSHOP

DEFINITION

Homocysteine is a nonprotein amino acid and an intermediate in methionine metabolism that arises when methionine (through *S*-adenosylmethionine) acts as a donor in methylation reactions (Fig. 216-1). The fate of homocysteine is either remethylation to methionine or transsulfuration of serine (through cystathionine) to cysteine. Homocystinuria results from the accumulation of homocysteine because of a defect in either transsulfuration or remethylation. The classic finding of the disulfide homocystine in urine gives this class of disorders its common name. The free sulfhydryl form, homocysteine, is present in lower amounts in blood. The term *total homocyst(e)ine* is used to describe the mix of homocysteine and homocystine present as sulfhydryl and disulfide, although here the term *total homocysteine* is considered equivalent. The defining finding in blood is hyperhomocysteinemia, which is distributed about 10% as free homocysteine and 90% as protein-bound and soluble disulfides (e.g., homocystine or cysteine-SS-homocysteine).

EPIDEMIOLOGY

Incidence and Prevalence

Minimum estimates of the incidence of cystathionine β-synthase deficiency by newborn screening programs have ranged from 1 in 60,000 to 1 in 300,000 live births, varying with the population and the screening method. Estimates of its incidence in Europe have been in the area of 1 in 40,000, which corresponds to a carrier (heterozygote) frequency of about 1%, but studies screening for known mutations suggest that the prevalence may be more than twice that rate. The incidence of severe homocysteine remethylation defects appears to be less than 1 in 500,000. In contrast, partial remethylation deficiencies seem to have a much greater incidence, which may be clinically relevant in the predisposition to thrombotic disorders, because evidence of deficiency has been reported in 15 to 30% in some series of patients with vaso-occlusive disease. The methylenetetrahydrofolate reductase (MTHFR) C677T polymorphic allele is homozygous (T/T) in approximately 10% of Western populations.

PATHOBIOLOGY

The classic form of homocystinuria is cystathionine β-synthase deficiency, which results in decreased transsulfuration and hypermethioninemic hyperhomocysteinemia. Homocystinuria may also result from defective remethylation, as in a deficiency of MTHFR, or from a disorder in the delivery, generation, or utilization of the methylcobalamin cofactor of methionine synthase. Defects of remethylation give rise to hyperhomocysteinemia with normal or low methionine. All these disorders are inherited in an autosomal recessive manner (Table 216-1).

Homocysteine has effects on vascular endothelium, platelets, and coagulation factors that predispose to thrombosis. Endothelial dysfunction can be elicited in normal individuals when hyperhomocysteinemia is induced transiently. There is evidence of inflammatory mediator activation in experimental systems related to the pro-oxidant effects of homocysteine, but there remains some controversy about the relevance of these factors in humans. Modification of connective tissue proteins may cause the skeletal and ocular manifestations associated with homocystinuria. These effects are probably related to fibrillin, which is a component of the matrix of periosteum and perichondrium, the major component of the zonular fibers of the ocular lens, and a protein singularly rich in cysteine. Fibrillin structure is affected by the linking of homocysteine to cysteine; as a result, some features of homocystinuria are also associated with fibrillin mutations (Marfan syndrome; Chapter 268). The neurologic effects of homocysteine may be due predominantly to agonism of the *N*-methyl-D-aspartate receptor by homocysteic acid, although cerebral vascular effects may contribute as well.

CLINICAL MANIFESTATIONS

Cystathionine β-synthase deficiency is pleiotropic, with effects in the eye, skeleton, and central nervous and vascular systems (Table 216-2). The eye and skeletal system changes resemble those in Marfan syndrome. Nontraumatic dislocation of the ocular lens can be an initial finding. Some abnormality of the skeletal system develops in almost all untreated patients. Between one third and three fourths of untreated patients have mild or moderate mental retardation, and cerebrovascular thrombosis may play a role in the neurologic picture. Affected patients are at lifelong risk of thromboembolic phenomena, which are the major cause of mortality in those with untreated disease. Arterial and venous occlusion, in small or large vessels, may occur at

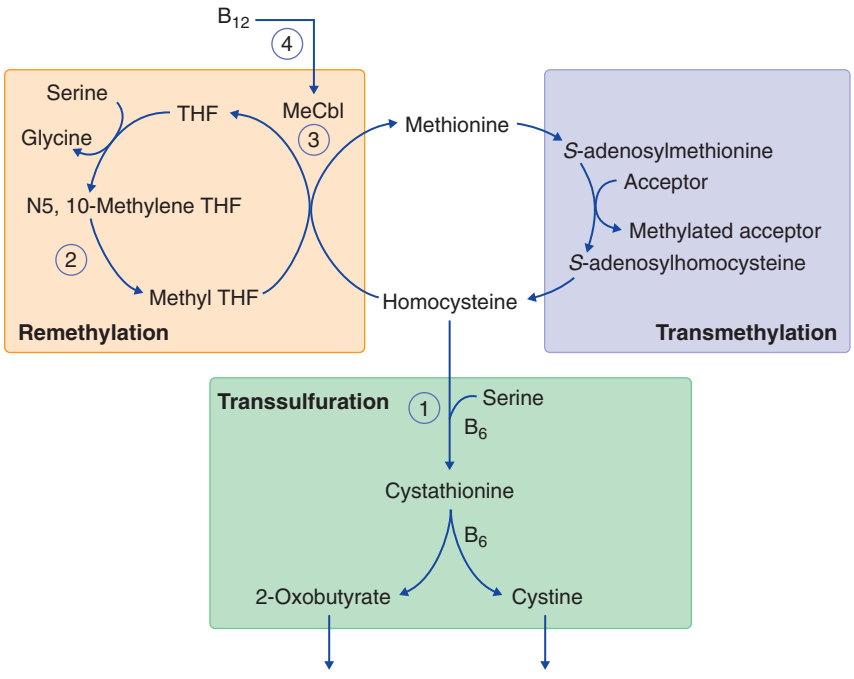

FIGURE 216-1. Pathways of homocysteine metabolism. The systems of remethylation, transmethylation, and transsulfuration are marked. Steps discussed are numbered: (1) cystathionine β-synthase; (2) methylenetetrahydrofolate reductase; (3) methionine synthase and methyltransferase reductase; (4) systems of cobalamin absorption, distribution, and reduction. B_6 = pyridoxine; B_{12} = cyanocobalamin/hydroxocobalamin; MeCbl = methylcobalamin; THF = tetrahydrofolate.

TABLE 216-1 GENETIC DEFECTS ASSOCIATED WITH HOMOCYSTINURIA

FUNCTIONAL DEFECT	COMMON NAME	ENZYME DEFECT	GENE	CHROMOSOME LOCUS
Transsulfuration	"Classic" homocystinuria	Cystathionine β-synthase	*CBS*	21q22.3
Remethylation	Folate-dependent homocystinuria	Methylenetetrahydrofolate reductase	*MTHFR*	1p36.3

TABLE 216-2 CLINICAL FEATURES OF HOMOCYSTINURIA

	Biochemical Features			*Clinical Features*	
CLASS	**HCYS**	**MET**	**MMA**	**SYSTEM**	**SIGNS**
Cystathionine β-synthase deficiency	↑	↑	–	Ocular	Ectopia lentis, myopia, glaucoma, optic atrophy, retinal detachment
				Skeletal	Elongated and thinned bones, arachnodactyly, genu valgum, pectus malformation, scoliosis
				Vascular	Thromboembolic events (arterial or venous)
				Neurologic	Mental retardation in untreated cases, cerebrovascular thromboses, seizures
					Psychiatric disorders, personality disorder
Methylenetetrahydrofolate reductase deficiency	↑	↓	–	Ocular	Ectopia lentis
				Vascular	Thromboses
				Neurologic	Variable—psychiatric to severe neurologic
Transcobalamin II deficiency	–/↑	–/↓	+/–	Hematologic	Pancytopenia, macrocytosis
				Pansystemic	MMA, ketoacidosis, stomatitis
Cbl F	–/↑	?	+/–	Pansystemic	MMA, macrocytosis, stomatitis
Cbl C, Cbl D	–/↑	–/↓	+	Hematologic	Pancytopenia
				Neurologic	Mental retardation
Cbl E, Cbl G	↑	–/↓	–	Vascular	Vaso-occlusive phenomena
				Neurologic	Spasticity, dystonia

Cbl = cobalamin; Hcys = homocystinemia/homocystinuria; Met = plasma methionine; MMA = methylmalonic acidemia.

any time in life, including infancy. Treatment with pyridoxine, the cofactor of the enzyme, may be effective in nearly half these patients, particularly those with relatively high residual activity and spared amounts of immunologically detectable enzyme. Blood total homocysteine concentrations may be intermediately elevated in heterozygotes, especially after a methionine load, and heterozygotes are at some increased risk for vaso-occlusive events. Although increased vascular complications have not been formally demonstrated in outcome studies of obligate heterozygotes, a considerable number of studies show a highly disproportionate fraction of patients with various vaso-occlusive complications who manifest either total blood homocysteine concentrations or fibroblast cystathionine β-synthase activities that fall in the range observed for heterozygotes.

MTHFR deficiency has been described in a limited number of patients, and the spectrum of manifestations includes neurologic symptoms, thrombosis, and lens dislocation, but without conspicuous skeletal changes. Severe deficiencies may present in infancy with cerebral hypoplasia and profound developmental delay. Partial deficiencies and thermolabile variants (including homozygosity for the 677T polymorphism) have been observed in otherwise normal subjects who have premature vaso-occlusive disorders. Relative risks are not well established. Meta-analysis of incidence studies have predicted that lowering total homocysteine concentrations by 3 μmol/L could reduce the risk of heart disease by 11 to 16% and stroke by 19 to 24%, but recent secondary intervention studies did not confirm a benefit, perhaps because of an insufficient statistical power. Polymorphisms in MTHFR have also been associated with spinal closure defects, a class of disease known to be influenced by folate. Cobalamin metabolic disorders generally occur in early childhood and are characterized by neurologic symptoms, megaloblastic anemia, and, in some cases, methylmalonic acidemia.

DIAGNOSIS

Qualitative detection using sodium nitroprusside led to the recognition of homocystinuria early in the history of biochemical genetics, but it is neither specific nor sensitive. Assay of plasma amino acids by routine methods may not reveal homocysteine as a result of the high degree of protein binding. Because of lower protein concentrations, routine amino acid analysis of urine is more successful, hence the common name *homocystinuria.* The preferred diagnostic method is total homocysteine, which is measured in plasma treated with a reducing agent to release bound homocysteine before deproteinization. Plasma amino acids indicate a transsulfuration or remethylation defect, depending on the presence or absence of hypermethioninemia (see Table 216-2). The clinical diagnosis of remethylation defects is facilitated by the detection of urine methylmalonate and blood vitamin B_{12} and folate. The normal range of total homocysteine in blood extends up to about 15 μmol/L, and it may be more than 50% higher 2 to 4 hours after an oral methionine load. A standard methionine load (100 mg/kg) may identify individuals with partial defects, which could increase their susceptibility to vascular disease.

TREATMENT Rx

Cystathionine β-synthase deficiency is responsive to administration of the cofactor pyridoxine in about 50% of cases. Doses of 100 to 500 mg/day have been used successfully. Higher doses of pyridoxine should be given cautiously because of the risk of peripheral neuropathy. Responsiveness is documented by the elimination of free homocysteine in blood and urine as pyridoxine is added, but measurement of total homocysteine demonstrates that the effect is generally far less than complete. Betaine (*N,N,N*-trimethylglycine, Cystadane) is effective in reducing homocysteine through an alternative remethylation step. This drug is particularly important in pyridoxine-unresponsive cases, but it may also be used as an adjunct in responsive patients. Betaine 6 g/day in divided doses is the typical regimen, but considerably higher doses have been used. The dose in children is generally 100 to 250 mg/kg. There have been two reports of cerebral edema associated with betaine, presumably caused by unusually high levels of methionine or betaine. In the absence of pyridoxine responsiveness, special diets are adopted to restrict methionine and supplement cysteine. Folic (or folinic) acid may be effective in remethylation defects, and it is also generally used as a supplement (10 to 20 mg/day) in all forms of homocystinuria. Vitamin B_{12} preparations may be life-saving in disorders of cobalamin metabolism, although their effectiveness in the most common

forms of cobalamin C or D defects is far from complete. Initial doses are usually 1000 μg/day, and hydroxocobalamin may be more effective than cyanocobalamin. It is prudent to adopt measures to decrease thrombosis, such as using low-dose aspirin or dipyridamole and avoiding smoking and oral contraceptives. Nitrous oxide may also be relatively contraindicated because it can inhibit methionine synthase. Surgery poses serious risks but can be performed safely as long as attention is paid to the patient's hydration and coagulation status.

PROGNOSIS

In cases of cystathionine β-synthase deficiency, pyridoxine responsiveness generally correlates with higher residual enzyme activity, and the prognosis is significantly better than that for unresponsive cases, with or without treatment. Skeletal, ocular, vascular, and neurologic risks are all reduced with successful treatment. Without the early institution of treatment, the median IQ in a large outcome study was 57 for unresponsive patients and 78 for responsive patients. With early treatment, pyridoxine-unresponsive patients have a nearly normal median IQ. For patients who are responsive to treatment, the prognosis for intellectual development is very good, but significant elevations in total homocysteine generally persist, and some increased risk for vascular complications probably remains.

THE PORPHYRIAS

KARL E. ANDERSON

DEFINITION

Porphyrias are due to altered activity of specific enzymes of the heme biosynthetic pathway and, when clinically expressed, are associated with striking accumulations of heme pathway intermediates. Porphyria cutanea tarda (PCT), the most common of these disorders, is primarily an acquired, iron-related disorder. The others occur only with mutations of an enzyme in the heme biosynthetic pathway. Porphyrias are more prevalent and more often manifested in adults than are most metabolic diseases and are likely to be encountered by physicians in many disciplines. The three most common porphyrias differ considerably from each other and are managed differently.

The Heme Biosynthetic Pathway and the Porphyrias

The genes encoding all eight enzymes of this important pathway (Fig. 217-1) have been sequenced and their chromosome locations identified (Table 217-1). Loss-of-function mutations for each enzyme have been associated with specific types of porphyrias, with the exception of δ-aminolevulinic acid (ALA) synthase. Loss-of-function mutations of the erythroid-specific form of this enzyme (ALAS2), the first in the pathway, are found in X-linked sideroblastic anemia. Interestingly, however, gain-of-function mutations of this enzyme were recently identified in a variant, X-linked form of erythropoietic protoporphyria (EPP) (standard abbreviations for these diseases are shown in Table 217-1). Because all porphyrias are heterogeneous at the molecular level, different mutations are to be expected in unrelated families.

Heme is synthesized in the largest amounts in bone marrow and liver, where it is used primarily to make hemoglobin and cytochrome P-450 enzymes, respectively. Hepatic heme biosynthesis is regulated primarily by the ubiquitous form of ALA synthase (ALAS1), which is rate limiting and under sensitive feedback control by a regulatory pool of cellular heme. Hepatic ALAS1 is induced by many of the same drugs and steroids that induce P-450 enzymes. Additional pathway enzymes and cellular uptake of iron are important in regulating heme synthesis in erythroid cells.

Intermediates in the pathway (see Fig. 217-1) are normally conserved during heme synthesis and excreted only in small amounts. The porphyrin precursors ALA and porphobilinogen (PBG) are normally excreted in much larger amounts than porphyrins. Porphyrinogens undergo auto-oxidation outside cells and are excreted primarily as porphyrins. ALA, PBG, and porphyrinogens are colorless and nonfluorescent. Porphyrins are reddish and fluoresce on exposure to long-wave ultraviolet light. ALA, PBG, uroporphyrin, and the heptacarboxyl, hexacarboxyl, and pentacarboxyl porphyrins are excreted mostly in urine; coproporphyrin (a tetracarboxyl porphyrin), in urine and bile; and harderoporphyrin and protoporphyrin, in bile and feces.

CLASSIFICATION

Porphyrias are classified as erythropoietic or hepatic types, depending on whether overproduction of heme pathway intermediates occurs primarily in bone marrow or liver, and also on the basis of clinical features. The acute porphyrias are characterized by neurologic effects. In the cutaneous porphyrias, photosensitivity results from activation of porphyrins by long-wave ultraviolet light (UVA) with generation of oxygen radicals that damage the skin.

THE MOST COMMON PORPHYRIAS

The three most common types of porphyrias differ markedly from each other with regard to major clinical manifestations, exacerbating factors, tests important for diagnosis, and effective therapies (Table 217-2). Because their features are so distinct, a feature learned about one of these porphyrias will not apply to the others. On the other hand, acute intermittent porphyria (AIP) and PCT (see Table 217-2) share some important features with certain other less common porphyrias.

Acute Intermittent Porphyria

AIP, an autosomal dominant disorder, results from an approximately 50% deficiency of PBG deaminase. Penetrance is low, that is, most subjects with PBG deaminase deficiency remain asymptomatic.

EPIDEMIOLOGY

AIP occurs in all races. Its prevalence in most countries has not been precisely estimated, but it may be most common (perhaps 5 per 100,000) in northern European populations.

PATHOBIOLOGY

More than 300 different mutations of the gene encoding PBG deaminase have been identified. Most mutations decrease enzyme activity in all tissues. However, there are two isoenzymes of PBG deaminase, an erythroid-specific and a ubiquitous or "housekeeping" form, both of which are transcribed by alternative messenger RNA (mRNA) splicing from the same gene. The erythroid-specific isoenzyme is encoded by exons 2 to 15, and the erythroid promoter, which functions only in erythroid cells, is found immediately upstream from exon 2. The ubiquitous enzyme is encoded by exons 1 and 3 to 15, and the ubiquitous promoter is immediately upstream from exon 1. For some mutations—in or near exons 1 or 3—only the ubiquitous isoenzyme is deficient. Therefore, in individuals with this type of mutation, the enzyme activity is deficient in nonerythroid tissues but normal in erythrocytes.

The fact that most heterozygotes are asymptomatic and have normal levels of ALA and PBG indicates that the partial deficiency of PBG deaminase does not of itself greatly impair hepatic heme synthesis or induce ALAS1. However, when certain drugs, hormones, or nutritional factors induce hepatic ALAS1, which can occur directly or by inducing cytochrome P-450 enzymes and increasing the demand for heme synthesis, the deficient enzyme becomes limiting for heme synthesis. ALA and PBG accumulate in the liver and increase in the plasma and urine. Excess porphyrins originate nonenzymatically from PBG or enzymatically from ALA transported to tissues other than the liver.

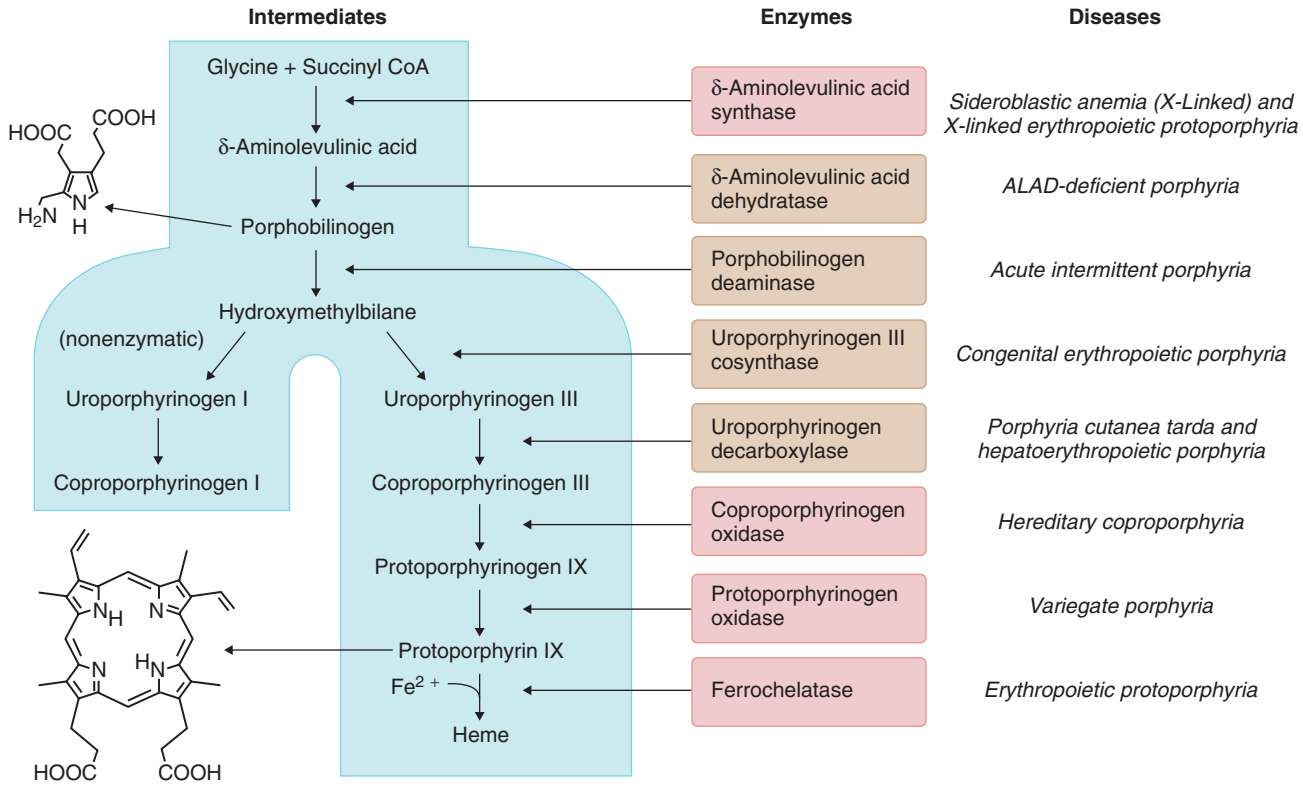

FIGURE 217-1. Intermediates and enzymes of the heme biosynthetic pathway and the major diseases of porphyrin metabolism that have been associated with altered activity of specific enzymes. The initial and last three enzymes (in *pink*) are mitochondrial, and the other four (in *brown*) are cytosolic. Heme is synthesized from glycine and succinyl coenzyme A (CoA). Intermediates in the pathway include δ-aminolevulinic acid (an amino acid used exclusively for heme synthesis), porphobilinogen (a pyrrole), and hydroxymethylbilane (a linear tetrapyrrole). Uroporphyrinogen III cosynthase catalyzes closure of hydroxymethylbilane, with inversion of one of the pyrroles, to form a porphyrin macrocycle, uroporphyrinogen III (nonenzymatic closure occurs without inversion of this pyrrole, forming uroporphyrinogen I, which is not metabolized beyond coproporphyrinogen I). The next two enzymes result in decarboxylation of six of the eight side chains of uroporphyrinogen III, with sequential formation of heptacarboxyl porphyrinogen, hexacarboxyl porphyrinogen, pentacarboxyl porphyrinogen, tetracarboxyl porphyrinogen (coproporphyrinogen III), tricarboxyl porphyrinogen (harderoporphyrinogen), and dicarboxyl porphyrinogen (protoporphyrinogen IX). The final two enzymes catalyze oxidation of protoporphyrinogen IX to protoporphyrin IX and insertion of ferrous iron into the porphyrin macrocycle to form heme (iron protoporphyrin IX). With the exception of protoporphyrin IX, all porphyrin intermediates are in their reduced forms (hexahydroporphyrins or porphyrinogens). Chemical structures of two intermediates are shown. ALAD = δ-aminolevulinic acid dehydratase.

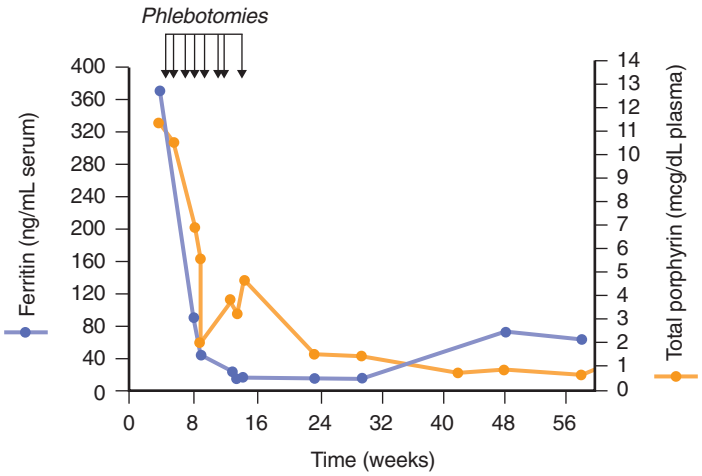

FIGURE 217-2. Treatment of porphyria cutanea tarda by repeated phlebotomy. The patient was a 37-year-old woman with a history of excess alcohol intake and chronic hepatitis C. Each *arrow* indicates removal of 450 mL of whole blood. Phlebotomies are stopped when serum ferritin is near the lower limit of normal. Further iron depletion is of no additional benefit and may cause anemia and associated symptoms. Plasma porphyrins become normal, and appearance of new skin lesions ceases within several months. After remission, ferritin can return to normal without recurrence, in most cases. In some cases, relapses occur and respond to another course of phlebotomies. (Modified from Anderson KE. The porphyrias. In Boyer T, Wright T, Manns M, eds. *Zakim and Boyer's Hepatology*. Philadelphia: WB Saunders; 2006:1391-1432.)

Most drugs that are harmful in AIP induce hepatic ALAS1 and cytochrome P-450 enzymes. Some, such as sulfonamide antibiotics, are harmful for reasons not understood. Reduced calorie and carbohydrate intakes enhance induction of ALAS1 in animals and can increase ALA and PBG in AIP and precipitate symptoms. The peroxisome proliferator-activated receptor-γ coactivator 1α (PGC-1α) mediates induction of ALAS1 by fasting and is an important link between nutritional status and acute porphyrias.

Porphyrias and related disorders associated with increased ALA have similar neurologic manifestations, but the mechanism of neural damage is not established. It seems most likely that ALA or another product of the heme pathway is neurotoxic. ALA is structurally analogous to γ-aminobutyric acid (GABA) and can interact with GABA receptors. Alternatively, heme deficiency in nervous tissue may lead to neurologic dysfunction.

CLINICAL MANIFESTATIONS

Symptoms occur intermittently as acute attacks in some heterozygotes lasting for several days or longer, usually followed by complete recovery. There is often no family history of porphyria. Attacks are rare before puberty. Abdominal pain, the most common symptom, is usually steady and poorly localized, but it may be cramping. Tachycardia, hypertension, restlessness, fine tremors, and excess sweating may be due to sympathetic overactivity. Other manifestations include nausea and vomiting; constipation; pain in the limbs, head, neck, or chest; muscle weakness; and sensory loss. Ileus, with distention and decreased bowel sounds, is common. However, increased bowel sounds and diarrhea may be seen. Because the abdominal symptoms are neurologic rather than inflammatory, tenderness, fever, and leukocytosis are generally absent or mild. Dysuria and bladder dysfunction may occur. Recurrent attacks tend to be similar in a given patient.

Peripheral neuropathy in AIP is primarily motor and results from axonal degeneration. This does not develop in all patients with acute attacks, even when abdominal symptoms are severe. Rarely, motor neuropathy develops apart from abdominal symptoms. Weakness most commonly begins in proximal muscles (often requiring a careful examination to be detected) and more often in the arms than in the legs. It can be asymmetrical and focal. Tendon reflexes may be little affected or hyperactive in early stages but are usually decreased or absent with advanced neuropathy. Cranial and sensory nerves can be affected. Progression to respiratory and bulbar paralysis and death is unlikely if porphyria is promptly recognized, harmful drugs are discontinued, and appropriate treatment is instituted. Sudden death, presumably from cardiac arrhythmia, sometimes occurs.

TABLE 217-1 ENZYMES OF THE HEME BIOSYNTHETIC PATHWAY AND CLASSIFICATION AND INHERITANCE OF DISEASES ASSOCIATED WITH THEIR ALTERED ACTIVITIES*

ENZYME	CHROMOSOME LOCATION	DISEASE	INHERITANCE	*Classifications of Porphyrias*			
				HEPATIC	ERYTHROPOIETIC	ACUTE	CUTANEOUS
ALA synthase							
Erythroid	Xp11.21	Sideroblastic anemia	X-linked recessive				
		X-linked protoporphyria	X-linked recessive		X		X
Housekeeping	3p21	None known					
ALA dehydratase	9q34	ALA dehydratase-deficient porphyria (ADP)	Autosomal recessive	X (?)		X	
Porphobilinogen deaminase†	11q24.1→ q24.2	Acute intermittent porphyria (AIP)	Autosomal dominant	X		X	
Uroporphyrinogen III cosynthase	10q25.2→q26.3	Congenital erythropoietic porphyria (CEP)	Autosomal recessive		X		X
Uroporphyrinogen decarboxylase	1p34	Porphyria cutanea tarda (PCT)‡	Autosomal dominant	X			X
		Hepatoerythropoietic porphyria (HEP)	Autosomal recessive	X	X		X
Coproporphyrinogen oxidase	3q12	Hereditary coproporphyria (HCP)	Autosomal dominant	X		X	X
Protoporphyrinogen oxidase	1q23	Variegate porphyria (VP)	Autosomal dominant	X		X	X
Ferrochelatase	18q21.3	Erythropoietic protoporphyria (EPP)	Autosomal recessive§		X		X

*The most precise classification is according to the specific enzyme deficiencies. Other classifications based on the major tissue site of overproduction of heme pathway intermediates (hepatic vs. erythropoietic) or the type of major symptoms (acute neurovisceral vs. cutaneous) are useful but not precise or mutually exclusive.
†This enzyme is also known as *hydroxymethylbilane synthase* and formerly as *uroporphyrinogen I synthase*.
‡Inherited deficiency of uroporphyrinogen decarboxylase is partially responsible for familial (type 2) porphyria cutanea tarda.
§EPP was previously classified as autosomal dominant with variable penetrance but is now recognized as recessive at the molecular level, with inherited mutations affecting both *FECH* alleles. Most patients have a null mutation trans to a hypomorphic mutation, IVS3-48T>C, that is common in the population but does not itself cause disease.
ALA = δ-aminolevulinic acid.

TABLE 217-2 THE THREE MOST COMMON HUMAN PORPHYRIAS AND THE MAJOR FEATURES OF THESE DISORDERS THAT ARE DISTINCTLY DIFFERENT FROM EACH OTHER

	PRESENTING SYMPTOMS; TREATMENT	EXACERBATING FACTORS	MOST IMPORTANT SCREENING TESTS
Acute intermittent porphyria	Neurovisceral (acute); heme, glucose	Drugs (mostly P-450 inducers), progesterone, dietary restriction	Urinary porphobilinogen
Porphyria cutanea tarda	Blistering skin lesions (chronic); phlebotomy, low-dose hydroxychloroquine	Iron, alcohol, estrogens, hepatitis C virus, halogenated hydrocarbons	Plasma (or urine) porphyrins
Erythropoietic protoporphyria	Painful skin and swelling (mostly acute); β-carotene		Total erythrocyte protoporphyrin

The central nervous system can be involved. Anxiety, insomnia, depression, disorientation, hallucinations, and paranoia, which can be especially severe during acute attacks, may suggest a primary mental disorder or hysteria. Seizures may occur as an acute neurologic manifestation of AIP, as a result of hyponatremia, or secondary to causes unrelated to porphyria. Hyponatremia may be due to hypothalamic involvement and inappropriate antidiuretic hormone secretion, vomiting, diarrhea and poor intake, or excess renal sodium loss.

An attack may resolve rapidly after several days. Attacks during the luteal phase of the menstrual cycle usually resolve with onset of menses. Even advanced neuropathy seen with a prolonged attack is potentially reversible. Frequently recurring attacks and chronic symptoms including pain and depression sometimes occur.

Chronic hepatic abnormalities are common in AIP. Risk for hepatocellular carcinoma (not associated with hepatitis B or C) is also increased. AIP may predispose to chronic hypertension and be associated with impaired renal function.

Homozygous AIP is extremely rare. It presents in early childhood primarily with delayed development and neurologic dysfunction, but not with acute attacks.

Precipitating Factors

Certain drugs, steroid hormones, and nutritional alterations are commonly implicated in causing attacks. Features such as onset after puberty and more frequent clinical expression in women suggest that endogenous hormones are important. Recurrent cyclic attacks are troublesome in some women and occur when progesterone levels are highest. Progesterone and its metabolites are potent inducers of hepatic ALAS1, whereas estrogens are not. Exacerbations may be seen after administration of progestin-containing steroid combinations. Although pregnancy is usually well tolerated (despite high progesterone levels), attacks may become more frequent, and hyperemesis gravidarum, reduced calorie intake, and harmful drugs (e.g., metoclopramide) may contribute.

Drugs remain important as causes of AIP attacks. Barbiturates and sulfonamides are most notorious, whereas benzodiazepines, which have largely replaced barbiturates in clinical practice, are less hazardous. The major drugs known to be harmful or safe in the acute porphyrias are listed in Table 217-3. Many drugs are not easily classified. Advice can be sought from interactive websites maintained by the European Porphyria Initiative *(www.porphyria-europe.com)* or from the American Porphyria Foundation *(www.porphyriafoundation.com)*. Some drugs and other factors that contribute in porphyria cutanea tarda are seldom implicated in acute porphyrias (see later).

Attacks may be provoked by reduced calorie intake (usually instituted in an effort to lose weight), infections, and major surgery. Cigarette smoke contains chemicals that can induce hepatic heme synthesis and may predispose to attacks. Attacks are almost always due to two or more factors acting in an additive fashion. Probably for this reason, (1) drugs may produce attacks in adults but rarely in children, (2) anticonvulsants do not produce attacks in all PBG deaminase-deficient subjects, and (3) barbiturate anesthetics more frequently exacerbate porphyria if symptoms are present before anesthetic exposure.

DIAGNOSIS

A high index of suspicion is necessary for diagnosis of AIP and other acute porphyrias because they are uncommon, their symptoms are nonspecific,

TABLE 217-3 SELECTED DRUGS CONSIDERED UNSAFE AND SAFE IN ACUTE INTERMITTENT PORPHYRIA, HEREDITARY COPROPORPHYRIA, AND VARIEGATE PORPHYRIA

UNSAFE	SAFE
Alcohol	Acetaminophen
Barbiturates*	Acetazolamide
Calcium-channel blockers	Allopurinol
Carbamazepine*	Amiloride
Carisoprodol*	Angiotensin-converting enzyme inhibitors†
Clonazepam	Angiotensin receptor antagonists†
Danazol*	Aspirin
Diclofenac and possibly other nonsteroidal anti-inflammatory drugs*	Atropine
Ergots	β-Adrenergic antagonists†
Ethchlorvynol*	Bromides
Glutethimide*	Cimetidine
Griseofulvin*	Erythropoietin*,‡
Mephenytoin	Estrogens*,§ (?)
Meprobamate* (also mebutamate,* tybutamate*)	Gabapentin
Methyprylon	Gentamicin
Metoclopramide*	Glucocorticoids
Phenytoin*	Insulin
Primidone*	Narcotic analgesics
Progesterone and synthetic progestins*	Ofloxacin
Pyrazinamide*	Penicillin and derivatives
Pyrazolones (aminopyrine, antipyrine)	Phenothiazines
Rifampin*	Ranitidine*,‡
Succinimides (ethosuximide, methsuximide)	Streptomycin
Sulfonamide antibiotics*	Tetracycline
Valproic acid*	

*Porphyria is listed as a contraindication, warning, precaution, or adverse effect in U.S. labeling for these drugs. For drugs listed here as unsafe, absence of such cautionary statements in U.S. labeling does not imply lower risk.
†Some drugs in these classes may be safer than others: see websites of the American Porphyria Foundation (*www.porphyriafoundation.com*) and the European Porphyria Initiative (*www.porphyria-europe.com*).
‡Although porphyria is listed as a precaution in U.S. labeling, these drugs are regarded as safe by other sources.
§There is little evidence that estrogens alone are harmful in acute porphyrias. They have been implicated as harmful mostly on the basis of experience with estrogen-progestin combinations and because they can exacerbate porphyria cutanea tarda.

and physical findings are minimal. In some European countries, almost all families with acute porphyrias have been identified and studied, but in the United States, many cases still present without a known family history. The diagnosis of acute porphyria is established initially by demonstrating a marked increase in urinary PBG. Urinary PBG excretion in excess of approximately 6 mg/day is virtually diagnostic of AIP, variegate porphyria (VP), or hereditary coproporphyria (HCP). Excretion is generally in the range of 50 to 200 mg/day for PBG (reference range, 0 to 4 mg/day) and 20 to 100 mg/day for ALA (reference range, 0 to 7 mg/day) during attacks of AIP, but increases are less in HCP and VP, and these levels generally decrease with clinical improvement. PBG levels become normal after hemin therapy (usually transiently) and sometimes with prolonged clinical latency. Urinary ALA and PBG decrease to normal levels more readily in HCP and VP than in AIP. Fecal porphyrins are usually normal or minimally increased, which distinguishes AIP from HCP and VP. Urinary uroporphyrin and coproporphyrin are often considerably increased and erythrocyte protoporphyrin may be slightly increased in AIP, but these findings are not specific.

PBG levels often remain variably elevated between attacks of AIP. Diagnosis of a recurrent attack is based on clinical findings, rather than by a particular level of increased PBG, and exclusion of other potential causes of the presenting symptoms.

Laboratory testing for acute porphyrias becomes less sensitive with time after symptoms have subsided. However, in many cases, these disorders may still be recognized and differentiated by more extensive testing to include urinary ALA and PBG, porphyrins in urine and in plasma and feces, and erythrocyte PBG deaminase. An attempt to provoke increases in ALA and PBG for diagnostic purposes by glycine loading or administration of phenobarbital may be dangerous and is not definitive.

Decreased PBG deaminase (most conveniently measured in erythrocytes) helps confirm a diagnosis of AIP. However, erythrocyte PBG deaminase activity is normal in some AIP patients because (1) some PBG deaminase mutations only reduce the nonerythroid enzyme (as noted earlier), (2) erythrocyte PBG deaminase has a wide normal range (up to three-fold) that overlaps the AIP range, and (3) the erythrocyte enzyme is increased by inapparent concurrent conditions that stimulate erythropoiesis. Furthermore, this measurement is not useful in acutely ill patients because it does not distinguish between active and latent stages of AIP, and is normal in other acute porphyrias. The assay is useful for analysis of pedigrees of known AIP patients if it is established that an index case has a low value. However, because DNA studies are more dependable, it is now recommended that the specific PBG deaminase mutation be determined, and then relatives can be tested reliably for latent AIP. Diagnosis in utero is possible but seldom indicated in view of the favorable outlook for most PBG deaminase-deficient subjects.

TREATMENT

Rx

Acute attacks usually require hospitalization for treatment of severe pain, nausea, and vomiting and for the intravenous administration of glucose and hemin. Patients should be observed for neurologic complications, respiratory impairment, electrolyte imbalances, and nutritional status. Precipitating factors—usually multiple—should be identified and removed whenever possible. Symptomatic therapy includes narcotic analgesics, which are usually required for severe pain, and small to moderate doses of a phenothiazine for nausea, vomiting, anxiety, and restlessness. Short-acting benzodiazepines in low doses may be safe for insomnia if a minor tranquilizer is required. Bladder distention may require catheterization. After recovery, continued treatment with a phenothiazine is seldom indicated.

Hemin therapy and carbohydrate loading are both specific therapies because they repress hepatic ALAS1 and overproduction of ALA and PBG. Hemin is more effective and should be initiated early, but only after the initial diagnosis of acute porphyria is confirmed by a marked increase in urinary PBG (spot samples of urine, plasma, and feces are saved for later differentiation of AIP, HCP, and VP). Diagnosis is more difficult after hemin is started, which at least transiently lowers ALA and PBG, often to normal levels. Recurrent attacks in patients with persistently high levels of PBG are diagnosed primarily on clinical grounds, and a spot urine sample may be obtained for PBG measurement and treatment with hemin started before the result is available.

The standard regimen for hemin treatment is 3 to 4 mg of hemin per kilogram of body weight infused intravenously once daily for 4 days. A longer course of treatment is seldom necessary if treatment is started early. Efficacy is reduced and recovery less rapid when treatment is delayed and neuronal damage is more advanced. It is not effective for chronic symptoms of AIP. Hemin is available in the United States as a lyophilized hematin (hydroxyheme) preparation. The product is unstable when it is reconstituted with sterile water, and degradation products adhere to endothelial cells, platelets, and coagulation factors, causing a transient anticoagulant effect and frequently a phlebitis at the site of infusion. Reconstitution with human albumin enhances the stability of hematin and prevents these side effects. Heme arginate (available in Europe and South Africa) is more stable and has fewer side effects.

Carbohydrate loading may suffice for mild attacks (e.g., pain not requiring narcotics, and without paresis, seizures, or hyponatremia) and can be given orally as sucrose, glucose polymers, or carbohydrate-rich foods. If oral intake is poorly tolerated or contraindicated by distention and ileus, intravenous administration of glucose (at least 300 g daily) is usually indicated, although larger amounts may be more effective. However, this may entail administration of a large volume of fluids and increase the risk for hyponatremia. A central venous line facilitates more complete parenteral nutrition support and avoids excess fluid volumes. The effect of glucose is mediated in part by elevation of insulin, which reduces expression of PGC-1α in the liver.

Treatment of seizures is problematic because almost all antiseizure drugs can exacerbate AIP. Bromides, gabapentin, and probably vigabatrin can be given safely. β-Adrenergic blocking agents may control tachycardia and hypertension in acute attacks of porphyria, but they may be hazardous in patients with hypovolemia, in whom increased catecholamine secretion may be an important compensatory mechanism. Cimetidine has been reported to be beneficial, but controlled studies are lacking, and it should not be used in place of hemin. Numerous other therapies have been tried in this disease but have not been consistently useful.

Liver transplantation can be curative for patients with repeated disabling attacks that are refractory to hemin therapy and prophylaxis, but without advanced motor neuropathy. This experience, albeit limited to date, strongly indicates that the liver is central to the neurologic manifestations of this disease.

PREVENTION

Some specific measures are helpful in preventing clinical expression of AIP. Family members should be screened, preferably by DNA methods, to detect latent cases. Potentially harmful drugs should be avoided. "Crash diets" for weight reduction and even brief periods of starvation (e.g., during postoperative periods or intercurrent illnesses) should be avoided; diet regimens for obesity should provide for gradual weight loss during periods of clinical remission of porphyria. Gonadotropin-releasing hormone analogues can prevent frequent cyclic attacks in women; oophorectomy is not an acceptable option for preventing cyclic attacks. Single hemin infusions once or twice weekly sometimes prevent frequently recurring attacks. Because suicide is a risk in AIP, a preventive approach is appropriate, especially in patients with chronic symptoms and depression.

PROGNOSIS

If acute attacks are treated promptly, inciting factors removed, and precautions taken to prevent further attacks, the outlook for patients with AIP is usually very good. Recurrent attacks occur in some patients and can be disabling, but they do not occur throughout adult life. Chronic pain, depression, and other symptoms can increase the risk for suicide but may improve in the long term.

Most relatives with PBG deaminase deficiency never develop symptoms, especially if they have normal urinary porphyrin precursors. Such individuals with latent AIP may be less sensitive to inducing drugs or other factors that exacerbate AIP than are patients with prior porphyric symptoms, but they should follow the same precautions as those who have had symptoms.

Porphyria Cutanea Tarda

DEFINITION

Porphyria cutanea tarda (PCT), the most common and readily treated form of porphyria, is an iron-related disorder caused by inhibition of uroporphyrinogen decarboxylase (UROD) in the liver. It presents with blistering cutaneous lesions on sun-exposed areas.

PATHOBIOLOGY

PCT is mostly an acquired disorder in which hepatic UROD activity is reduced to less than about 20% of normal. (The hepatic UROD protein remains at its genetically determined level, as measured immunochemically.) A UROD inhibitor has been isolated as a uroporphomethene (derived from uroporphyrinogen by oxidation of one of its four methane bridges, or possibly from hydroxymethylbilane); iron, along with one or more cytochrome P-450 enzymes, and oxidative stress are believed to be involved in its formation. A normal or increased amount of hepatic iron is essential for development of PCT, although iron does not directly inhibit UROD. Multiple genetic, viral, and chemical susceptibility factors are known, and at least several are combined in individual patients.

Most patients with manifest PCT (~80%) do not have *UROD* mutations and are classified as sporadic (type 1). Those with *UROD* mutations are said to have familial (type 2) disease but usually present sporadically (without a family history of PCT) because penetrance of familial PCT is low. Heterozygous carriers of *UROD* mutations are more susceptible because their genetically determined levels of UROD are half-normal from birth. Type 2 cases can be distinguished by finding half-normal UROD activity in erythrocytes, but DNA studies are more reliable. Clustering of related individuals with features of type 1 PCT, including absence of *UROD* mutations, has been referred to as type 3, but the genetic basis is not known. Types 1 to 3 are clinically similar, although age at disease onset may on average be earlier in type 2.

Halogenated polyaromatic hydrocarbons are rarely associated with PCT in humans. Most notably, an extensive outbreak of porphyria occurred in eastern Turkey in 1955 to 1958 after seed wheat containing the fungicide hexachlorobenzene was consumed during a famine. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD, dioxin) has been implicated in smaller outbreaks. Such exposures are seldom evident in sporadic cases of PCT.

Most of the following susceptibility factors are readily identified clinically in patients with PCT. Several are found in almost all patients, although none is essential.

- **Alcohol** abuse has long been recognized as an important contributor and may increase hepatic iron by downregulation of hepcidin, induce cytochrome P-450 enzymes, and cause oxidative stress in hepatocytes.
- **Smoking** (Chapter 31) has been considered a potential contributor more recently. Constituents of cigarette smoke can induce hepatic cytochrome P-450 enzymes that may be involved in generation of a UROD inhibitor (especially CYP1A2).
- **Estrogen** use is strongly associated with PCT in women and may also lead to the production of reactive oxygen species in hepatocytes.
- **Hepatitis C**, which downregulates hepcidin and causes hepatic oxidative stress and steatosis, is highly prevalent in PCT in most geographic areas (e.g., 70% or greater in the United States and southern Europe).
- **Human immunodeficiency virus infection** is less commonly associated but is probably an additional risk factor for PCT.
- **Hemochromatosis gene *(HFE)* mutations** (Chapter 219) favor increased iron absorption by downregulation of hepcidin. About 10% of PCT patients of northern European origin are homozygous for the *C282Y* mutation, and a corresponding number are *C282Y/H63D* compound heterozygotes.
- **UROD mutations,** which identify patients with type 2 disease, are most reliably found by DNA studies; most will have half-normal erythrocyte UROD activity.

Other factors undoubtedly are important. Reduced levels of antioxidants, such as vitamin C and carotenoids, have been reported. A *CYP1A2* polymorphism that favors induction of this enzyme was more common in PCT than in controls in several case series. Drugs are sometimes associated with PCT and may play an additive role. Those so indicated in U.S. labeling are several nonsteroidal anti-inflammatory drugs, sulfonylureas, and busulfan. Associations with systemic lupus erythematosus, bone marrow disorders, and end-stage renal disease have been described. Because porphyrins are poorly dialyzed, porphyrin levels are often much higher in patients with advanced renal disease, and skin lesions are more severe.

PCT is a chronic disease, and massive amounts of porphyrins accumulate in the liver, probably over many months, before excess porphyrins appear in plasma and urine. Hepatic ALAS1 may be little increased because the amount of excess porphyrins produced in PCT is small relative to the rate of hepatic heme formation. This contrasts with the acute porphyrias, in which much larger amounts of intermediates are excreted as porphyrin precursors, particularly during attacks, and ALA synthase is substantially induced.

The pattern of porphyrins that accumulate in PCT is complex and characteristic. Decarboxylation of uroporphyrinogen occurs in four sequential steps. Therefore, when UROD is markedly deficient, uroporphyrin and the heptacarboxyl, hexacarboxyl, and pentacarboxyl porphyrins (type I and III isomers derived from the corresponding porphyrinogens) accumulate. In addition, pentacarboxyl porphyrinogen can be metabolized by coproporphyrinogen oxidase to a series of tetracarboxyl porphyrinogens termed *isocoproporphyrinogens*. The corresponding isocoproporphyrins are excreted primarily in bile and feces and are diagnostic of UROD deficiency.

CLINICAL MANIFESTATIONS

Cutaneous photosensitivity is the major clinical feature. Vesicles and bullae develop most commonly on the dorsum of the hands as well as on the face, forearms, legs, and feet. Sun-exposed skin becomes friable, and minor trauma may precede the formation of bullae or cause denudation of the skin. Small white plaques (milia) may precede or follow vesicle formation. Involved skin tends to heal slowly. Hypertrichosis and hyperpigmentation sometimes occur even in the absence of vesicles. Thickening, scarring, and calcification of affected skin (pseudoscleroderma) may be striking. Neurologic effects are not observed.

Abnormal liver test results—especially transaminases—are common in PCT and can occur in the absence of hepatitis C. Liver histopathology is nonspecific, other than the finding of fluorescence due to porphyrins, which appear as inclusions in fixed tissue. Liver iron is often increased. Risk for cirrhosis and hepatocellular carcinoma increases with disease duration. Rarely, hepatic tumors themselves contain and presumably produce excess porphyrins. Some of these cases have resembled PCT.

DIAGNOSIS

Skin lesions in PCT, VP, and HCP are indistinguishable clinically and histologically. It is important to differentiate these conditions by laboratory testing before therapy is started. A predominance of uroporphyrin and heptacarboxyl porphyrin in urine is diagnostic of PCT, and increased isocoproporphyrin in feces provides further confirmation. In PCT, urinary ALA may be slightly increased, whereas PBG is normal. Total fecal porphyrins are usually less increased in PCT than in HCP and VP. Plasma porphyrins are virtually always increased in patients with porphyrias causing blistering skin lesions; the fluorescence spectrum of plasma can distinguish VP and erythropoietic protoporphyria from PCT (see later).

TREATMENT Rx

All three types of PCT respond to treatment; with remission, hepatic UROD activity returns to its genetically determined level (which for type 2 is half-normal). A course of phlebotomies is the preferred treatment. Patients are also advised to discontinue alcohol, estrogens, iron supplements, or other contributing factors. Because iron stores in PCT are seldom markedly increased, removal of only 5 to 8 units of blood at 2-week intervals is usually sufficient. Many more phlebotomies are needed in the minority of patients with very high ferritin levels. Plasma (or serum) ferritin and porphyrin levels should be followed (Fig. 217-2). Deferoxamine, an iron chelator, may be effective but is much less efficient.

A course of low-dose hydroxychloroquine (100 mg) or chloroquine (125 mg) twice weekly for several months is usually effective when repeated phlebotomies are contraindicated. The mechanism of their effects in PCT, which involves release of porphyrins from hepatocytes, has not been established. If usual doses of these drugs are given to patients with PCT, marked increases in photosensitivity and porphyrin levels in plasma and urine are seen and may be accompanied by nausea, malaise, fever, and hepatocellular damage. Although these adverse effects are generally transient and are followed by complete remission, it is prudent to avoid them by use of a low-dose regimen. These may not be effective in patients with marked iron overload.

Therapy is more difficult when PCT occurs with advanced renal disease. However, treatment with recombinant erythropoietin can mobilize excess iron, support phlebotomy, and lead to remission of PCT in these patients.

Erythropoietic Protoporphyria

DEFINITION

EPP, which is the third most common porphyria in adults and the most common in children, causes nonblistering photosensitivity of the skin. EPP is usually due to a deficiency of ferrochelatase (FECH), with increased protoporphyrin in erythrocytes, plasma, bile, and feces. Urine porphyrins are not increased. Rarely, the EPP phenotype results from gain of function mutations of ALAS2.

PATHOBIOLOGY

Several different underlying molecular abnormalities can cause this disease. In more than 90% of affected families, EPP is due in part to 1 of about 110 reported severe mutations of the ferrochelatase gene (*FECH*). FECH activities, however, are as low as 15 to 25% of normal in patients with EPP, which is accounted for by inheritance of a severe *FECH* mutation from one parent and a common hypomorphic *FECH* mutation from the other. The latter is an intronic single nucleotide alteration, IVS3-48T>C, that results in expression of an aberrantly spliced mRNA that is degraded by a nonsense-mediated decay mechanism, which decreases the steady-state level of FECH mRNA. The IVS3-48T>C mutation by itself does not cause disease, even when it is homozygous. Because both FECH alleles are altered in affected individuals, inheritance of the disease is described as recessive at the molecular level. In a few families, two severe *FECH* mutations (and not the IVS3-48T>C mutation) are found, with at least one allele producing some enzyme protein. Late-onset cases of EPP may be associated with a myeloproliferative disorder and expansion of a clone of erythroid cells carrying a somatic or inherited *FECH* mutation.

Examination of lineages in a recently described variant form of EPP, in which FECH activity is normal and there are no *FECH* mutations, suggested X-linked inheritance. Because the *ALAS2* gene, which encodes the erythroid-specific form of ALAS, had been localized to the X chromosome, this observation led to the discovery of gain of function C-terminal deletions of this gene in these families. X-linked EPP is also termed *X-linked protoporphyria*.

Erythrocyte protoporphyrin is increased in many red cell disorders, such as iron deficiency, anemia of chronic disease, and lead poisoning, and is mostly complexed with zinc. FECH activity accounts for formation of zinc protoporphyrin as well as heme. In EPP, the large amounts of protoporphyrin in erythrocytes is mostly free, and only 0 to 15% is complexed with zinc. In X-linked EPP, in which FECH is normal, free protoporphyrin is increased, but zinc protoporphyrin may account for 15 to 50% of the total. Free protoporphyrin diffuses more readily into plasma than does zinc protoporphyrin, especially after light exposure.

Protoporphyrin is markedly increased in bone marrow, erythrocytes, and bile, and less increased in plasma and feces in EPP. Bone marrow reticulocytes that are actively synthesizing heme and hemoglobin are the primary source of the excess protoporphyrin entering the plasma in EPP. Circulating erythrocytes and perhaps the liver contribute smaller amounts. Protoporphyrin is increased in plasma and undergoes hepatic uptake, biliary excretion, and perhaps enterohepatic circulation. Protoporphyrin in large amounts is cholestatic and can cause liver disease that may progress rapidly.

CLINICAL MANIFESTATIONS

Photosensitivity substantially affects lifestyle and quality of life, typically begins early in childhood, and is distinctly different from other cutaneous porphyrias. Burning, itching, erythema, and swelling can occur within minutes of sun exposure. Diffuse edema of sun-exposed areas may resemble angioedema (Chapter 260). Characteristic chronic changes include skin lichenification, leathery pseudovesicles, labial grooving, and nail changes. Scarring is rarely severe or deforming. Vesicles, pigment changes, friability, and hirsutism are unusual. No fluorescence of the teeth and (except with severe hepatic failure) no neuropathic manifestations are present. Drugs that exacerbate hepatic porphyrias are not known to worsen EPP but are generally avoided as a precaution.

Mild microcytic anemia is common, and erythropoiesis and iron absorption may be decreased. These effects may be mediated by excess protoporphyrin, but the mechanism is unclear. Hemolysis is uncommon or mild in uncomplicated cases. Gallstones containing protoporphyrin may require cholecystectomy if they are symptomatic.

Liver function is usually normal in this condition. However, less than 5% of patients with EPP develop *protoporphyric hepatopathy*, which results from the cholestatic effects of protoporphyrin, and can progress rapidly to death from liver failure. Intercurrent factors such as viral hepatitis, alcohol, iron deficiency, fasting, and oral contraceptive steroids have played a role in some patients. Because protoporphyric hepatopathy progressively impairs hepatobiliary excretion of protoporphyrin, plasma and erythrocyte porphyrins increase further, photosensitivity worsens, often with skin blistering, and even a severe motor neuropathy may develop.

DIAGNOSIS

Delay in diagnosis of this porphyria is longer on average than with any other. An increase in erythrocyte protoporphyrin that is primarily free (not complexed with zinc) is diagnostic of EPP. Both free and zinc protoporphyrin are increased in the X-linked form of the disease. Because laboratory methods and terminology are inconsistent, measurement of total erythrocyte protoporphyrin is preferred for initial screening, followed, if elevated, by fractionation of free and zinc protoporphyrin. Plasma porphyrins are more light sensitive and often less elevated than in other cutaneous porphyrias, especially with mild disease. Urinary porphyrins and porphyrin precursors are normal. Hepatic complications of EPP are heralded by abnormal liver tests and increasing levels of erythrocyte and plasma protoporphyrin. Some patients with undiagnosed photosensitivity since childhood are first recognized to have EPP with onset of hepatopathy in adult life.

TREATMENT Rx

β-Carotene (Lumitene) was originally developed primarily for treatment of EPP and found to be beneficial in large series of patients. Its mechanism of action may involve quenching of singlet oxygen or free radicals. Carotenemia with mild, dose-related skin discoloration is expected. Iron supplements are warranted in patients with marginal levels of serum ferritin. Vitamin D and calcium supplements, hepatitis A and B immunizations, and avoidance of alcohol and other hepatotoxins are recommended. Calorie restriction and drugs or hormone preparations that impair hepatic excretory function should be avoided.

Protoporphyric hepatopathy may improve at least partially when treated with transfusions to correct anemia, hemin, cholestyramine, ursodeoxycholic acid, and vitamin E. Liver transplantation is sometimes required. Filters for operating room lights are available to prevent severe skin and peritoneal burns. Hematopoietic stem cell transplantation (Chapter 181) corrects protoporphyrin overproduction and is increasingly considered to prevent damage to the transplanted liver.

LESS COMMON PORPHYRIAS

ALA Dehydratase-Deficient Porphyria

In this rare autosomal recessive disorder, ALA dehydratase is markedly reduced (usually 1 to 2% of normal). Only six cases (all males) with a total of 11 mutant alleles have been documented, but it is likely that cases are commonly undiagnosed. Three cases were in adolescents, with symptoms resembling AIP. Severe neurologic impairment beginning in childhood was observed in one case. An adult-onset case was associated with a myeloproliferative disorder. Urinary ALA and coproporphyrin III and erythrocyte zinc protoporphyrin are increased. In this and other disorders in which ALA accumulates, coproporphyrin III may originate from excess ALA by metabolism in tissues other than its tissue of origin.

Lead poisoning (Chapter 21) and hereditary tyrosinemia type 1 are also associated with ALA dehydratase deficiency and can present with symptoms (abdominal pain, ileus, and motor neuropathy) that are strikingly similar to those of the acute porphyrias. Lead concentrates in erythroid cells and reversibly inhibits erythrocyte ALA dehydratase by displacing zinc from the enzyme. In lead poisoning, as in ALA dehydratase-deficient porphyria, erythrocyte protoporphyrin and urinary coproporphyrin are increased. In hereditary tyrosinemia type 1, a deficiency of fumarylacetoacetase leads to accumulation of succinylacetone (2,3-dioxoheptanoic acid). This structural analogue of ALA is a potent inhibitor of ALA dehydratase. Other heavy metals or styrene exposure can also inhibit ALA dehydratase.

Congenital Erythropoietic Porphyria

DEFINITION

Congenital erythropoietic porphyria (CEP) is an autosomal recessive disorder that is due to a deficiency of uroporphyrinogen III cosynthase (UROS, also known as *uroporphyrinogen III synthase*). Fewer than 250 cases have been reported.

PATHOBIOLOGY

Many different *UROS* mutations have been identified in CEP. Most patients have unrelated parents and have inherited a different mutation from each parent. The severity of the disease is variable and relates to the degree of enzyme deficiency caused by the particular mutations. Hydroxymethylbilane (the substrate of the deficient enzyme) accumulates and is converted nonenzymatically to uroporphyrinogen I, which is metabolized to coproporphyrinogen I. These porphyrinogens and the corresponding porphyrins accumulate in bone marrow erythroid cells that are actively synthesizing hemoglobin and lead to intramedullary and intravascular hemolysis. Even in the most severe cases, some residual UROS activity is present, and heme production is actually increased in response to hemolysis. Splenomegaly can contribute to anemia and cause leukopenia and thrombocytopenia. The liver is not affected, and drugs and other factors that are harmful in the hepatic porphyrias do not affect this erythropoietic disease.

CLINICAL MANIFESTATIONS

In most cases, reddish urine and severe cutaneous photosensitivity are noted in early infancy. In a few very severe cases, CEP was manifested as nonimmune hydrops, and intrauterine transfusions were administered. Neonatal hyperbilirubinemia may be present at birth, but phototherapy may cause marked blistering and scarring and should be avoided. Late-onset cases are likely to be associated with myeloproliferative disorders and expansion of a clone of cells carrying a *UROS* mutation.

Lesions on sun-exposed skin resemble those in porphyria cutanea tarda but are usually more severe. Bullae and vesicles are likely to rupture and become infected, which contributes to loss of digits and facial features and corneal scarring. Other features include areas of hypopigmentation and hyperpigmentation and hypertrichosis. Porphyrins are deposited in the teeth (producing a red-brown color termed *erythrodontia*) and in bone. Bone demineralization can be substantial and due in part to marrow hyperplasia and possibly vitamin D deficiency. Hemolysis and splenomegaly are almost always present, but there are no neurologic manifestations. Life expectancy is often shortened by infections or hematologic complications.

DIAGNOSIS

Porphyrin levels and excretion are generally much greater in CEP than in other forms of porphyria. Porphyrins are primarily uroporphyrin I and coproporphyrin I in urine and mostly coproporphyrin I in feces. ALA and PBG are normal. In most cases, uroporphyrin I predominates in erythrocytes. A predominance of protoporphyrin in red cells has been described in some cases with milder disease. Cutaneous features of CEP are readily distinguished from erythropoietic protoporphyria but may resemble hepatoerythropoietic porphyria (see later) and homozygous cases of VP and HCP. These conditions are distinguishable by patterns of porphyrins and porphyrin precursors and should be confirmed by molecular studies.

TREATMENT Rx

Protection of the skin from sunlight and minor trauma and prompt treatment of secondary bacterial infections help prevent scarring and mutilation. Improvement may occur after splenectomy. Oral charcoal may be helpful by increasing fecal excretion of porphyrins. Blood transfusions, sometimes combined with hydroxyurea, may suppress erythropoiesis sufficiently to reduce porphyrin overproduction. Vitamin D and calcium supplementation is recommended. Hematopoietic stem cell transplantation (Chapter 181) may be the most effective current therapy. Gene therapy may eventually be possible.

PREVENTION

In affected families, heterozygotes can be detected by molecular studies, and CEP can be diagnosed in utero. Therefore, options are available to prevent genetic transmission.

Hepatoerythropoietic Porphyria

This rare autosomal recessive disease is clinically similar to CEP but is the homozygous form of familial (type 2) porphyria cutanea tarda, with porphyrin patterns in urine and feces resembling that disease. In addition, erythrocyte UROD activity is markedly decreased, and erythrocyte zinc protoporphyrin is substantially increased. At least one of the *UROD* mutations in a patient with hepatoerythropoietic porphyria (HEP) expresses some enzyme activity because two null mutations would be lethal. Increased erythrocyte protoporphyrin probably reflects an earlier accumulation of uroporphyrinogen III in erythroblasts, which after completion of hemoglobin synthesis, is metabolized to protoporphyrin. A similar explanation can account for increased erythrocyte protoporphyrin in other homozygous forms of porphyria.

Hereditary Coproporphyria and Variegate Porphyria

EPIDEMIOLOGY

These autosomal dominant acute hepatic porphyrias are clinically similar to AIP but are less common in most countries. Unlike AIP, these disorders can cause blistering cutaneous photosensitivity. Variegate porphyria is prevalent in South Africa, where most cases have been traced to a couple who emigrated from Holland in the late 1600s, one of whom carried a disease-causing mutation.

Pathobiology

Hereditary coproporphyria (HCP) and variegate porphyria (VP) are due to approximately 50% deficiencies of coproporphyrinogen oxidase (CPO) and protoporphyrinogen oxidase (PPO), respectively. Many different mutations in the genes for these enzymes have been described. A specific mutation of the *PPO* gene (R59W) is common in South Africa. ALA and PBG are increased during acute attacks, although the degree and duration of increases are usually less than in AIP. Increases in ALA and PBG occur when hepatic ALA synthase (ALAS1) is induced by factors such as endogenous steroids, drugs, and nutritional alterations and because PBG deaminase activity is almost as low as ALAS1 activity even in the normal liver. Coproporphyrinogen III may accumulate in VP because of a functional association between CPO and the deficient PPO in mitochondria. Furthermore, coproporphyrinogen is more readily lost from the liver than are other porphyrinogens, and

TABLE 217-4 FIRST-LINE LABORATORY TESTS FOR SCREENING FOR PORPHYRIAS AND SECOND-LINE TESTS FOR FURTHER EVALUATION WHEN THE INITIAL TEST RESULT IS POSITIVE*

	Symptoms Suggesting Porphyria		
		CUTANEOUS PHOTOSENSITIVITY	
TESTING	ACUTE NEUROVISCERAL SYMPTOMS	*Blistering*	*Nonblistering*
First line	Urinary ALA, PBG, and total porphyrins (quantitative; random urine)‡	Total plasma porphyrins†	Total erythrocyte protoporphyrin
Second line	Urinary ALA, PBG, and total porphyrins§ (quantitative) Total fecal porphyrins§ Erythrocyte PBG deaminase Total plasma porphyrins†	Erythrocyte porphyrins Urinary ALA, PBG, and total porphyrins§ (quantitative) Total fecal porphyrins§	Fractionate free and zinc protoporphyrin

*All tests are quantitative, except for a rapid method for urinary PBG using a kit. DNA studies are indicated after a diagnosis has been established biochemically.
†The preferred method is by direct fluorescent spectrophotometry.
‡Semiquantitative testing for PBG using a kit is preferred in acutely ill patients (see text).
§Random urine with measured creatinine or a 24-hour collection. Fractionation of urinary and fecal porphyrins is useful only if the total is increased.
ALA = δ-aminolevulinic acid; PBG = porphobilinogen.

its loss increases further when heme synthesis is stimulated. In one form of HCP, termed *harderoporphyria*, a structurally altered CPO with reduced substrate affinity results in accumulation of harderoporphyrin (tricarboxyl porphyrinogen) as well as coproporphyrinogen. The excess porphyrinogens are auto-oxidized to the corresponding porphyrins. Rare homozygous cases of HCP and VP have severe photosensitivity and developmental abnormalities but few acute attacks.

Clinical Manifestations

Drugs, steroids, and nutritional factors that are detrimental in AIP provoke exacerbations of HCP and VP. Neurologic manifestations are identical to those in AIP. Blistering skin lesions, which are much more common in VP than in HCP, are identical to those in PCT and may occur apart from the neurovisceral symptoms. Impaired biliary excretion by concurrent liver diseases or drugs such as contraceptive steroids can cause porphyrin retention and worsen photosensitivity.

Diagnosis

Urinary ALA and PBG are commonly increased during acute attacks. With resolution of symptoms, ALA and PBG normalize more readily than in AIP. Increases in urinary porphyrins are more persistent. A marked, isolated increase in fecal coproporphyrin III is distinctive for HCP. Fecal coproporphyrin and protoporphyrin are about equally increased in VP. The fluorescence spectrum of plasma porphyrins (at neutral pH) is characteristic and useful for rapidly distinguishing VP from the other porphyrias and is the most sensitive porphyrin test, in adults, for detection of VP, including latent cases. However, identification of specific CPO and PPO mutations is recommended and facilitates screening of relatives.

TREATMENT

Rx

Acute attacks of both HCP and VP are treated as in AIP. The striking decreases in attacks and deaths from VP in South Africa have been attributed to identification of latent cases, avoidance of potentially harmful drugs, and better treatment during acute attacks. Avoiding sunlight and wearing clothing material designed to protect the skin from sunlight are helpful to prevent photosensitivity. Phlebotomies and hydroxychloroquine are not effective.

Dual Porphyria

Dual porphyria refers to patients with porphyria and deficiencies of more than one enzyme of the heme biosynthetic pathway. Examples include deficiencies of both PBG deaminase and UROD (with symptoms of AIP, PCT, or both), UROS and CPO, and ALA dehydratase and CPO. Dual enzyme deficiencies may be suspected from patterns of porphyrin precursors and porphyrins, but molecular diagnosis is essential.

LABORATORY DIAGNOSIS OF PORPHYRIAS

Porphyrias in patients with symptoms are readily detected and misdiagnoses avoided by relying on a few first-line tests that are both specific and sensitive, and on further testing when an initial result is abnormal. This avoids overuse of tests that are expensive and commonly misinterpreted. The preferred tests for screening, as outlined in Table 217-4, are the following:

1. Urinary porphyrin precursors (ALA and PBG) and total porphyrins for patients with concurrent or recent neurovisceral symptoms—for initial diagnosis of AIP, HCP, VP, and very rarely, ADP. Increases are expected to be so striking during an attack of acute porphyria that quantitation in a random urine sample is highly informative. A substantial increase in PBG is highly specific for AIP, HCP, or VP, and is not found in other medical conditions. Assays for PBG employ Ehrlich's aldehyde (*p*-dimethylaminobenzaldehyde), which forms red-purple chromogens with PBG, urobilinogen, and other substances in urine. Qualitative methods for increased PBG (e.g., the Watson-Schwartz and Hoesch tests) are obsolete. A kit that is reliable for screening for increased PBG in urine includes color standards to aid interpretation (Trace PBG kit, Thermo Fisher Scientific).
2. Plasma total porphyrins in patients with blistering skin lesions—to detect PCT, HCP, VP, CEP, and HEP. Total plasma porphyrins are virtually always increased in patients with active, blistering skin lesions due to these conditions. Measurement of urinary porphyrins is an alternative, but elevations are less specific. Fractionation of urine or plasma porphyrins during screening is not helpful because slight elevations in individual porphyrins are not diagnostically important if the total is normal. Measurement of plasma porphyrins is best carried out by a simple and direct fluorometric method. Plasma porphyrins in VP are mostly covalently bound to plasma proteins and may not be detected by other methods.
3. Total erythrocyte protoporphyrin for patients with nonblistering photosensitivity—to detect EPP.

More extensive biochemical testing is required if an initial screening test provides a positive result or may also be necessary initially if subclinical porphyria is suspected. This should include not only urinary ALA, PBG, and total porphyrins, total plasma porphyrins, and erythrocyte protoporphyrin, but also fractionation of urinary porphyrins and fecal total porphyrins (and fractionation if elevated). If plasma total porphyrins are elevated, fluorometric scanning (particularly to differentiate VP) should be done. Elevation in urinary porphyrins (especially coproporphyrin) in the absence of increases in plasma, erythrocyte, or fecal porphyrins is nonspecific, is common in liver and bone marrow disorders and other medical conditions, and is unlikely to indicate a type of porphyria. Erythrocyte protoporphyrin is increased in many red cell disorders, such as iron deficiency and lead poisoning, but in these conditions, it is complexed with zinc rather than metal free, as in EPP. Fecal porphyrin determinations are semiquantitative and subject to interference by diet and other factors. Once a biochemical diagnosis of a specific type of porphyria is established, molecular studies are important to identify the inherited mutation. In most cases of PCT, there is no underlying *UROD* mutation, but a thorough evaluation for all major susceptibility factors is clinically important.

Laboratory testing of asymptomatic relatives is usually not appropriate until test results have firmly established a diagnosis of porphyria in an index case. Results of testing of the index case guide the choice of tests for relatives. Consultation with a physician and laboratory with experience in testing for

porphyrias is helpful in these situations. Cytosolic heme biosynthetic pathway enzymes (ALA dehydratase, PBG deaminase, UROS, and UROD) can be measured in erythrocytes. This is not recommended for initial screening of patients with symptoms suggestive of porphyria. The other heme pathway enzymes are mitochondrial and are measured in cells such as lymphocytes; these assays are not widely available. Demonstration of a specific mutation in a family greatly facilitates detection of relatives who carry the same mutation.

Laboratory data that were the basis for an original diagnosis of porphyria should remain available for future reference. Incorrect diagnoses of porphyria are not uncommon when in fact symptoms are due to other diseases. There is little evidence for the suggestion that porphyria is common in disorders such as multiple chemical sensitivity syndrome.

WILSON'S DISEASE

STEPHEN G. KALER

DEFINITION

Wilson's disease is an autosomal recessive disorder of copper transport. Affected individuals accumulate abnormal levels of copper in the liver and later in the brain as a consequence of mutations in both alleles of the Wilson's disease gene *(ATP7B)*. The gene was identified in 1993 and encodes a copper-transporting ATPase expressed primarily in the liver, where its major function is excretion of hepatic copper into the biliary tract.

The clinical condition was first described in 1912 by S. A. K. Wilson, an American neurologist working in England. Thirty-six years later, pathologist J. N. Cummings proposed an etiologic connection with copper overload. Therapy with copper chelation by penicillamine was introduced in 1956 by J. M. Walshe, a British physician working at Boston City Hospital in Massachusetts.

EPIDEMIOLOGY

The incidence of Wilson's disease, defined as the occurrence of new cases, is approximately 1 in 30,000 to 40,000 live births. For special populations in which consanguineous mating is common, the risk of autosomal recessive traits such as Wilson's disease is higher.

In the general population, the prevalence of heterozygous gene carriers (defined as the ratio of all individuals with one mutant *ATP7B* allele to the population at risk of harboring one) is estimated to be 1 in 90. These individuals may represent a group susceptible to liver disease related to environmental copper exposure.

PATHOBIOLOGY

Individuals consume 1 to 3 mg of dietary copper daily, of which approximately 50% is absorbed through the gastrointestinal tract. Most diets contain adequate amounts of copper, and certain foods (e.g., shellfish, liver, mushrooms, chocolate, nuts) contain particularly high quantities. In normal homeostasis, copper is absorbed from the stomach and duodenum, where absorption is mediated by specific copper uptake genes (e.g., *hCTR1*). The Menkes disease gene *(ATP7A)*, which encodes a copper-transporting ATPase with high homology to *ATP7B*, transports copper from intestinal epithelial cells into the blood stream, where it is bound by albumin or amino acids and carried to the liver and other organs and tissues.

Within the liver, copper may be (1) incorporated into ceruloplasmin, a multifunctional 132-kD α_2-glycoprotein enzyme containing six or seven copper atoms per molecule; (2) used in the synthesis of other copper-requiring enzymes; (3) bound by metallothionein, a low-molecular-weight, cysteine-rich protein that provides a storage and detoxification depot for copper and other trace metal elements; or (4) excreted into the bile.

In Wilson's disease, metallation of ceruloplasmin is usually impaired, reflecting impaired transport of copper into the trans-Golgi compartment, where processing of ceruloplasmin occurs. This results in low circulating levels of the ceruloplasmin holoenzyme. Copper excretion into bile is invariably impaired, producing massive hepatic copper overload if the disease is unrecognized. These findings indicate that copper incorporation into ceruloplasmin and biliary excretion of copper are both mediated by the Wilson's disease gene product in the normal state.

Circulating levels of ceruloplasmin and total serum copper are low in many patients with Wilson's disease. However, these biochemical abnormalities are not necessarily associated with liver disease, as illustrated by the inherited disorders aceruloplasminemia, Menkes disease, and occipital horn syndrome. A feature that distinguishes Wilson's disease from these conditions is the amount of non-ceruloplasmin-bound serum copper, which is about five times normal in Wilson's disease patients.

Thus, the major pathophysiologic component of Wilson's disease is hepatic copper overload resulting from defective biliary excretion of the metal. If this diagnosis goes unrecognized, copper overload subsequently involves other tissues, including the brain, which is particularly sensitive to perturbations in trace metal homeostasis.

CLINICAL MANIFESTATIONS

Presenting clinical features of Wilson's disease include nonspecific liver disease, neurologic abnormalities, psychiatric illness, hemolytic anemia, renal tubular Fanconi's syndrome, and various skeletal abnormalities.

Age influences the specific presentation in Wilson's disease. Nearly all individuals who present with liver disease are younger than 30 years, whereas those presenting with neurologic or psychiatric signs may range in age from the first to the fifth decade. This reflects the sequence of events in the pathogenesis of this disease (see earlier discussion). However, regardless of clinical presentation, some degree of liver disease is invariably present. In one series of 400 adult patients with Wilson's disease, approximately 50% presented with neurologic and psychiatric symptoms, 20% with neurologic and hepatic symptoms, and 20% with purely hepatic symptoms.

In patients with neurologic presentations, abnormalities include speech difficulty (dysarthria), dystonia, rigidity, tremor or choreiform movements, abnormal gait, uncoordinated handwriting, and (rarely) a combined motor and sensory peripheral neuropathy. Wilson's disease may properly be classified as a movement disorder. The neurologic signs and symptoms reflect a predilection for involvement of the basal ganglia (e.g., caudate, putamen) in the brains of these individuals. Parkinson's disease or other movement disorders may be mistakenly diagnosed.

In psychiatric presentations, changes in personality (irritability, anger, poor self-control), depression, and anxiety are common symptoms. Patients presenting in this fashion are typically in their late teens or early 20s, a period during which substance abuse is also a diagnostic consideration. Wilson's disease should be formally excluded in all teenagers and young adults with new-onset psychiatric signs.

In hepatic presentations, signs and symptoms include jaundice, hepatomegaly, edema, and ascites. Secondary endocrine effects of liver disease may include delayed puberty or amenorrhea. Viral hepatitis and cirrhosis are often initial diagnostic considerations in individuals with Wilson's disease.

In addition to the brain and liver, the eye is a primary site of copper deposition in Wilson's disease, producing a pathognomonic sign—the Kayser-Fleischer ring (Fig. 218-1). The Kayser-Fleischer ring is a golden to green-brown annular deposition of copper in the periphery of the cornea. This important diagnostic sign first appears as a superior crescent, then develops inferiorly and ultimately becomes circumferential. Slit lamp examinations are required to detect rings in their early stage of formation. Copper can also accumulate in the lens and produce "sunflower" cataracts.

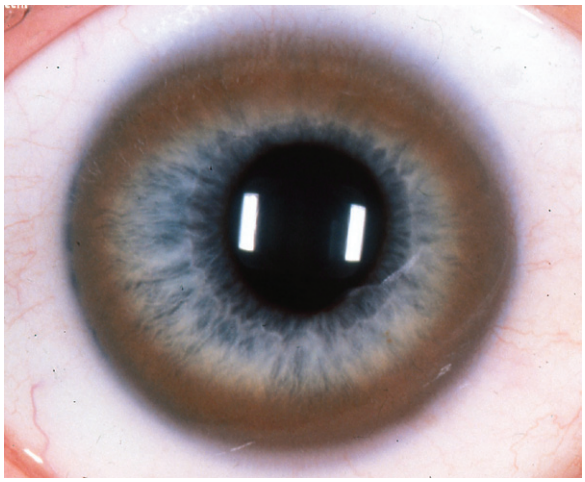

FIGURE 218-1. Kayser-Fleischer ring in a newly diagnosed patient with Wilson's disease.

Approximately 95% of patients with neurologic signs manifest the Kayser-Fleischer ring, compared with approximately 65% of those with hepatic presentations. Copper chelation therapy causes fading and even disappearance of corneal copper over time.

Hemolytic anemia resulting from the direct toxic effects of copper on red blood cell membranes has been observed in Wilson's disease. This is usually associated with the release of massive quantities of hepatic copper into the circulation, a phenomenon that can be sudden and catastrophic.

Renal dysfunction in Wilson's disease is tubular in nature and leads to abnormal losses of amino acids, electrolytes, calcium, phosphorus, and glucose. This effect is presumably related to copper toxicity. High copper levels have been noted previously in the kidneys of patients with Wilson's disease. Treatment with copper chelation often improves the renal disturbances.

There can be skeletal effects of Wilson's disease, including osteoporosis and rickets; these may be attributable to renal losses of calcium and phosphorus. Osteoarthritis primarily affecting the knees and wrists also occurs in Wilson's disease patients and may involve excess copper deposition in the bone and cartilage.

DIAGNOSIS

The presence of the clinical abnormalities described earlier is valuable in the clinical diagnosis of Wilson's disease. Laboratory findings that support the diagnosis include low levels of serum copper and serum ceruloplasmin, elevated hepatic transaminase levels, aminoaciduria, and hemolytic anemia. Incorporation of radiolabeled ^{64}Cu into serum ceruloplasmin, measured as the appearance of copper in the serum after an oral load, is a highly specific diagnostic test; patients with Wilson's disease incorporate very little ^{64}Cu into ceruloplasmin.

Increased urinary excretion of copper (>100 mg/24 hours) is another easily performed and important diagnostic test for this disorder. Acid-washed (copper-free) collection containers should be used. A variation involving serial urine copper measurements is the penicillamine "challenge," in which 500 mg of penicillamine is administered orally after collection of a baseline 24-hour urine specimen. The penicillamine dose is repeated after 12 hours, the midpoint of the second 24-hour urine collection. A several-fold increase in copper excretion in the second collection is highly suggestive of the diagnosis. Some workers believe the challenge does not add enormously to the diagnostic evaluation compared with the baseline measurement alone.

Although it is an invasive technique, percutaneous needle liver biopsy for quantitative measurement of hepatic copper remains the "gold standard" for diagnosis. Hepatic copper values greater than 200 mg/g of dry weight (normal, 20 to 50 mg/g dry weight) are characteristic of Wilson's disease. Atomic absorption spectrometry is the preferred method; histochemical staining for copper in a liver biopsy specimen is unreliable.

A Wilson's disease mutation database (http://www.wilsondisease.med.ualberta.ca/database.asp) contains nearly 300 different mutations reported at the *ATP7B* locus. For families in which the mutant alleles have been determined, molecular diagnosis is highly reliable.

In summary, in the absence of formal molecular evidence, the diagnosis of Wilson's disease can be reliably rendered by the presence of at least two of the following: a positive family history, Kayser-Fleischer rings, Coombs-negative hemolytic anemia, low serum copper and ceruloplasmin, elevated hepatic copper, increased 24-hour urine copper, and a positive penicillamine challenge result.

TREATMENT Rx

Penicillamine, a free thiol that binds (chelates) copper, does not formally correct the basic defect of impaired copper excretion in the bile; however, it greatly enhances urinary excretion of copper and thereby prevents copper overload and its effects. Faithful compliance with oral penicillamine treatment has enabled the good health of thousands of Wilson's disease patients worldwide over the past 50 years. Pyridoxine (vitamin B_6) should be prescribed concomitantly to counter the vitamin B_6 deficiency that tends to develop with long-term penicillamine administration.

Certain individuals are intolerant of penicillamine. Significant side effects include nephrotoxicity; hematologic abnormalities; and a distinctive rash, elastosis perforans serpiginosa, which often involves the neck and axilla. Furthermore, in some Wilson's disease patients with neurologic presentations, penicillamine treatment induces paradoxical worsening of the clinical phenotype.

Even though penicillamine is the therapy with the longest experience, other pharmaceutical agents are available that may eventually supplant it as a first-line drug. For example, triethylene tetramine dihydrochloride (trien) is a suitable alternative chelating agent with a somewhat less significant side effect profile.

Oral zinc acetate also has proved highly effective in Wilson's disease. The mechanism involves induction of metallothionein synthesis in intestinal epithelial cells; increased metallothionein synthesis results in greater binding of dietary copper and thus decreased absorption. Zinc monotherapy has particular value in young, presymptomatic patients; in patients who are pregnant, given the possible fetal teratogenic effects of other compounds; and as maintenance therapy for patients after their initial "de-coppering" is accomplished. Zinc acetate has minimal side effects. The only drawback to its use is the relatively long time (4 to 6 months) needed to restore the proper copper balance if zinc is used alone in the initial stages of treatment.

Tetrathiomolybdate is a molecule that forms stable tripartite complexes with protein and copper. This drug both decreases copper absorption and reduces circulating free copper. It is fast acting and can restore normal copper balance within several weeks, compared with the several months required with other copper chelators or with zinc. Tetrathiomolybdate is especially appropriate for the initial treatment of patients with neurologic presentations, based on a completed clinical trial.[1]

Regardless of the specific regimen chosen, treatment of Wilson's disease is lifelong, because noncompliance eventually leads to fulminant liver failure.

Liver transplantation is a rare consideration in Wilson's disease because the condition is typically responsive to medical therapy. It is generally necessary only when delayed diagnosis or poor compliance results in irreversible hepatic damage.

Apart from pharmacologic treatment, there are several other important considerations in the treatment of Wilson's disease. These include dietary restriction of shellfish and liver, both copper-rich foods. The major sources of patients' drinking water should be tested for copper concentration and avoided if levels approach 1.3 mg/L, which is the current maximum contaminant level goal (MCLG) established by the U.S. Environmental Protection Agency. The MCLG for copper in drinking water is set at a concentration at which no known or expected adverse health effects occur and for which there is an adequate margin of safety.

In newly diagnosed patients, there is frequently a need for speech therapy and physical or occupational therapy, as well as psychological and genetic counseling.

Wilson's Disease Heterozygotes

There is some debate about the risk of copper overload among individuals who are heterozygous for Wilson's disease. Even though Wilson's disease is a classic autosomal recessive trait—that is, requiring two mutant alleles at the *ATP7B* locus for expression of the disease—a report from the National Academy of Sciences suggested that heterozygous Wilson's disease carriers may be a relatively sensitive population in terms of copper overload, particularly when dietary or drinking water copper exposure is higher than usual. Abnormally increased urinary copper excretion has been documented among some siblings of Wilson's disease patients, although genetic confirmation of the carrier or noncarrier status of these individuals was not available. Further patient and family studies are needed to formally address these questions.

PROGNOSIS

The prognosis in Wilson's disease is generally favorable. Current therapeutic approaches can prevent or reverse most of the significant clinical signs

and symptoms, including Kayser-Fleischer rings. However, if treatment is stopped, potentially fatal liver damage inevitably occurs.

FUTURE DIRECTIONS

Gene therapy for Wilson's disease is a possibility. Because the Wilson's copper transporter is expressed most prominently and functions most critically in the liver, this organ could be specifically targeted by the use of adenoviral or adeno-associated viral vectors (e.g., AAV8). Hepatocyte transfer, an alternative to gene therapy, may also be applicable to the treatment of liver-specific metabolic disorders through therapeutic liver repopulation.

IRON OVERLOAD (HEMOCHROMATOSIS)

BRUCE R. BACON

DEFINITION AND EPIDEMIOLOGY

Hereditary hemochromatosis (HH) is a common inherited disorder of iron metabolism. The genetic abnormality responsible in most patients with typical HH is found in homozygous form in about 1 in 250 persons of northern European descent. It is characterized by an increase in iron absorption from the upper gastrointestinal tract, with subsequent tissue iron deposition in parenchymal cells of the liver, heart, pancreas, joints, and endocrine organs. The autosomal recessive inheritance pattern of HH was clearly shown in the 1970s, and the gene responsible for most cases of HH was identified in 1996 by investigators using a positional cloning technique. The gene is called *HFE* and encodes for a novel major histocompatibility complex (MHC) class 1–like molecule that binds with transferrin receptor (TfR) and affects hepcidin homeostasis (Fig. 219-1). Recent prospective population studies have demonstrated that only about 50% of patients who are homozygous for the major mutation found in *HFE* (called C282Y) have evidence of phenotypic expression of iron overload, and only a small percentage (<10%) go on to develop tissue damage from excess iron deposition. These studies have changed modern thinking about HH and must be considered when evaluating patients for this disease in a physician's office and when developing national health policy regarding screening for this genetic disorder.

The discovery of *HFE* has had a tremendous impact in a number of areas. The ability to accurately diagnose disorders of iron overload has been strengthened, family screening is improved, and the evaluation of patients with other forms of liver disease complicated by moderate to severe iron overload is possible. Furthermore, with the discovery of *HFE*, a considerable new body of knowledge regarding the mechanisms of iron absorption has been identified, both in the normal situation and in the pathologic condition seen when *HFE* mutations are present.

PATHOBIOLOGY

Classification of Iron Overload Syndromes

The term *hereditary hemochromatosis* should be reserved for inherited disorders of iron metabolism (see Fig. 219-1) that lead to tissue iron loading (Table 219-1). The most common form of this disease, *HFE*-related HH, is caused primarily by homozygosity for the C282Y mutation in the *HFE* gene. Other heritable forms of iron overload have also been recognized (non-*HFE*-related HH). These include (1) autosomal recessive forms of HH characterized by rapid iron accumulation and caused by mutations in the genes for hemojuvelin and hepcidin (also called juvenile hemochromatosis), (2) an autosomal dominant form of HH caused by mutations in the ferroportin gene, (3) an autosomal recessive form of HH resulting from mutations in the gene for *TfR-2*, and (4) rare forms of HH resulting from mutations in the *DMT-1* gene or in the regulatory region of ferritin messenger RNA. Some other types of iron overload may have a familial or inherited component, but the genes involved have not yet been identified. For example, African iron overload is a familial disorder of iron loading prevalent in sub-Saharan Africa that is exacerbated by the ingestion of iron-rich home-brewed beer. Many of these patients have mutations in ferroportin. The degree of iron loading can be similar to that seen in *HFE*-related HH, but the cellular and lobular distribution of iron is different. In addition, a rare disorder termed neonatal iron overload is characterized by a modest increase in hepatic iron accompanied by severe liver injury present at birth.

It has been recognized over the last several years that many patients who have *HFE*-linked hemochromatosis have no evidence of iron overload. With this in mind, four stages of HH have been described:

1. Genetic predisposition with no phenotypic abnormality
2. Iron overload (approximately 2 to 5 g total body iron) without symptoms
3. Iron overload with mild or early symptoms
4. Iron overload with organ damage, such as cirrhosis

The ability to establish a genetic diagnosis has led to a much greater understanding of genotype-phenotype correlations.

Genetics and Pathophysiology of Hemochromatosis

Since the classic linkage studies of Simon and colleagues in the mid-1970s, it has been known that the gene for hemochromatosis is located in the human leukocyte antigen (HLA) region on chromosome 6. In 1996 a team of molecular geneticists using a positional cloning technique identified a candidate gene for HH, which is now called *HFE*. *HFE* codes for a novel MHC class 1–like molecule, which, like all MHC proteins, requires interaction with β_2-microglobulin for normal presentation on the cell surface. Three principal missense mutations have been identified in *HFE:* one results in a change of cysteine at position 282 to tyrosine (Cys282 → Tyr, C282Y), the second results in a change of histidine at position 63 to aspartate (His63 → Asp, H63D), and the third results in a change of serine at position 65 to cysteine (Ser65 → Cys, S65C). A few other mutations have been identified in *HFE*, but their frequency is low and their clinical impact is limited. In the original study by Feder and associates, 83% of typical phenotypic HH patients were found to be homozygous for the C282Y mutation. Several other studies from around the world in predominantly white populations demonstrated that, among patients with typical hemochromatosis, about 85 to 90% were homozygous for C282Y. Thus, about 10 to 15% of patients with typical HH have some reason other than C282Y homozygosity for their iron overload.

Nearly all absorption of dietary iron occurs in the duodenum, where iron may be taken up either as ionic iron or as heme. Ionic iron requires reduction to the ferrous state, which is accomplished by the ferric reductases (e.g., duodenal ferric reductase), expressed on the luminal surface of the duodenal enterocytes (see Fig. 219-1). This ferrous iron crosses the apical membrane via divalent metal transporter 1, and iron taken up by the enterocyte is either stored as ferritin or transferred across the basolateral membrane to the plasma. This latter process occurs via the iron transporter ferroportin and requires oxidation of iron to the ferric state by the ferroxidase hephaestin.

Hepcidin is a 25–amino acid peptide that influences systemic iron status such that it is now considered to be the principal iron regulatory hormone (see Fig. 219-1). Dysregulation of hepcidin expression is thought to play a role in the pathogenesis of HH. Patients with *HFE*-related HH have low hepatic expression of hepcidin, as do *HFE* knockout mice, despite excess hepatic iron stores. Conversely, overexpression of hepcidin in *HFE* knockout mice prevents the HH phenotype. Studies have revealed that iron-induced regulation of hepcidin expression involves a bone morphogenetic protein

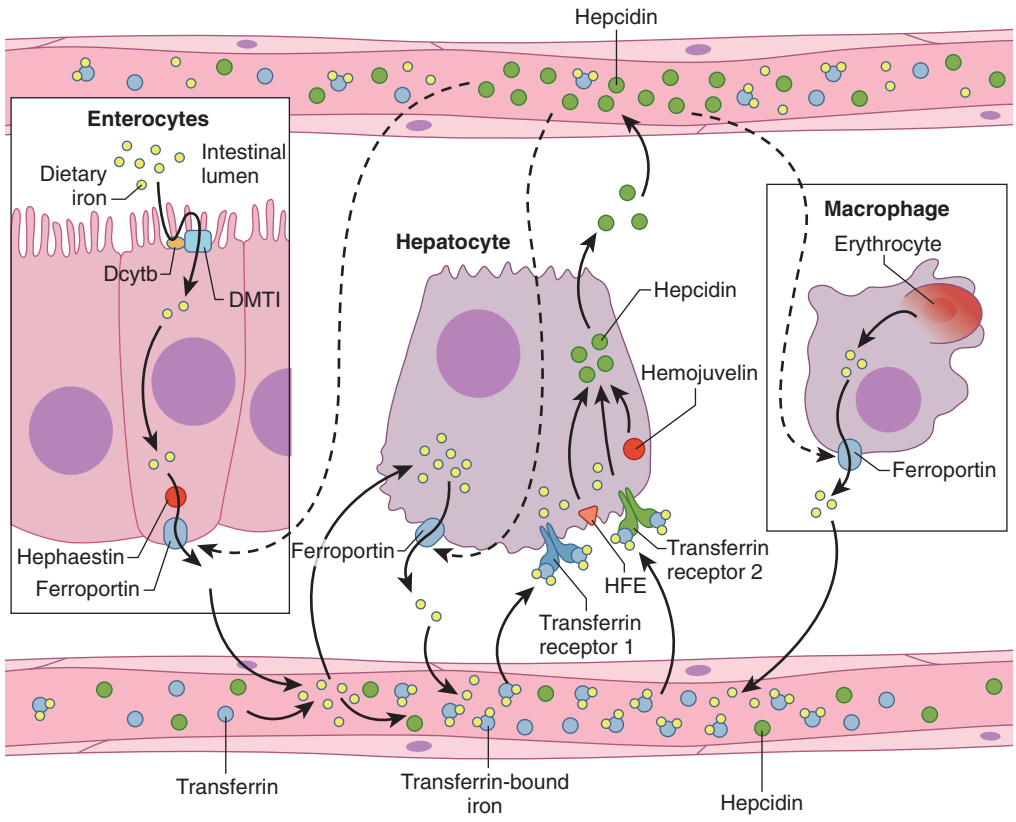

FIGURE 219-1. Orchestration of iron homeostasis. In the duodenal enterocyte, dietary iron is reduced to the ferrous state by duodenal ferric reductase (Dcytb), transported into the cell by divalent metal transporter 1 (DMT1), and released by way of ferroportin into the circulation. Hephaestin facilitates enterocyte iron release. Hepatocytes take up iron from the circulation either as free iron or as transferrin-bound iron (through transferrin receptors 1 and 2). Transferrin receptor 2 may serve as a sensor of circulating transferrin-bound iron, thereby influencing expression of the iron regulatory hormone hepcidin. The hepcidin response is also modulated by HFE and hemojuvelin. Hepcidin is secreted into the circulation, where it downregulates the ferroportin-mediated release of iron from enterocytes, macrophages, and hepatocytes (dashed lines). (From Fleming RE, Bacon BR. Orchestration of iron homeostasis. *N Engl J Med*. 2005;352:1741-1744.)

Excessive parenteral iron administration

(BMP)–dependent signaling pathway. BMPs bind to specific receptors on hepatocytes, thereby triggering SMAD protein–dependent activation of hepcidin expression. Selective inhibition of BMP signaling abrogates iron-induced upregulation of hepcidin. Hemojuvelin is a BMP coreceptor and facilitates the binding of BMP to its receptor; knockout of the hemojuvelin gene markedly decreases BMP signaling and hepcidin expression and causes iron overload. It has been hypothesized that *TfR-2* in hepatocytes may act as an iron sensor. Mutations in *TfR-2* cause a rare form of HH in humans, and *TfR-2* mutant mice have an HH phenotype. In HH, excess iron (both transferrin bound and non–transferrin bound) is avidly taken up by hepatocytes and stored. Iron stores increase to the point at which iron-induced oxidative damage occurs, resulting in cell injury and cell necrosis with phagocytosis by Kupffer cells. Iron-laden Kupffer cells become activated and produce profibrogenic cytokines (transforming growth factor-β, platelet-derived growth factor), which stimulate hepatic stellate cells to synthesize excess collagen and other matrix proteins. Increased fibrosis and then cirrhosis result.

CLINICAL MANIFESTATIONS

Several symptoms and clinical findings have been identified in patients with fully established HH, and all physicians should be aware of these symptoms and findings, which are summarized in Tables 219-2 and 219-3. Table 219-4 summarizes the typical laboratory findings in symptomatic and asymptomatic patients with HH. Recent series have revealed that many asymptomatic patients who are C282Y homozygotes are now coming to medical attention because they are identified by family screening studies or population surveys or after abnormal iron studies are discovered on routine blood chemistry testing. It is ideal to identify patients who have some phenotypic expression with abnormal iron studies but no evidence of organ damage. Several large population screening studies have shown evidence of phenotypic expression with abnormal iron studies in about 40 to 50% of C282Y homozygotes, but less than 10% of these individuals actually have signs and symptoms of the disease.

DIAGNOSIS

Because patients with genetic abnormalities can be identified before there is evidence of phenotypic expression, the method of diagnosing HH has undergone a change. The role of liver biopsy has lessened considerably with the advent of genetic testing. Nonetheless, some general principles should be acknowledged. If the diagnosis of HH is being considered, blood tests,

including transferrin saturation (serum iron ÷ transferrin or total iron binding capacity × 100%) and ferritin levels, should be obtained. A recent study from the HEIRS trial showed that transferrin saturation does not need to be measured in the fasting state to obtain reliable results. In patients with symptoms (see Table 219-2), both these values are elevated; however, transferrin saturation is typically the earliest phenotypic marker of HH and may be elevated in young C282Y homozygotes with normal ferritin levels. Serum ferritin is sometimes elevated in other conditions, such as certain cancers and chronic inflammatory disorders, in which there is no evidence of iron overload. Furthermore, in patients with other types of liver disease, such as chronic hepatitis C, nonalcoholic steatohepatitis, and alcoholic liver disease, ferritin levels can be elevated in as many as half the patients studied. Thus, ferritin is relatively sensitive but not specific for iron overload in the presence of these other disorders. The development of a widely available genetic test has contributed to better characterization of patients with underlying liver disease and abnormal serum iron studies.

In the past, if an elevated transferrin saturation or ferritin level was identified, a liver biopsy would be performed to establish a diagnosis using histochemical iron stains and biochemical determination of the hepatic iron

concentration with calculation of the hepatic iron index (HII). The HII is the patient's hepatic iron concentration (in µmol/g dry weight) divided by the patient's age in years. Previously, when the HII was greater than 1.9, the diagnosis of HH was established. Recent studies with genetic testing have shown that many (>50%) HH patients may have an HII less than 1.9. Thus, the HII is no longer important in the diagnosis of HH.

Currently, when abnormal iron studies are identified, it is reasonable to proceed to genetic testing. Among individuals who are C282Y homozygotes or compound heterozygotes (C282Y/H63D), liver biopsy is reserved for those with elevated liver enzymes or ferritin levels greater than 1000 ng/mL (Fig. 219-2). Several studies have shown that advanced fibrosis or cirrhosis is not seen in HH patients when ferritin levels are less than 1000 ng/mL or when liver enzymes are normal. Accordingly, as genetic testing has become more widely available, liver biopsy is less necessary.

When liver biopsy is performed, iron deposition is found preferentially in a periportal (acinar zone 1) region of the hepatic lobule, with a decrease in gradient in acinar zones 2 and 3. With significant iron loading, sinusoidal lining cell (Kupffer cell) iron deposition can be identified, and iron can be found in bile duct cells and in fibrous tissue in portal tracts or septa. In patients with secondary iron overload related to alcoholic liver disease or chronic viral hepatitis, iron deposition is typically in Kupffer cells as well as in hepatocytes, and it occurs in a panlobular (as opposed to a periportal) distribution. Histologic evaluation of iron-staining patterns provides information complementary to that obtained by traditional biochemical testing for iron overload along with genetic testing.

TREATMENT

Even though there have been advances in the molecular and cellular biologic understanding of HH, and although the impact of *HFE* mutation analysis on diagnosis has been significant, the treatment of HH remains simple, inexpensive, and safe. Patients should have therapeutic phlebotomy of 500 mL of whole blood (approximately 200 to 250 mg of iron, depending on the hemoglobin concentration) on a weekly basis, if tolerated. Therapeutic phlebotomy should be performed until iron-limited erythropoiesis develops, identified by failure of the hemoglobin level and hematocrit to recover before the next phlebotomy. It is reasonable to monitor transferrin saturation and ferritin levels periodically (every 3 months) to predict iron stores' return to normal and

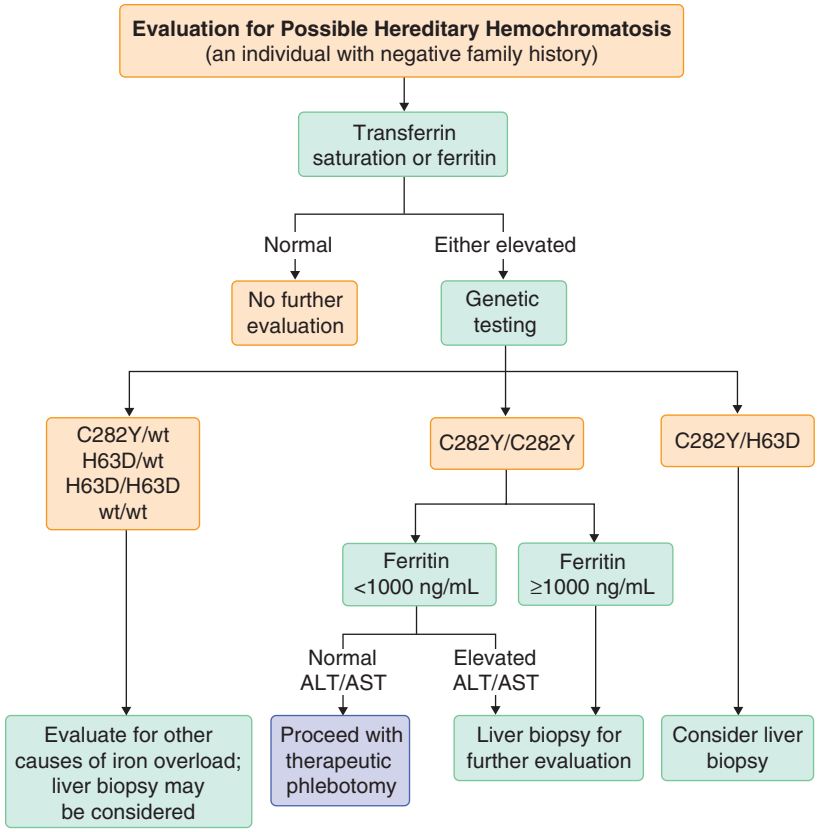

FIGURE 219-2. Algorithm for evaluation of possible hereditary hemochromatosis in a person with a negative family history. ALT = alanine transaminase; AST = aspartate transaminase.

to provide encouragement to patients who are undergoing phlebotomy. Therapeutic phlebotomy should be continued until the transferrin saturation is less than 50% and the ferritin level is less than 50 ng/mL. It is not necessary for patients to become anemic or iron deficient—just depleted of excess iron stores. Some patients may require weekly phlebotomy for 1 year or longer. Once the initial therapeutic phlebotomy has been completed, most patients require maintenance phlebotomy, with 1 unit of blood removed every 2 to 3 months. This requirement is derived empirically, with the intent being to maintain transferrin saturation at less than 50% and ferritin at less than 50 ng/mL.

With successful iron depletion, patients have an improved sense of well-being, right upper quadrant abdominal pain dissipates, liver test results improve, and diabetes may be easier to manage. Established cirrhosis, arthropathy, and testicular atrophy generally do not improve.

Iron chelation therapy may be necessary for patients who are anemic and cannot tolerate phlebotomy. Parenteral infusions (administered either subcutaneously using an infusion pump or intravenously overnight via a port) of deferoxamine are used. Ototoxicity and ocular toxicity are possible with deferoxamine, and appropriate monitoring should be performed. An orally administered iron chelator, deferasirox, is approved and available for treating secondary iron overload in patients with iron-loading anemias. This therapy is not yet approved for HH in the United States and is quite expensive.

PREVENTION

Family Screening

Once an HH proband is recognized, all first-degree relatives should be offered testing. In the past, HLA haplotyping was performed, but now *HFE* mutation analysis is recommended, along with the determination of transferrin saturation and ferritin levels. In probands with children, *HFE* mutation analysis is performed in the spouse to accurately predict the genotype in the child. If the spouse has either mutation, testing of the child is necessary, although the value and availability of genetic testing in children are debated. If an adult relative of a C282Y homozygote is identified and is either a C282Y homozygote or a compound heterozygote, and if blood iron studies are abnormal, a presumptive diagnosis can be made, and therapeutic phlebotomy can be initiated using the guidelines already discussed.

Population Screening

Because HH is a common disorder with a well-described treatment and a long latent period (i.e., time before disease occurs), some have suggested that it is an ideal candidate for population screening by genetic testing. However, recent studies have showed a less than expected phenotypic expression and a decreased number of patients with clinical manifestations of iron-mediated disease, raising questions about this recommendation. Initial results from a large National Institutes of Health–sponsored screening study in North America demonstrated a prevalence of C282Y homozygosity of 1 in 227. The C282Y homozygotes had higher ferritin levels than the general population, but 25% had normal ferritin levels. When screening for iron overload as opposed to screening for *HFE*-linked HH, transferrin saturation should be measured. In this situation, when abnormal iron studies are identified and the patient does not have a mutation in *HFE*, liver biopsy should be considered to clarify the situation relative to iron stores.

PROGNOSIS

If patients are identified, diagnosed, and treated before the development of cirrhosis, their life expectancy is the same as for an age- and sex-matched control population. If patients are not identified and treated before the development of cirrhosis, they are at risk for premature death from either complications of chronic liver disease or hepatocellular cancer. Treated cirrhotic patients are still at risk for hepatocellular cancer and should undergo surveillance abdominal imaging every 6 to 12 months.

Mutation Analysis in Patients with Liver Disease

Many patients with liver disease have abnormalities in serum parameters of iron metabolism. These abnormalities are more commonly seen in patients with hepatocellular liver diseases than in those with cholestatic liver diseases. Several clinical studies have shown that approximately 50% of patients with alcoholic liver disease, chronic viral hepatitis C, and nonalcoholic steatohepatitis (NASH) have abnormalities in serum iron studies. Usually this abnormality is an elevation in serum ferritin, but elevated transferrin saturation is occasionally seen as well. When liver biopsy is performed, increased iron deposits can be seen, usually in a panlobular distribution, with iron in both hepatocytes and sinusoidal lining cells (Kupffer cells). Hepatic iron concentrations may be slightly increased or normal. When *HFE* mutations have been evaluated in patients with alcoholic liver disease, there has been no increased incidence of either C282Y or H63D (either heterozygote or homozygote) compared with control populations. Furthermore, there was no increase in *HFE* mutations in patients with alcoholic liver disease who had an increased amount of fibrosis. Thus, the abnormal iron studies frequently seen in patients

with alcoholic liver disease are most likely due to mechanisms other than mutations in *HFE*.

In chronic hepatitis C, the relationship of abnormal iron studies and elevated hepatic iron concentration with a response to interferon monotherapy has been known for several years. Numerous studies have shown that patients who fail to respond to interferon monotherapy have a higher hepatic iron concentration than those who do respond. A corollary to this observation involves therapeutic phlebotomy to deplete iron stores in the hope of improving response to therapy. Reduction in iron stores by therapeutic phlebotomy does reduce liver enzymes and has had some marginal beneficial effect on liver histology, but it does not have any virologic effects. When *HFE* mutation analysis has been investigated in patients with chronic hepatitis C, the frequency of C282Y and H63D has been equivalent to that in control populations. Most studies have shown that when *HFE* mutations are present, they correlate with increased iron stores seen histologically. Some studies have shown a synergistic effect with the development of fibrosis. At present, it is recommended that *HFE* mutation analysis be done when abnormal iron studies are seen in patients with chronic hepatitis C. Also, iron stains are typically performed on liver biopsy samples when biopsies are done to grade and stage chronic hepatitis C. If iron stores are increased, it is reasonable to perform therapeutic phlebotomy to deplete excess iron stores before initiating antiviral therapy.

In patients with NASH, several studies have provided conflicting results. Some have shown an increase in *HFE* mutations in patients with NASH, and others have shown no difference from control populations. When there has been an increased prevalence of *HFE* mutations in NASH, there has been good correlation between abnormal serum parameters of iron and a correlation with hepatic iron concentration. Furthermore, some studies have shown an increase in fibrosis in NASH patients with *HFE* mutations. Finally, one study showed a reduction in elevated liver enzymes and improvement in parameters of insulin resistance in patients with NASH treated by phlebotomy to produce near iron deficiency. These observations suggest an interaction between the expression of fatty liver disease and iron metabolism. Finally, in porphyria cutanea tarda (PCT), the relationship between abnormalities of iron metabolism and the role of therapeutic phlebotomy has been known for many years. Also, it has recently been shown that as many as 70% of patients with PCT are infected with hepatitis C virus, and many patients with PCT drink excessive amounts of alcohol. An increased prevalence of *HFE* mutations has been shown in both European and American studies of PCT patients, and the use of phlebotomy to deplete excess iron stores is still recommended.

Thus, *HFE* mutation analysis is of value in patients with PCT and may be of value in patients with chronic hepatitis C and NASH. It is probably not of value in patients with alcoholic liver disease.

NUTRITION'S INTERFACE WITH HEALTH AND DISEASE

DOUGLAS C. HEIMBURGER

OLD AND NEW PARADIGMS IN THE SCIENCE OF NUTRITION

Nutrition science was characterized by two major phases in the 20th century. During the first phase, nutrition scientists discovered, characterized, and synthesized the essential nutrients and described their deficiency syndromes in detail. The dietary requirements for these nutrients were estimated and periodically updated as recommended dietary allowances (RDAs). Beginning in 1997, the RDAs were reformulated in a series of volumes containing dietary reference intakes (DRIs); in addition to the recommended intakes judged to be sufficient to meet the nutrient requirements of nearly all healthy individuals, the DRIs include estimates of tolerable upper intake levels—that is, the highest intake levels likely not to pose any adverse health risks.

More fundamentally, the DRIs focus on accumulating evidence related to the relationships of diet and nutritional status to the diseases that plague Western societies, such as coronary heart disease, cancer, diabetes, and the other leading causes of death. DRIs recommend intake levels that not only prevent deficiencies but also may promote long-term health and disease prevention.

NUTRITION'S INFLUENCE ON MORTALITY AND MORBIDITY

Evidence of a Connection between Diet and Disease

It has been estimated that between 300,000 and 800,000 deaths per year could be prevented in the United States if Americans followed evidence-based dietary recommendations. Substantial additional benefits from reduced morbidity and enhanced functional status would also accrue. However, the causal connections between diet and chronic diseases are difficult to tease out of the complex network of other risk factors, including social and behavioral variables, so a wide variety of studies must be relied on to establish these connections with reasonable certainty.

Epidemiologic studies are unable to infer causal relationships and may be confounded by variables that have not been examined. They are also challenged by the difficulty of accurately assessing the diets of free-living individuals.

Animal and in vitro studies can overcome some of these drawbacks but may be confounded by experimental conditions that differ from those encountered by humans. A large number of prospective, randomized human intervention trials have been undertaken to test the effects of dietary change on risk for disease. However, even these trials are not always conclusive because of pitfalls associated with selecting study populations and isolating individual dietary factors.

Taken together, epidemiologic, animal, in vitro, and intervention studies are proving that human dietary habits contribute importantly to the pathogenesis of most of the major causes of death in developed countries.

Diseases Influenced by Nutrition

Table 220-1 lists 8 of the top 15 causes of death in the United States that are influenced by nutrition. Five are strongly linked to dietary habits, and three are associated with alcohol abuse. The table also outlines dietary contributions to obesity, atherosclerosis, osteoporosis, diverticular disease, and neural tube defects. A meta-analysis indicates that vitamin D supplementation reduces mortality in adults.■ Table 220-2 summarizes the 2005 Dietary Guidelines for Americans, and Table 220-3 compares dietary recommendations promulgated by professional societies for risk reduction and/or management of the major chronic diseases. The close agreement among these recommendations enhances their credibility.

Coronary Heart Disease

Nutritional influences on the leading cause of death in the United States, coronary heart disease (CHD), have been the subject of a great deal of research. The overall U.S. mortality rate from CHD peaked in the 1960s and, in a trend that has surprised medical science, has declined steadily since then. Changes in lifestyle, including diet, are responsible for a substantial proportion of this decline. Elevated plasma low-density lipoprotein (LDL) cholesterol levels are a major risk factor for CHD and peripheral atherosclerosis, and they correlate strongly with dietary saturated fat intake and less strongly with cholesterol intake. Intake of both these substances in the United States is derived largely from foods of animal origin, such as meats, dairy products, and eggs. Attempts to produce less atherogenic substitutes for some of these foods have not always proved beneficial. For instance, hydrogenation of vegetable oils to create margarine and shortening results in the formation of *trans*-fatty acids, which affect serum cholesterol levels in a manner similar to—and are perhaps even worse than—the saturated fatty acids found in butter and lard. LDL cholesterol levels can be lowered modestly by increasing the intake of soluble fiber from legumes, fruits, vegetables, and flax seed, as well as by consuming proteins and isoflavones from soy foods. LDL must be oxidized before it induces injury to the arterial wall. Although adequate dietary levels of the antioxidant vitamins C and E and β-carotene have been shown to inhibit LDL oxidation, pharmacologic doses of these vitamins have not reduced CHD events when tested in randomized trials. In fact, pharmacologic doses of vitamin E (>400 IU/day) and other antioxidants have no benefit and may increase all-cause mortality.■

Epidemiologic evidence suggests that fish consumption may reduce CHD risk, perhaps through the action of omega-3 fatty acids. Evidence also indicates that moderate consumption of alcohol, especially wine, is associated with a decreased risk for CHD, possibly by increasing high-density lipoprotein (HDL) cholesterol levels, preventing the oxidation of LDL, or both. The polyphenols in red wine are also apparently beneficial. Traditional Mediterranean lifestyle patterns—with diets high in vegetables, fruits, olive oil, fish, nuts, complex grains and carbohydrates, and red wine, along with physical activity—are associated with reduced risks of cardiovascular disease.■ A conservative estimate suggests that moderate dietary modification by the U.S. population, consisting mainly of replacing saturated fats with complex carbohydrates, fiber, monounsaturated fats, and fish, could easily lead to a 10% reduction in serum cholesterol levels and a 20% or greater reduction in CHD. The actual risk reduction could be much greater.

Cancer

Nutrients, non-nutritive dietary constituents, and nutritional status can influence the risk for cancer in a variety of ways. Nutrition interacts with each step of carcinogenesis (carcinogen activation and tumor initiation, promotion, and progression). Excess energy intake may favor the generation of free radicals and reduce the body's ability to detoxify carcinogens. By contrast, antioxidant nutrients scavenge free radicals and other (pre)carcinogens and may thereby inhibit their activation, their ability to initiate mutations, or both. Folic acid may improve a cell's ability to preserve, repair, and methylate its DNA, either preventing or reversing the tendency toward mutation. Folic acid supplementation, however, may increase the cancer risk in some individuals, so supplementation beyond the levels present in multivitamins is not advised.■ Obesity has emerged as a major risk factor for many cancers, perhaps by inducing insulin resistance and elevating serum levels of insulin, insulin-like growth factor, and related hormones. Excessive alcohol intake promotes tumor growth.

Lung Cancer

Evidence indicates that the number-one cancer killer, lung cancer (Chapter 197), is influenced by diet. Although the most important causal factor is cigarette smoking, consumption of fruits and vegetables is inversely associated with lung cancer risk in both smokers and nonsmokers. It is probable that both nutrients and the non-nutritive phytochemicals in fruits and vegetables are responsible for the protective effects. However, in view of the disappointing results of randomized trials of supplementation with β-carotene, which increased mortality from lung cancer and other causes, antioxidant supplements should not be relied on to reduce disease risk.

Breast Cancer

The number-two cause of cancer deaths in women, breast cancer (Chapter 204), is positively associated with obesity, especially when excess adiposity is located predominantly in the abdomen, and with physical inactivity. The positive association between obesity and postmenopausal breast cancer has been attributed in part to the synthesis of estrogen (a risk factor for breast

TABLE 220-1 DIETARY INFLUENCES ON MAJOR CAUSES OF DEATH AND MORBIDITY IN THE UNITED STATES

CAUSE OF DEATH OR MORBIDITY	FACTORS ASSOCIATED WITH DECREASED RISK	FACTORS ASSOCIATED WITH INCREASED RISK
DEATH		
Heart disease	Intake of complex carbohydrates, particular fatty acids (e.g., monounsaturated, polyunsaturated, and omega-3 fatty acids from fish), soluble fiber, polyphenols, soy proteins, antioxidants (vitamins E and C, β-carotene, selenium), folic acid, moderate alcohol	Intake of saturated fat, cholesterol, excess calories, sodium; abdominal distribution of body fat
Cancer	Intake of fruits and vegetables (for β-carotene; vitamins A, C, D, and E; folic acid; calcium; selenium; phytochemicals), fiber	Intake of excess calories, fat, alcohol, red meat, salt- and nitrite-preserved meats, possibly grilled meats; abdominal distribution of body fat
Cerebrovascular disease	Intake of potassium, calcium, omega-3 fatty acids	Intake of sodium, alcohol (as with hypertension)
Accidents		Excess alcohol consumption
Diabetes mellitus	Intake of fiber	Intake of excess calories, fat, alcohol; abdominal distribution of body fat
Suicide		Excess alcohol consumption
Chronic liver disease and cirrhosis		Excess alcohol consumption
Hypertension and hypertensive renal disease	Intake of fruits and vegetables, potassium, calcium, magnesium, omega-3 fatty acids	Intake of sodium, alcohol, excess calories, total and saturated fat; abdominal distribution of body fat
MORBIDITY		
Obesity		Intake of excess calories and fat
Osteoporosis	Intake of calcium, vitamin D, vitamin K	Intake of excess vitamin A, sodium, protein
Diverticular disease, constipation	Intake of fiber	
Neural tube defects	Intake of folic acid	

cancer) in adipose tissue. Epidemiologic evidence suggests that alcohol intake may also be a risk factor for this disease, particularly in women with lower intakes of folic acid.

Colorectal Cancer

Colorectal cancer (Chapter 199) is the third leading cause of cancer mortality in men and women. The risk for colorectal cancer correlates positively with the intake of red meat (especially when it is overcooked) and dietary fat and with obesity, and the risk correlates inversely with the intake of calcium and folic acid. Evidence regarding the effect of dietary fiber is somewhat equivocal, but the preponderance of evidence points to a protective effect; there is no evidence of harm. Higher physical activity is associated with a 30 to 50% lower risk for colon cancer.

Summary

The interaction of all these influences is powerful enough to suggest that diet and physical inactivity contribute to well over 35% of cancer deaths in Western countries. Even though the independent influences of potentially protective nutrients such as carotenoids, vitamins C and E,[5,6] folic acid, selenium,[7] and fiber are not known with certainty, because they are all present in vegetables and fruits, a liberal intake of fruits and vegetables is strongly recommended. A very large randomized trial indicated that lowering dietary fat intake did not reduce rates of breast cancer[8] or colon cancer,[9] but it is very likely that maintaining an appropriate body weight and being physically active can reduce cancer risks.

Hypertension

Elevated blood pressure (Chapter 67) is a major risk factor for stroke, CHD, heart failure, peripheral vascular disease, and renal disease. It is often associated with obesity, especially abdominal obesity, and weight reduction in obese hypertensives generally leads to an improvement in blood pressure. Sodium restriction also usually reduces blood pressure levels. The Dietary Approaches to Stop Hypertension (DASH) diet, which is rich in fruits, vegetables, and low-fat dairy products and advocates a reduced saturated and total fat content, can also decrease blood pressure levels; reducing one's sodium intake provides an additional benefit when included as part of the DASH diet.[10] Because alcohol intake elevates blood pressure, its use should be limited in hypertensive patients.

Diabetes Mellitus

Type 2 diabetes mellitus (Chapter 237) is strongly associated with obesity, especially abdominal obesity. Sugar consumption does not lead to diabetes, except to the extent that it may promote weight gain. The previous recommendation to restrict total carbohydrate intake in diabetics has been abandoned for lack of evidence; 55 to 60% of a diabetic's energy intake should come from carbohydrates, preferably unrefined carbohydrates that include fiber. Because higher-fat diets tend to promote both obesity and CHD, for which diabetics are at high risk, dietary fat intake should be kept low. Alcohol can cause hypoglycemia, hyperglycemia, and increased triglyceride levels in diabetics, and its use should be limited. In both diabetics and nondiabetics, excess alcohol intake is responsible for many deaths, particularly from accidents and liver disease, and it is a factor in some suicides.

Osteoporosis

Osteoporosis (Chapter 251) is influenced by several dietary factors. Inadequate calcium intake during adolescence can result in suboptimal peak bone mass in early adulthood, and during later life it can lead to accelerated bone loss, thereby increasing the risk for osteoporosis. Sodium and protein, which are consumed by Americans in greater quantities than required, may promote excess bone loss. Excessive supplementation with vitamin A reduces bone mass and increases fracture risk. Vitamin D, vitamin K, and magnesium assist in maintaining optimal bone mass.

Other Conditions

Obesity

The causes and health effects of obesity, the most prevalent nutritional disorder in the United States, are reviewed in Chapter 227. The metabolic syndrome, a constellation that includes obesity with an enlarged waist circumference; increased serum glucose, triglycerides, and blood pressure; and reduced HDL cholesterol, is strikingly prevalent in the United States and is a major risk factor for CHD, cancer, type 2 diabetes, and hypertension (Chapter 67).

Intestinal Diverticular Disease

Low dietary fiber intake causes constipation, and it is thought to be a cause of intestinal diverticular disease.

TABLE 220-2 DIETARY GUIDELINES FOR AMERICANS: KEY RECOMMENDATIONS FOR THE GENERAL POPULATION

ADEQUATE NUTRIENTS WITHIN CALORIE NEEDS
Consume a variety of nutrient-dense foods and beverages within and among the basic food groups while choosing foods that limit the intake of saturated and *trans*-fats, cholesterol, added sugar, salt, and alcohol.
Meet recommended intakes for energy needs by adopting a balanced eating pattern, such as the U.S. Department of Agriculture (USDA) Food Guide or the Dietary Approaches to Stop Hypertension (DASH) eating plan.
WEIGHT MANAGEMENT
To maintain body weight in a healthy range, balance calories consumed from foods and beverages with calories expended.
To prevent gradual weight gain over time, make small decreases in food and beverage calories and increase physical activity.
PHYSICAL ACTIVITY
Engage in regular physical activity and reduce sedentary activities to promote health, psychological well-being, and a healthy body weight.
To reduce the risk for chronic disease in adulthood, engage in at least 30 minutes of moderate-intensity physical activity, above usual activity levels, at work or at home on most days of the week.
For most people, greater health benefits can be obtained by engaging in physical activity of more vigorous intensity or longer duration.
To help manage body weight and prevent gradual, unhealthy body weight gain in adulthood, engage in approximately 60 minutes of moderate- to vigorous-intensity activity on most days of the week while not exceeding caloric intake requirements.
To sustain weight loss in adulthood, participate in at least 60-90 minutes of daily moderate-intensity physical activity while not exceeding caloric intake requirements. Some people may need to consult a health care provider before engaging in this level of activity.
Achieve physical fitness by including cardiovascular conditioning, stretching exercises for flexibility, and resistance exercises or calisthenics for muscle strength and endurance.
FOOD GROUPS TO ENCOURAGE
Consume a sufficient amount of fruits and vegetables without exceeding energy needs: 2 cups of fruit and 2½ cups of vegetables per day are recommended for a reference 2000-calorie intake, with higher or lower amounts depending on the calorie level.
Choose a variety of fruits and vegetables each day. In particular, select from all five vegetable subgroups (dark green, orange, legumes, starchy vegetables, and other vegetables) several times a week.
Consume ≥3 ounce-equivalents of whole-grain products/day, with the rest of the recommended grains coming from enriched or whole-grain products. In general, at least half the grains should come from whole grains.
Consume 3 cups/day of fat-free or low-fat milk or equivalent milk products.
FATS
Consume <10% of calories from saturated fatty acids and <300 mg/day of cholesterol, and keep *trans*-fatty acid consumption as low as possible.
Keep total fat intake between 20 and 35% of total calories, with most fats coming from sources of polyunsaturated and monounsaturated fatty acids such as fish, nuts, and vegetable oils.
When selecting and preparing meat, poultry, dry beans, and milk or milk products, choose those that are lean, low fat, or fat free.
Limit intake of fats and oils high in saturated and/or *trans*-fatty acids, and choose products low in such fats and oils.
CARBOHYDRATES
Choose fiber-rich fruits, vegetables, and whole grains often.
Choose and prepare foods and beverages with little added sugar or caloric sweeteners, such as amounts suggested by the USDA Food Guide and the DASH eating plan.
Reduce the incidence of dental caries by practicing good oral hygiene and consuming sugar- and starch-containing foods and beverages less frequently.
SODIUM AND POTASSIUM
Consume <2300 mg sodium/day (approximately 1 teaspoon of salt).
Choose and prepare foods with little salt. At the same time, consume potassium-rich foods such as fruits and vegetables.
ALCOHOLIC BEVERAGES
Those who choose to drink alcoholic beverages should do so sensibly and in moderation—defined as the consumption of up to 1 drink/day for women and up to 2 drinks/day for men.
Alcoholic beverages should not be consumed by some individuals, including those who cannot restrict their alcohol intake, women of childbearing age who may become pregnant, pregnant and lactating women, children and adolescents, individuals taking medications that can interact with alcohol, and those with specific medical conditions.
Alcoholic beverages should be avoided by individuals engaging in activities that require attention, skill, or coordination, such as driving or operating machinery.
FOOD SAFETY
To avoid microbial food-borne illnesses, do the following:
Clean hands, food contact surfaces, and fruits and vegetables. Meat and poultry should not be washed or rinsed.
Separate raw, cooked, and ready-to-eat foods while shopping, preparing, or storing foods.
Cook foods to a safe temperature to kill microorganisms.
Chill (refrigerate) perishable food promptly, and defrost foods properly.
Avoid raw (unpasteurized) milk or any products made from unpasteurized milk, raw or partially cooked eggs or foods containing raw eggs, raw or undercooked meat and poultry, unpasteurized juices, and raw sprouts.

Congenital Neural Tube Defects

Inadequate maternal folic acid intake has been definitively proved to be a major risk factor for congenital neural tube defects such as spina bifida and myelomeningocele. For this reason, cereal and grain products have been fortified in the United States with folic acid since 1998.

TRANSLATING EVIDENCE INTO DIETARY CHANGE

Thus, the evidence is strong that dietary habits can influence the incidence and severity of many incapacitating or lethal diseases in the United States. No justification exists for the belief that modification of the "usual" American diet is unnecessary or futile. The only questions are whether change is feasible and what is required to effect it. Various health agencies and the U.S. government have used public education, particularly the publication of dietary goals, as their primary means (see Table 220-3). The Department of Agriculture and the Department of Health and Human Services have developed and periodically revised the Dietary Guidelines for Americans (see Table 220-2) and a food guidance system, now called MyPyramid (Fig. 220-1). Although some have commented that MyPyramid, released in 2005, is complex and overly ambitious, both it and the Dietary Guidelines for Americans are more evidence based than previous versions, and MyPyramid provides detailed recommendations tailored to individual characteristics entered online by the user.

Physicians can influence their patients' health by encouraging them to optimize their dietary habits and providing them with instructional materials

TABLE 220-3 DIETARY GUIDELINES PROMULGATED BY NATIONAL ORGANIZATIONS*

	Organization				
	U.S. DEPARTMENT OF AGRICULTURE AND DEPARTMENT OF HEALTH AND HUMAN SERVICES: DIETARY GUIDELINES FOR AMERICANS 2005	**NATIONAL CHOLESTEROL EDUCATION PROGRAM ADULT TREATMENT PANEL III: THERAPEUTIC LIFESTYLE CHANGE DIET (2002)**	**NATIONAL HIGH BLOOD PRESSURE EDUCATION PROGRAM/JOINT NATIONAL COMMITTEE: 7 DIETARY APPROACHES TO STOP HYPERTENSION (DASH, 2006)**	**AMERICAN DIABETES ASSOCIATION (2004)**	**AMERICAN CANCER SOCIETY (2006)**
Indication or objective	General health promotion and disease prevention	Elevated cholesterol, heart disease prevention	Prehypertension and hypertension	Diabetes	Cancer prevention
NUTRIENT/FOOD GROUP					
Total energy	Adequate energy intake to maintain a healthy weight		Reduce energy intake to lose weight if overweight	Reduced energy intake and modest weight loss can improve glycemia and insulin resistance	Balance calorie intake with physical activity; choose foods and drinks that help achieve and maintain a healthy weight
Fruits/vegetables	2 cups of fruit and 2.5 cups of vegetables/2000 calories/day		8-10 servings/day		≥5 servings/day
Meat			≤6 servings/day		Limit consumption of processed and red meats
Dairy	2-3 servings/day of low-fat dairy		2-3 servings/day of low-fat dairy		
Grains	≥3 ounce-equivalents of whole-grain products		6-8 servings of whole grains and whole-grain products		Choose whole grains over processed (refined) grains
Fat	20-35% of daily energy intake	25-35% of daily energy intake	<27% of daily energy intake		
Saturated fats	<10% of daily energy intake	<7% of daily energy intake	6% of daily energy intake	<10% of daily energy intake; those with LDL cholesterol ≥100 may benefit from lowering saturated fat to <7%	
Polyunsaturated fats	Up to 10% of daily energy intake	Up to 10% of daily energy intake		Up to 10% of daily energy intake	
Monounsaturated fats	10-20% of daily energy intake	Up to 20% of daily energy intake		15-20% of daily energy intake; combination of MUFA and carbohydrates should equal 60-70% of total energy intake	
Trans-fats	<1% of daily energy intake	Intake should be kept low		Intake should be minimized	
Cholesterol	<300 mg/day	<200 mg/day	150 mg/day	<300 mg/day; those with LDL cholesterol ≥100 may benefit from lowering cholesterol intake to 200 mg/day	
Carbohydrates	45-65% of daily energy intake	50-60% of daily energy intake	55% of daily energy intake	Total amount of carbohydrate is more important than the source or type	
Sugar	Limit added sugars			Sucrose and sucrose-containing foods do not need to be restricted	
Protein		Approximately 15% of daily energy intake	18% of daily energy intake	10-20% of daily energy intake if renal function is normal	
Alcohol	Up to 2 drinks/day for men and up to 1 drink/day for women; persons in special circumstances (e.g., pregnancy, history of alcoholism) should abstain		<2 drinks/day for men and <1 drink/day for women	If individuals choose to drink, limit to 2 drinks/day for men and 1 drink/day for women	No more than 1 drink/day for women and 2 drinks/day for men
Sodium	Up to 2300 mg/day		<2400 mg/day	<2400 mg/day	
Potassium			4700 mg/day		
Calcium			1250 mg/day	1000-1500 mg/day	
Magnesium			500 mg/day

NUTRITIONAL ASSESSMENT

BRUCE R. BISTRIAN

GOALS AND IMPORTANCE OF NUTRITIONAL ASSESSMENT

Nutritional assessment in clinical medicine has three primary goals: to identify the presence and type of malnutrition, to define health-threatening obesity, and to devise suitable diets as prophylaxis against disease later in life. The focus of this chapter is on the diagnosis of protein-energy malnutrition because of its wide prevalence and major impact on disease outcome. Other deficiency diseases are of much less relevance in that most occur in conjunction with protein-energy malnutrition or in specific disease states, such as thiamine deficiency in alcoholic liver disease and fat-soluble vitamin deficiency in malabsorptive states. The classic deficiency diseases, whether primary or secondary, are considered elsewhere in those chapters specifically dealing with the diseases mentioned here. The widespread availability of parenteral and enteral therapeutic measures since the mid-1980s that can provide adequate feeding regimens for virtually any disease condition makes a rudimentary knowledge of the pathophysiology of protein-energy malnutrition and its nutritional assessment essential for all primary care practitioners (Chapter 220).

CLINICAL NUTRITIONAL ASSESSMENT

Clinical assessment of protein nutritional status is based principally on the clinical history, physical examination including simple anthropometry, and measurement of the levels of several secretory proteins.

Clinical History

Although detailed dietary assessment can at times be helpful, in most circumstances physicians can safely limit their diet questions to whether patients have been following a prescribed diet, how much alcohol they drink, and whether they habitually take dietary supplements, including vitamins, minerals, and herbs. In ambulatory patients, the ability to maintain usual and adequate weight generally indicates that serious micronutrient deficiency is probably not the result of dietary inadequacy. Isolated vitamin deficiencies in the absence of weight loss or symptoms are rare, except perhaps for folate and vitamin B_{12} (Chapter 167). Although nutritional anemias do exist, the role of dietary deficiency in folic acid–related or vitamin B_{12}–related anemias is minimal in the absence of underlying disease or weight loss. Only iron deficiency is a reasonable cause of dietary anemia (Chapter 162). By contrast, full dietary assessment and diet prescriptions are likely to help patients with conditions such as fat malabsorption accompanied by weight loss, cramps, or diarrhea. Such evaluations are most effectively carried out by dietitians. Thus, detailed nutritional assessment of protein-energy malnutrition with secondary assessment of vitamin and mineral deficiencies is usually needed only when protein-energy malnutrition or a specific disorder known to interfere with nutrient metabolism coexists, such as celiac disease, pernicious anemia, or nutrient-drug interactions. Even then, the assessment should emphasize the likely deficiencies. For fat malabsorption (Chapter 142), one should check levels of the fat-soluble vitamins A, D, E, and K, important divalent and trivalent cations (calcium [Ca^{2+}], zinc [Zn^{2+}], magnesium [Mg^{2+}], and iron [Fe^{3+}]), and phosphorus and alkaline phosphatase. When ileal resection has occurred, serum vitamin B_{12} levels should be measured, and the potential for bile salt depletion should be considered. Weight loss resulting from short-gut syndrome should prompt assessment of the fat-soluble vitamins, folic acid, vitamin B_{12}, calcium, magnesium, phosphorus, zinc, and iron. At least initially, levels of the water-soluble vitamins likely to have clinical impact such as thiamine and ascorbic acid should be checked, but provision of the full complement of vitamins should be routine in the management of this condition. Measurements of body water status (weight, blood urea nitrogen, serum creatinine, serum sodium) and acid-base balance (serum carbon dioxide combining power, chloride and potassium, and urine and arterial pH) should be obtained if the diarrhea is profuse (Chapter 142).

Clinically obvious marasmus, cachexia syndromes, and hypoalbuminemic malnutrition (protein-energy undernutrition), the three common types of protein-energy malnutrition, affect 25 to 50% of patients hospitalized for acute care and are secondary to the underlying disease in most instances. Many of these patients can benefit from nutritional support and require a thorough clinical nutritional assessment, including a dietary history, physical examination, and laboratory tests that serve to confirm clinical impressions. The history should list information about the timing and amount of weight loss, medical illnesses, medications, gastrointestinal symptoms (abdominal pain, diarrhea, dysphagia), diet habits (eating fewer than two meals per day, alcohol consumption, dietary supplement intake, dental status), social habits (eating alone, needing assistance in self-care), economic status (having enough money for food), and mental status, particularly the presence of depressive symptoms. A special focus should be reserved for elderly people, in whom protein-energy malnutrition secondary to these last factors is more common (Chapter 23).

Nutritional Support

Four factors principally determine the timing, need, and appropriateness of nutritional support: (1) the presence and severity of protein-energy malnutrition, defined primarily by degree of weight loss and weight-to-height ratio as a percentage of standard or body mass index (BMI); (2) the presence and severity of the systemic inflammatory response, defined principally by the serum albumin level but also by the presence of fever, leukocytosis, and increased band forms; (3) the actual or expected duration of inadequate nutritional intake; and (4) the prognosis of the underlying condition. Well-nourished individuals have a 7- to 10-day reserve of energy and protein to withstand a moderate systemic inflammatory response without adverse nutritional consequences. Greater degrees of systemic inflammatory response and preexisting protein-energy malnutrition dramatically shorten the period that semistarvation, defined as consuming less than 50% of the energy and protein needs, can be tolerated.

Weight Loss

A recent unintended weight loss of 10 lb, or more than 5% of usual weight, should prompt efforts to diagnose the underlying disorder or social circumstance. Weight loss alone does not distinguish the composition of tissue loss, which can range from 25 to 30% lean tissue in semistarvation alone to 50% lean tissue loss following semistarvation plus injury and as much as 75% of the weight loss with the severest forms of injury, severe sepsis, major body burns, severe closed head injury, and multiple trauma. Therefore, unintentional weight loss of more than 10 lb indicates a need for thorough nutritional assessment. Weight loss in excess of 10% of usual weight should be considered to represent protein-energy malnutrition that will impair physiologic function, particularly muscle strength and endurance. Weight loss in excess of 20% should be considered severe protein-energy malnutrition that will substantially impair most organ systems. If major elective surgery is planned (Chapter 439), such individuals would benefit from adequate feeding preoperatively or at least early nutritional intervention postoperatively. If palliative or curative radiation therapy or systemic chemotherapy is planned, adequate feeding during therapy with the use of supplemental formulas, tube feeding, or parenteral nutrition (in that order) is indicated. However, if the weight loss represents end-stage systemic illness, commonly seen as a cachexia syndrome of loss of weight and muscle mass with symptoms of weakness (e.g., cancer; end-stage liver, renal, or lung disease; acquired immunodeficiency syndrome) for which no primary therapy is planned or is effective, invasive nutritional support is rarely indicated.

Physical Examination

Although the patient's external appearance and a check of the skin, eyes, mouth, hair, and nails often provide clues to the presence of nutritional abnormalities (Table 221-1), the physical findings of deficiency syndromes of vitamins, essential fatty acids, and trace metals are relatively insensitive and nonspecific. With respect to protein-energy malnutrition, only the marasmic form of semistarvation resulting from semistarvation alone and cachexia syndromes resulting from semistarvation and a mild systemic inflammatory response are evident at examination. Loss of subcutaneous fat and skeletal muscle is manifested by sunken temples, thin extremities, wasting of the muscles of the hand, and, rarely, edema. Although kwashiorkor in children is characterized by severe edema and a potbelly appearance from hepatomegaly and ascites, one rarely encounters these clinical signs in cases of hypoalbuminemic malnutrition that develops in the setting of systemic inflammation resulting from disease in industrialized societies.

Body Weight

The most useful element in the physical examination is body weight, which is expressed as a relative value to evaluate the patient in relation to the healthy population. Weight and height are easily obtained, and standards for comparison have been established (Table 221-2). Although newer standards are available, they reflect the increasing prevalence of obesity in the U.S. population. Use of the 1959 standards allows the same tables to be used to diagnose significant protein-energy malnutrition (<85% of desirable weight, which approximates the fifth percentile) and significant obesity, defined as obesity predisposing to excessive mortality risk (>130% of desirable weight or BMI of ≥30). Although severe protein-energy malnutrition often occurs at levels greater than 85% of desirable weight because of the greater likelihood of preexisting obesity, this condition is generally detected by percentage of weight loss or by upper arm anthropometry. Height can be measured in a reclining patient with a tape measure, and in certain situations the clinician may rely on the patient's history. The major confounding variable that limits the value of weight and height as an index of protein-energy malnutrition is the tendency for water retention with disease, and thus weight gain may not reflect an increase in lean body mass or protein content. Fluid retention is particularly a problem in patients with hypoalbuminemic malnutrition because of the effects of aldosterone, antidiuretic hormone, and insulin stimulated by the stress response, which causes sodium and fluid retention. Fluid retention, however, does not usually confound weight assessment in patients who are first seen at the physician's office, except in those patients with diseases such as cardiac failure, end-stage liver disease, and severe renal disease in whom the disturbance in water metabolism results from the underlying disease and not principally from the hormonal response to systemic inflammation.

TABLE 221-1 CLINICAL SIGNS AND SYMPTOMS OF NUTRITIONAL INADEQUACY IN ADULT PATIENTS

	CLINICAL SIGN OR SYMPTOM	NUTRIENT
General	Wasted, skinny appearance	Calorie
	Loss of appetite	Protein-energy, zinc
Skin	Psoriasiform rash, eczematous scaling	Zinc, vitamin A, essential fatty acids
	Pallor	Folate, iron, vitamin B_{12}, copper
	Follicular hyperkeratosis	Vitamin A, vitamin C
	Perifollicular petechiae	Vitamin C
	Flaking dermatitis	Protein-energy, niacin, riboflavin, zinc
	Bruising	Vitamin C, vitamin K
	Pigmentation changes	Niacin, protein-energy
	Scrotal dermatosis	Riboflavin
	Thickening and dryness of skin	Linoleic acid
Head	Temporal muscle wasting	Protein-energy
Hair	Sparse and thin, dyspigmented	Protein
	Easy to pull out	Protein
	Corkscrew hairs	Vitamin C
Eyes	History of night blindness (also impaired visual recovery after glare)	Vitamin A, zinc
	Photophobia, blurring, conjunctival inflammation	Riboflavin, vitamin A
	Corneal vascularization	Riboflavin
	Xerosis, Bitot's spots, keratomalacia	Vitamin A
Mouth	Glossitis	Riboflavin, niacin, folic acid, vitamin B_{12}, pyridoxine
	Bleeding gums	Vitamin C, riboflavin
	Cheilosis	Riboflavin, pyridoxine, niacin
	Angular stomatitis	Riboflavin, pyridoxine, niacin
	Hypogeusia	Zinc
	Tongue fissuring	Niacin
	Tongue atrophy	Riboflavin, niacin, iron
	Nasolabial seborrhea	Pyridoxine
Neck	Goiter	Iodine
	Parotid enlargement	Protein
Thorax	Thoracic rosary	Vitamin D
Abdomen	Diarrhea	Niacin, folate, vitamin B_{12}
	Distention	Protein-energy
	Hepatomegaly	Protein-energy
Extremities	Edema	Protein, thiamine
	Softening of bone	Vitamin D, calcium, phosphorus
	Bone tenderness	Vitamin D
	Bone ache, joint pain	Vitamin C
	Muscle wasting and weakness	Protein, calorie, vitamin D, selenium, sodium chloride
	Muscle tenderness, muscle pain	Thiamine
Nails	Spooning	Iron
	Transverse lines	Protein
Neurologic	Tetany	Calcium, magnesium
	Paresthesias	Thiamine, vitamin B_{12}
	Loss of reflexes, wristdrop, footdrop	Thiamine
	Loss of vibratory and position sense	Vitamin B_{12}
	Ataxia	Vitamin B_{12}
	Dementia, disorientation	Niacin
Blood	Anemia	Vitamin B_{12}, folate, iron, pyridoxine
	Hemolysis	Phosphorus, vitamin E

TABLE 221-2 DESIRABLE WEIGHT IN POUNDS IN RELATION TO HEIGHT FOR MEN AND WOMEN 25 YEARS OR OLDER*

Body Mass Index

The BMI, which is the weight in kilograms divided by the height in meters squared, has gained favor as a nutritional measure because of two valuable attributes. The measure is relatively independent of height, and the same standards apply to male and female patients. The following BMI values are used: normal nutrition, BMI of 20 to less than 25; significant protein-energy malnutrition, less than 18.5; overweight, from 25 to less than 30; and obesity, 30 or greater, with morbid obesity defined as a BMI of 40 and greater. Evidence from developing countries suggests that the BMI is better correlated with outcome than are weight and height.

Upper Arm Anthropometry

Approximately 50% of body fat is subcutaneous. The use of skinfold calipers to define the triceps skinfold (TSF) is the most practical technique to estimate body fat. Standards for skinfold measurement are available from the National Health and Nutrition Examination Surveys I and II and were derived from a probability sample of the U.S. population. Generally, a value lower than the fifth percentile is used to define abnormality (Table 221-3). The principal value of the TSF measurement is to determine the arm muscle circumference (AMC) or arm muscle area.

$$\text{AMC (cm)} = \text{arm circumference} - (\pi)(\text{TSF [mm]})/10$$

The AMC is a specific measure of protein-energy malnutrition if the fifth or tenth percentile is chosen as the cutoff point, and it is particularly valuable in patients in edematous states and in amputees, in whom weights are inaccurate or insensitive. The TSF and AMC measurements are most useful in initially defining marasmic-type malnutrition or the mixed disorder. Many dietitians are skilled in upper arm anthropometry.

Serum Proteins

Despite many concerns, the serum albumin level remains the traditional standard for nutritional assessment by virtue of its extensive history and its continued use to separate the two principal forms of protein-energy malnutrition. Hypoalbuminemia is a strong predictor of risk for morbidity and mortality in both hospitalized and ambulatory patients. In almost all cases, except perhaps for hereditary analbuminemia, excessive loss secondary to nephrotic syndrome (Chapter 123), and, occasionally, protein-losing enteropathy, hypoalbuminemia identifies the recent or ongoing presence of a systemic inflammatory response. A value for serum albumin of less than 3.5 g/dL is considered to indicate a mild systemic inflammatory response, whereas a value of less than 2.4 g/dL represents a severe systemic inflammatory response, reflecting systemic inflammation that produces anorexia (limiting

food intake) and increases protein catabolism and thus accelerates the development of protein-calorie malnutrition. With a half-life for albumin of 18 to 20 days and the fractional replacement rate of about 10% per day, the return of serum albumin to normal takes about 2 weeks of feeding when the stress response remits. Adequate feeding in the presence of systemic inflammation will not increase the serum albumin concentration, even though substantial nutritional benefit will occur in terms of wound healing and immune function. Levels of other proteins, such as transferrin, prealbumin, and retinol-binding protein with respective half-lives of 7 days, 2 days, and half a day, also fall acutely with injury and respond more quickly when systemic inflammation remits. Serum transferrin also varies with iron status, however, and prealbumin and retinol-binding protein vary with dietary carbohydrate and renal function. As a result, these proteins do not reliably identify the presence and severity of the systemic inflammatory response any better than does albumin, but they reflect the nutritional response more quickly when inflammation lessens.

Composite Screening Tools

Investigators have made numerous attempts to combine the various components of nutritional assessment, including clinical history, physical examination, anthropometry, and serum proteins, into a single score. Some of the more widely used tools include the following: the Subjective Global Assessment, which classifies patients as A, B, or C or as having normal, mild, or moderate malnutrition; the Nutritional Risk Index, which is based on weight loss and serum albumin only; and the more extensive evaluations with the Mini-Nutritional Assessment and Malnutrition Universal Screening Tool. A clear advantage of one technique over another has not been established.

NUTRITIONAL THERAPY AND ITS ASSESSMENT

The same indices that are used in the baseline nutritional assessment can be used to assess response to therapy, provided certain points are kept in mind.

Assessing Lean Body Mass and Total Body Water

In a stressed, hospitalized patient receiving nutritional support, day-to-day weight changes generally reflect changes in fluid balance rather than energy balance. In an ambulatory setting, weight increases or decreases are most likely to reflect changes in protein nutritional status and body fat because the underlying illness is usually less severe. Even the most sensitive research methods for assessing changes in lean body mass, however, do not offer major improvements in diagnosis in the more seriously ill patients. Techniques that measure total body water, such as isotope dilution and underwater weighing, from which lean tissue is extrapolated, fail to account for the distortion in hydration of lean tissue with illness. Surrogate measures of total body protein to estimate lean tissues such as total body potassium measurement and dual x-ray absorptiometry do not adjust for differing body composition with disease. A newer method, single-frequency or multifrequency body impedance analysis, does show promise as a simple, accurate, noninvasive method that may allow distinction between intracellular and extracellular water, with the former used to estimate lean tissue for an initial assessment. However, the inherent difficulties resulting from the greater disturbance of total body water in critically ill patients have not been overcome with this technique. Magnetic resonance imaging and total body nitrogen analysis are the most reliable tools for assessing the amount of lean tissue but are primarily useful for research purposes.

Restoration of Lean Tissue

In an unstressed patient with marasmus, appropriate protein and calorie intake should cause a positive nitrogen balance of 2 to 6 g/day (60 to 180 g lean tissue) and slow weight gain, depending on the positive energy balance. For instance, a 300-kcal excess of intake over expenditure would provide approximately 120 g of lean tissue (100-kcal equivalent) in addition to 200 kcal (22 g) as fat, for a total of approximately 140 g, or approximately one third of a pound of weight per day. Weight gains in excess of this number usually reflect sodium and thus water retention from the insulin stimulated by dietary carbohydrate. Such overhydration can be improved by reducing salt and limiting fluid intake. In patients with hypoalbuminemic malnutrition who are no longer stressed, a similar nutritional regimen will lead to a comparable gain of tissue, but weight change is often less as edema becomes mobilized, with normalization of serum albumin in 2 to 4 weeks and of retinol-binding protein, prealbumin, and transferrin more quickly. In stressed patients with hypoalbuminemic malnutrition, appropriate nutritional support often does not restore lean tissue but does improve other important functions, such as wound healing and immunocompetence. These are important treatment goals, and they improve the ultimate clinical outcome. Both the systemic inflammatory response and the limited activity level reduce the efficiency of skeletal muscle repletion, which represents 30% of body weight and 75% of actively metabolizing lean tissue. Functional testing of muscle strength and endurance, such as hand dynamometry, can be useful as a means of assessing this response but has not found wide clinical acceptance. Similarly, any reduction in other physiologic functions or impairment in the patient's ability to perform the usual activities of daily living will accentuate the consequences of protein-energy malnutrition. Cachexia syndromes reflect the loss of lean tissue with mild to moderate persistent inflammation due to an underlying chronic disease. Response to nutritional therapy is generally poor unless there is improvement or correction of the basic disease process.

Measures of Energy Expenditure and Caloric Need

Although caloric expenditure can now be reliably and easily measured with portable indirect calorimeters, estimated energy expenditure is sufficient in most clinical situations. The three components of total energy expenditure are basal energy expenditure (~55 to 65% of total energy expenditure), thermal effect of feeding (~10% of total energy expenditure), and activity energy expenditure (25 to 33%). An energy intake of 30 to 35 kcal/kg of body weight will maintain weight in most sedentary ambulatory patients, with adjustments upward or downward in 200- to 300-kcal increments as prompted by biweekly changes in weight. Although young, severely burned, or traumatized patients may require 35 to 40 kcal/kg in the acute phase to meet total energy expenditure, providing energy intakes principally as carbohydrates that exceed 35 kcal/kg substantially increases the likelihood of hyperglycemia. Evidence strongly implicates hyperglycemia in excess of 180 mg/dL as a major risk factor for nosocomial infection, thus emphasizing the importance of better glycemic control by the use of insulin infusions or by reducing the level of energy intake, or both. Most postoperative patients who require invasive nutritional support for mechanical or infectious complications usually require approximately 25 kcal/kg to meet energy needs and not more than 30 kcal/kg because of their older age and reduced activity and energy expenditure. Overfeeding should be avoided in such patients, and modest underfeeding for the first several weeks of acute illness may actually improve outcome in seriously ill patients.

PROTEIN-ENERGY MALNUTRITION

SAMUEL KLEIN

DEFINITION

Normal nutritional status represents a healthy relationship between nutrient intake and nutrient requirements. An imbalance between intake and requirements over time can lead to malnutrition, manifested by alterations in intermediary metabolism, organ function, and body composition. The term *protein-energy malnutrition* has been used to describe macronutrient deficiency syndromes, which include kwashiorkor, marasmus, and nutritional dwarfism in children and wasting associated with illness or injury in children and adults.

PATHOBIOLOGY

Primary protein-energy malnutrition is caused by lack of access to adequate nutrient intake and usually affects children and elderly persons. The functional and structural abnormalities associated with primary protein-energy malnutrition are often reversible with nutritional therapy. However, prolonged primary protein-energy malnutrition can cause irreversible changes in organ function and growth.

Secondary protein-energy malnutrition is caused by illnesses that alter appetite, digestion, absorption, or nutrient metabolism and can be divided into three general, but often overlapping, categories: (1) diseases that affect gastrointestinal tract function, (2) wasting disorders, and (3) critical illness. Gastrointestinal disease can cause protein-energy malnutrition by premucosal (maldigestion), mucosal (malabsorption), or postmucosal (lymphatic obstruction) defects (Table 222-1). The nutritional status of patients with protein-energy malnutrition caused by gastrointestinal tract dysfunction can often be restored to normal if adequate nutritional support can be provided by dietary manipulations, enteral tube feeding, or parenteral nutrition. Wasting disorders, such as cancer, acquired immunodeficiency syndrome (AIDS), and rheumatologic diseases, are characterized by involuntary loss of body weight and muscle mass in the setting of a chronic illness. These patients often experience wasting because of (1) inadequate nutrient intake related to anorexia and possibly gastrointestinal tract dysfunction and (2) metabolic abnormalities caused by alterations in regulatory hormones, cytokines, and systemic inflammation. The alterations in metabolism are responsible for the greater loss of muscle tissue observed in these patients than in those with pure starvation or semistarvation. Restoration of muscle mass is unlikely with nutritional support unless the underlying inflammatory disease is corrected. Weight gain that occurs after nutritional support is started is usually caused by increases in fat mass and body water, without significant increases in muscle tissue. Patients with critical illness exhibit marked metabolic alterations, manifested by increased energy expenditure, altered endogenous glucose production and lipolytic rates, and protein breakdown. Therefore, protein and energy requirements are increased in critically ill patients. However, providing aggressive nutritional support may ameliorate but does not prevent net lean tissue losses without correction of the underlying illness or injury.

TABLE 222-1 CLASSIFICATION OF MALDIGESTIVE AND MALABSORPTIVE DISORDERS

PRIMARY ABNORMALITY	PATHOPHYSIOLOGY	REPRESENTATIVE DISORDERS
Premucosal defect	Pancreatic insufficiency	Chronic pancreatitis Cystic fibrosis Pancreatic duct obstruction
	Bacterial overgrowth	Motility diseases Blind loop syndromes Small intestine diverticula
	Rapid gastric emptying and intestinal transit	Post–gastric surgery syndrome
Mucosal defect	Inadequate bowel syndrome	Intestinal resection Gluten-sensitive enteropathy Immunoproliferative small bowel disease Radiation enteritis Intestinal ischemia Crohn's disease AIDS enteropathy
Postmucosal defect	Lymphatic obstruction	Congenital intestinal lymphangiectasia Milroy's disease Secondary intestinal lymphangiectasia Retroperitoneal carcinoma Lymphoma Retroperitoneal fibrosis Chronic pancreatitis Tuberculosis Sarcoidosis Whipple's disease Constrictive pericarditis Chronic congestive heart failure

AIDS = acquired immunodeficiency syndrome.

METABOLIC RESPONSE TO STARVATION

The adaptive response to starvation involves a series of metabolic alterations that enhance the chance for survival by increasing the use of body fat as a fuel, sparing the use of glucose, minimizing body nitrogen losses, and decreasing energy expenditure. A marked shift in fuel use occurs during the first day of starvation. By 24 hours of fasting, the use of glucose as a fuel has decreased; only 15% of liver glycogen stores remain, and the rates of hepatic glucose production and whole body glucose oxidation have decreased. Conversely, endogenous fat stores become the body's major fuel, and the rates of adipose tissue lipolysis, hepatic ketone body production, and fat oxidation are increased. After 3 days of fasting, the rate of glucose production is reduced by one half, and the rate of lipolysis is more than double the value found at 12 hours of fasting. The increase in fatty acid delivery to the liver, in conjunction with an increase in the ratio of plasma glucagon to insulin concentration, enhances hepatic ketone body production. Ketone bodies provide a water-soluble fuel, derived from water-insoluble adipose tissue triglycerides, which can be safely transported through the circulation and which readily cross the blood-brain barrier. By 7 days of fasting, plasma ketone body concentrations have increased 75-fold, and ketone bodies provide 70% of the brain's energy needs. In addition, body energy requirements are substantially decreased by 7 days of fasting because of fatigue-induced decrease in physical activity and a 15% reduction in resting metabolic rate.

The use of ketone bodies by the brain greatly diminishes glucose requirements and thereby reduces the need for muscle protein degradation to provide glucose precursors. Furthermore, thyroid hormone inactivation and plasma ketones inhibit muscle protein breakdown and prevent rapid protein losses. If postabsorptive protein breakdown rates were to continue throughout starvation, a potentially lethal amount of muscle protein would be catabolized in less than 3 weeks. As fasting continues, the kidney becomes an important site for glucose production; glutamine, released from muscle, is converted to glucose in the kidney and accounts for almost half of total glucose production.

Adaptation is maximum during more prolonged starvation (>14 days of fasting). At this time, adipose tissue provides more than 90% of daily energy

requirements. Total glucose production has decreased to about 75 g/day, providing fuel for glycolytic tissues (40 g/day) and the brain (35 g/day). Muscle protein breakdown has decreased to less than 30 g/day, which causes a marked decrease in urea nitrogen production and excretion. The diminished urea load to the kidneys decreases urine volume to 200 mL/day, thereby minimizing fluid requirements. Resting energy expenditures decrease by approximately 25%. Prolonged starvation causes a marked decrease in body fat mass, muscle protein, and the sizes of most organs, whereas the weight and protein content of the brain remains relatively stable.

UNDERNUTRITION-INDUCED ALTERATIONS IN TISSUE MASS AND FUNCTION

BODY COMPOSITION. All body tissue masses are affected by undernutrition, but fat mass and muscle mass are the most severely affected. In lean adults, these two tissues account for almost two thirds of body weight. Therefore, the loss of weight that occurs in malnourished patients is principally the result of a loss in muscle and fat mass. Body adipose tissue can be almost completely depleted and up to half of muscle mass can be consumed before death from starvation occurs.

BODY WATER. Many patients who are malnourished have intravascular volume depletion because of inadequate water and sodium intake. However, the percentage of body weight that is composed of water may be increased. Decreased plasma proteins, leaky capillaries, leaky cells, and increased interstitial ion content may cause intravascular volume depletion and expansion of the interstitial space. Therefore, malnourished patients may have diminished intravascular volume in the presence of whole body fluid overload.

SKIN. The skin is a large organ that regenerates rapidly: a basal cell of the dermis reaches the cornified layer and dies in 10 to 14 days. Frequently, undernutrition causes the skin to be dry, thin, and wrinkled, with atrophy of the basal layers of the epidermis and hyperkeratosis. Severe malnutrition may cause considerable depletion of skin protein and collagen. Patients with kwashiorkor experience sequential skin changes in different locations. Hyperpigmentation occurs first, followed by cracking and stripping of superficial layers, leaving behind hypopigmented, thin, and atrophic epidermis that is friable and easily macerated.

HAIR. Scalp hair becomes thin and sparse and is pulled out easily. In contrast, the eyelashes become long and luxuriant, and there may be excessive lanugo hair in children. Children with kwashiorkor experience hypopigmentation with reddish brown, gray, or blond discoloration. Adults may lose axillary and pubic hair.

GASTROINTESTINAL TRACT. Starvation and malnutrition cause structural and functional deterioration of the intestinal tract, pancreas, and liver. The total mass and protein content of the intestinal mucosa and pancreas are markedly reduced. Mucosal epithelial cell proliferation rates decrease, and intestinal mucosa becomes atrophic with flattened villi. The synthesis of mucosal and pancreatic digestive enzymes is reduced. Intestinal transport and absorption of free amino acids are impaired, whereas hydrolysis and absorption of peptides are maintained. Gastric and biliary secretions are diminished. The abdomen may become protuberant because of hypomotility and gas distention. Hepatomegaly is common in severe malnutrition because of excessive fat accumulation caused by decreased very low density lipoprotein synthesis and triglyceride export. Synthesis of most hepatic proteins is decreased.

HEART. Chronic undernutrition affects cardiac mass and function. Cardiac muscle mass decreases, and the decrease is accompanied by fragmentation of myofibrils. Bradycardia (heart rate can decrease to less than 40 beats/minute) and decreased stroke volume can cause a marked decrease in cardiac output and low blood pressure. For example, a hypocaloric diet in physiologically normal volunteers that caused a 24% decrease in body weight was associated with a 38% decrease in cardiac index.

LUNGS. Respiratory function is altered because of decreased thoracic muscle mass and electrolyte imbalances, which cause a decrease in vital capacity, tidal volume, minute ventilation, and ventilatory response to hypoxia.

KIDNEYS. Renal mass and function are relatively well preserved during undernutrition, provided adequate water is consumed to prevent a severe decrease in renal perfusion and acute renal failure. However, when malnutrition is severe, decreases are noted in kidney weight, glomerular filtration rate, the ability to excrete acid, the ability to excrete sodium, and the ability to concentrate urine. Mild proteinuria may also occur.

BONE MARROW. Severe undernutrition suppresses bone marrow red blood cell and white blood cell production and leads to anemia, leukopenia, and lymphocytopenia.

MUSCLE. Muscle function is impaired by malnutrition because of both a loss of muscle mass and impaired metabolism. Decreased sodium pump activity causes an increase in intracellular sodium and a decrease in intracellular potassium, which affects myocyte electrical potential, contributing to fatigue.

BRAIN. The weight and protein content of the brain remain relatively stable during long-term starvation. Therefore, the integrity of the brain is preserved at the expense of other organs and tissues. However, data from one study found that cerebral atrophy was associated with protein-energy malnutrition in children, a finding suggesting that the brain is not completely protected from malnutrition during childhood.

IMMUNE SYSTEM. Severe undernutrition causes atrophy of all lymphoid tissues, including thymus, tonsils, and lymph nodes. Cell-mediated immunity is diminished more than antibody production. Alterations in cell-mediated immunity cause impaired delayed cutaneous hypersensitivity and anergy. The ability to kill bacteria is diminished because of decreased complement and impaired neutrophil function. Gastrointestinal immunoglobulin A secretion is also decreased. Malnourished patients are at increased risk for opportunistic infections and should be considered immunocompromised.

ENDOCRINE SYSTEM. Decreased plasma insulin concentrations and glucose intolerance are common in severe malnutrition. Growth hormone is usually increased and is much greater in the kwashiorkor type than the marasmic type of protein-energy malnutrition. Serum thyroxine levels are low, and the conversion of thyroxine to triiodothyronine is decreased, with increased conversion to reverse triiodothyronine. Plasma cortisol concentration is usually greater than normal. The decrease in plasma leptin concentration that occurs early during energy restriction may be an important initiator of the neuroendocrine response to fasting.

ENERGY METABOLISM. Starvation and undernutrition decrease basal energy expenditure because of diminished organ size and function, increased conversion of active thyroid hormone to its inactive form, decreased sodium pump activity, decreased protein turnover, decreased body core temperature, absence of shivering and nonshivering thermogenesis, and suppression of sympathetic nervous system activity. Energy is also conserved by the onset of fatigue, which leads to decreased physical activity.

DEATH FROM STARVATION

At the terminal phase of starvation, body fat mass, skeletal muscle mass, and the size of most organs are markedly decreased. During this final phase of starvation, body fat stores are nearly depleted, energy derived from body fat decreases, and muscle protein catabolism is accelerated. The mechanism responsible for death from starvation in humans is not well understood, but many patients ultimately succumb to infection. It has been suggested that there are lethal levels of body weight loss (loss of 40% of body weight), of protein depletion (loss of 30 to 50% of body protein), of fat depletion (loss of 70 to 95% of body fat stores), or of body size (body mass index of 13 kg/m^2 for men and 11 kg/m^2 for women) in humans. The duration of survival depends on the amount of available endogenous fuels and the amount of lean tissue. Data from Irish Republican Army hunger strikers demonstrate that death occurs in lean men after approximately 2 months of starvation when more than 35% (~25 kg) of body weight is lost. Obese persons can survive much longer periods of starvation because of their increased fat stores and lean tissue mass. The longest reported fast is that of a severely obese (207 kg) man who safely lost 61% (126 kg) of his initial weight after completing a 382-day fast in which he ingested only acaloric fluids, vitamins, and minerals.

CLINICAL MANIFESTATIONS

Protein-Energy Malnutrition in Children

Undernutrition in children differs from that in adults because it affects growth and development. Much of our understanding of undernutrition in children comes from observations and studies in developing nations where poverty, inadequate food supply, and unsanitary conditions lead to a high prevalence of protein-energy malnutrition. The Waterlow classification of malnutrition and subsequent modification by the World Health Organization (WHO) are used widely and take into account that undernutrition affects childhood growth. Therefore, nutritional status is assessed by comparing a child's weight for height (wasting) and height for age (stunting) with normal standards (Table 222-2). The characteristics of the three major clinical

TABLE 222-2 WATERLOW AND WHO CLASSIFICATIONS OF PROTEIN-ENERGY MALNUTRITION IN CHILDREN

MEASURE	NORMAL	MILD	MODERATE	SEVERE
WEIGHT FOR HEIGHT (WASTING)				
Percentage of median NCHS standard	90-110	80-89	70-79	<70
Standard deviation from the NCHS median	+Z to −Z	−1.1 to −2 Z	−2.1 to −3 Z	≤−3 Z
HEIGHT FOR AGE (STUNTING)				
Percentage of median NCHS standard	95-105	90-94	85-89	<85
Standard deviation from the NCHS median	+Z to −Z	−1.1 to −2 Z	−2.1 to −3 Z	≤−3 Z

NCHS = National Center for Health Statistics; WHO = World Health Organization; Z = 1 standard deviation.

TABLE 222-3 FEATURES OF PROTEIN-ENERGY MALNUTRITION SYNDROMES IN CHILDREN

CHARACTERISTIC	KWASHIORKOR	MARASMUS	NUTRITIONAL DWARFISM
Weight for age (% expected)	60-80	<60	<60
Weight for height	Normal or decreased	Markedly decreased	Normal
Edema	Present	Absent	Absent
Mood	Irritable when picked up Apathetic when alone	Alert	Alert
Appetite	Poor	Good	Good

TABLE 222-4 CLASSIFICATION OF PROTEIN-ENERGY MALNUTRITION IN ADULTS BY BODY MASS INDEX

BODY MASS INDEX (KG/M^2)	NUTRITIONAL STATUS
18.5-24.9	Normal
17.0-18.4	Mildly malnourished
15.0-16.9	Moderately malnourished
<15.0	Severely malnourished

FIGURE 222-1. Kwashiorkor and marasmus in brothers. The younger brother, on the left, has kwashiorkor with generalized edema, skin changes, pale reddish yellow hair, and an unhappy expression. The older child, on the right, has marasmus, with generalized wasting, spindly arms and legs, and an apathetic expression. (From Peters W, Pasvol G, eds. *Tropical Medicine and Parasitology*, 5th ed. London: Mosby; 2002, Fig. 986.)

syndromes of protein-energy malnutrition in children are outlined in Table 222-3. Although these three syndromes are classified separately, they may coexist in the same patient. The use of mid-upper arm circumference has been proposed as a useful screening tool in underserved areas because height is difficult to measure accurately in ill children and accurate assessment of weight depends on access to functioning scales. Mid-upper arm circumference of up to 11.5 cm in children 1 to 5 years old can predict subsequent inpatient mortality as reliably as the Waterlow and WHO classifications.

MARASMUS. Weight loss and marked depletion of subcutaneous fat and muscle mass are the characteristic features in children with marasmus. Loss of fat and muscle makes ribs, joints, and facial bones prominent. The skin is thin, loose, and lying in folds. These children are typically weak and lethargic.

KWASHIORKOR. The word *kwashiorkor* comes from the Ga language of West Africa and can be translated as "disease of the displaced child" because it was commonly seen after weaning. The presence of peripheral edema distinguishes children with kwashiorkor from those with marasmus and nutritional dwarfism (Fig. 222-1). Children with kwashiorkor also have typical skin and hair changes (see earlier sections on hair and skin changes). The abdomen is protuberant because of weakened abdominal muscles, intestinal distention, and hepatomegaly, but these children do not have ascites. In fact, the presence of ascites should prompt the clinician to search for liver disease or peritonitis. Children with kwashiorkor are typically lethargic and apathetic when left alone but become quite irritable when they are picked up or held. Kwashiorkor is not caused by a relative deficiency in protein intake, as was previously believed; in fact, protein and energy intakes are similar in children with kwashiorkor and marasmus. The pathogenesis of kwashiorkor is not clear, but it is likely related to the physiologic stress of an infection that induces a deleterious metabolic cascade in an already malnourished child. This explains why kwashiorkor is an acute illness compared with the chronicity of undernutrition alone and why marasmus and kwashiorkor overlap. Kwashiorkor is characterized by leaky cell membranes that permit the movement of potassium and other intracellular ions to the extracellular space. The increased osmotic load in the interstitium causes water movement and edema.

NUTRITIONAL DWARFISM. The child with failure to thrive may be of normal weight for height but has short stature and delayed sexual development. Providing appropriate feeding can stimulate catch-up growth and sexual maturation.

Protein-Energy Malnutrition in Adults

The diagnosis of protein-energy malnutrition in adults is different from that in children because adults are no longer growing in height. Therefore, undernutrition in adults causes wasting rather than stunting and can be assessed by determining body mass index, defined as the patient's weight (in kilograms) divided by the patient's height (in meters squared) (Table 222-4). In addition, although kwashiorkor and marasmus can occur in adults, most studies of adult protein-energy malnutrition have evaluated hospitalized patients with secondary protein-energy malnutrition and coexisting illness or injury. The current methods that are used clinically to evaluate protein-energy malnutrition in hospitalized adult patients shift nutritional assessment from a diagnostic to a prognostic instrument in an attempt to identify patients who can benefit from nutritional therapy. Therefore, common nutritional assessment parameters are affected by non-nutritional factors that make it difficult to separate the influence of the disease itself from the contribution of inadequate nutrient intake. At present, no "gold standard" exists for determining protein-energy malnutrition in ill patients. The most commonly used methods include a careful history, physical examination, and selected laboratory tests.

TREATMENT

Initial Evaluation

A careful clinical examination is needed to identify life-threatening complications of protein-energy malnutrition that require immediate treatment. The presence of fluid, plasma glucose, electrolyte, and acid-base abnormalities should be determined. A search for infections (e.g., obtaining a white blood cell count, urine analysis and culture, blood cultures, and chest radiograph) should be considered even in the absence of physical findings because many patients are not able to mount a normal inflammatory response. The evaluation must also include a careful analysis of the possible route for nutritional support and whether the gastrointestinal tract can be used or parenteral nutrition is needed for refeeding.

Initial Supportive Care: Resuscitate and Stabilize

Judicious resuscitation with fluids and electrolytes may be necessary before beginning feedings, with frequent evaluations to prevent congestive heart failure from fluid overload. Vitamin supplementation should be given routinely. Severely malnourished patients are poikilothermic, and a warm ambient temperature and warming blankets may be necessary to raise their core temperature slowly. However, if warming blankets are used, patients must be carefully monitored to avoid hyperthermia.

Refeeding: Nutritional Rehabilitation

The goal of feeding the severely malnourished patient can be divided into three phases: (1) to prevent further deterioration and correct life-threatening abnormalities, (2) to restore normal organ function and metabolism, and finally (3) to replete deficient nutrient stores. Oral or enteral tube feedings are preferred to parenteral feeding because of fewer serious complications and enhanced gastrointestinal tract recovery. Feedings should be given in small amounts at frequent intervals to avoid overwhelming the body's limited capacity for nutrient processing and to prevent hypoglycemia, which can occur during brief nonfeeding intervals. Therefore, small amounts of oral feeding should be given frequently (every 1 to 4 hours), enteral tube feeding by continuous drip, or parenteral nutrition by continuous infusion. Sodium intake should be limited during early refeeding, but liberal amounts of phosphorus, potassium, and magnesium should be given to patients who have normal renal function. Daily monitoring of body weight, fluid intake, urine output, and plasma glucose and electrolyte values is critical during the first few days of refeeding so that nutritional therapy can be appropriately adjusted when necessary. Appetite will have usually improved during the second phase. Protein and energy intake should be marginally higher than estimated requirements to provide for adequate maintenance and repair. Additional protein and energy should be provided during phase 3 for repletion and synthesis of new tissue.

The use of nutrient-rich, ready-to-use therapeutic foods is an easy and effective approach for treating malnutrition at home, particularly in developing nations where access to appropriate foods is limited. The manufacturing and processing of ready-to-use-therapeutic foods make it possible to add functional ingredients in an attempt to improve clinical outcome. However, adding probiotics and prebiotics to standard nutritional therapy does not have additional therapeutic effects.

Refeeding Complications

Refeeding can be harmful and may even cause death because of impaired organ function and depleted nutrient stores resulting from previous starvation. The adverse consequences caused by initiating feeding too aggressively are known as the *refeeding syndrome* and usually occur within the first 5 days. (Refeeding syndrome as a complication of parenteral nutrition is briefly discussed in Chapter 224.) Refeeding syndrome complications include fluid overload, electrolyte imbalances, glucose intolerance, cardiac arrhythmias, and diarrhea.

Fluid Overload

Severely malnourished patients are at increased risk for fluid retention and congestive heart failure after nutritional therapy because of compromised cardiac and renal function. Because the ability to excrete sodium is impaired, even normal amounts of dietary sodium intake can be excessive. In addition, carbohydrates increase the concentration of circulating insulin, which stimulates sodium and water reabsorption by the renal tubule. The presence of heart failure requires discontinuation of feeding until cardiac status is stabilized.

Mineral Depletion

Carbohydrate refeeding stimulates insulin release and intracellular uptake of phosphate, which is used for protein synthesis and glucose metabolism. Therefore, plasma phosphorus concentrations can sometimes fall precipitously to less than 1 mg/dL after initiating nutritional therapy if adequate phosphate is not given. Severe hypophosphatemia, associated with muscle weakness, paresthesias, seizures, coma, cardiopulmonary decompensation, and death, has occurred in severely malnourished patients after they received enteral or parenteral nutritional therapy.

Decreased body cell mass and decreased sodium, potassium–adenosine triphosphatase activity, or leaky cell membranes in the malnourished patient lead to depletion of the major intracellular cations, potassium and magnesium. Nonetheless, serum potassium and magnesium concentrations may remain normal or near normal during starvation because of their release from tissue and bone stores. During refeeding, increases in protein synthesis, body cell mass, and glycogen stores require generous intakes of potassium and magnesium. In addition, hyperinsulinemia during refeeding increases cellular uptake of potassium and can cause a rapid decline in its extracellular concentrations.

Glucose Intolerance

Malnourished patients are predisposed to hypoglycemia because of decreased hepatic glucose production. However, starvation and malnutrition impair insulin's ability to suppress endogenous glucose production and stimulate glucose uptake and oxidation. Therefore, providing enteral or parenteral carbohydrates can cause hyperglycemia, glucosuria, dehydration, and hyperosmolar coma. Furthermore, because of the importance of thiamine in glucose metabolism, carbohydrate refeeding in patients who are thiamine deficient can precipitate Wernicke's encephalopathy (Chapter 425).

Cardiac Arrhythmias

Sudden death from ventricular arrhythmias can occur during the first week of refeeding in severely malnourished patients and has been reported in conjunction with severe hypophosphatemia. A prolonged QT interval may be a contributing cause of the rhythm disturbances.

Gastrointestinal Dysfunction

Alterations in gastrointestinal tract function limit the ability of the gastrointestinal tract to digest and absorb food. Mild diarrhea after initiating oral-enteral feeding usually resolves and is not clinically important if fluid and electrolyte homeostasis can be maintained. However, in some severely malnourished patients, oral feeding is associated with severe diarrhea and death. Therefore, aggressive fluid and electrolyte replacement and a search for enteric pathogens should be considered in patients with prolonged or severe diarrhea.

ENTERAL NUTRITION

STEPHEN A. MCCLAVE

The provision of early enteral nutrition (EN) to the critically ill patient in the intensive care unit (ICU) exerts a beneficial physiologic effect that down-regulates inflammation and improves patient outcome. Because the gut is the largest immune organ in the body, the timing, volume, and content of nutrient that is infused into the lumen of the gut have a major impact on the level of oxidative stress, the tone of systemic immune responses, and the likelihood for complications. A window of opportunity exists shortly after admission to the ICU, during which placement of enteral access and initiation of feeding will improve patient outcome, by reducing rates of infection, overall complications, organ failure, length of hospital stay, and in some disease processes,

even mortality. Failure to utilize the gut in critical illness results in a different physiologic response, whereby the gut becomes a proinflammatory organ and outcome is worsened. Depending on the patient population, the window of opportunity for such modulation may be very narrow. Burns are considered to be "nutritional emergencies," in which the window of opportunity may be as short as 3 to 6 hours before increased permeability occurs. In other disease processes, such as pancreatitis or major elective operations, the window may be longer (i.e., 48 to 72 hours). At some point, the ability to modulate the immune system and contain gut barrier function begins to diminish. Preventing increases in permeability of the gut is easier than containment once barrier function is compromised. The main purpose of early EN in the hospitalized critically ill patient then is to maintain gut integrity and modulate systemic immunity. With time, provision of nutrients to prevent the deterioration of nutritional status and the development of malnutrition becomes increasingly important. Therefore, EN is indicated in any critically ill patient who is unable to eat, and should be initiated as soon as the patient receives full volume resuscitation. If the patient is not critically ill, EN is indicated if the patient is anticipated to be unable to eat for more than 7 days. The only true contraindications to feeding are bowel ischemia, mechanical obstruction of the gut, and peritonitis. It is important for the clinician to realize that although ileus, pancreatitis, nausea, vomiting, and other such factors may make enteral feeding difficult, none is an absolute contraindication to providing EN.

PHYSIOLOGIC BENEFIT OF ENTERAL NUTRITION

The provision of EN maintains both the functional and structural integrity of the intestinal epithelium. Early EN stimulates intestinal contractility and causes release of trophic substances such as bile salts, gastrin, bombesin, and motilin. Good contractility controls the overall number of bacteria within the lumen of the gut by peristaltic movement of organisms downstream. EN stimulates the release of secretory immunoglobulin A (IgA), which helps coat luminal bacteria and prevents their adherence to the epithelial wall (Table 223-1). EN stimulates blood flow to the gut and supports the mass of gut-associated lymphoid tissue (GALT). EN stimulates the production of T_H2 anti-inflammatory CD_4 helper lymphocytes, which enter the systemic circulation and support immune function. Secretory IgA-producing immunocytes form mucosal-associated lymphoid tissue (MALT), which generates further production of secretory IgA. EN promotes the role of commensal bacteria, which provide *direct protection* by degrading bacterial toxins and *indirect protection* by preventing colonization of pathogenic organisms (such as *Pseudomonas aeruginosa*). By fermenting prebiotic fiber to short-chain fatty acids, commensal bacteria stimulate butyrate receptors in the colon, which further downregulates inflammation. EN also simulates the immune process of oral tolerance, which further supports the anti-inflammatory functions of T_H1 and T_H3 lymphocytes and the production of the anti-inflammatory agent transforming growth factor-β (TGF-β). The T_H2 cytokines that are produced in this process suppress the adhesion molecule E-selectin, which functions to trap neutrophils within the vasculature. T_H2 cytokines also stimulate the release of mucosal addressin cell adhesion molecule-1 (MAdCAM), which allows GALT cells to extirpate from the splanchnic circulation and return to the lamina propria of the gut.

The addition of certain pharmaconutrient agents to an enteral formula exerts a synergistic effect to the benefit already induced by standard enteral formula alone. The effect of the additional pharmaconutrients is most evident in cancer patients undergoing major elective operations and, to a lesser extent, in patients sustaining burns, trauma, sepsis, or respiratory failure requiring mechanical ventilation. The addition of arginine has a direct stimulant effect on immune function and thus may further support the T_H2 response, proliferation of lymphocytes and secretory IgA-producing immunocytes created by the delivery of enteral feeding. The addition of antioxidants, particularly selenium, serves to decrease oxidative stress. Providing fat in the form of fish oil reduces stimulation of the inflammatory ligand toll-Like receptor-4 (TLR-4) on macrophages, neutrophils, and adipocytes, reducing the production and generation of NFκ-B and tumor necrosis factor-β. Provision of fish oil generates alternative prostaglandins (PGE_3, PGE_1), leukotrienes (LTB_5), and thromboxane (TxA_3), which have a downregulatory effect on inflammatory mediators compared with similar products produced from omega-6 fatty acids (PGE_2, LTB_4, TxA_2). Glutamine added to an enteral formula serves as an antioxidant and helps maintain gut integrity. Zinc has a direct effect on the zona occludens, maintaining tight junctions between the gut epithelial cells.

TABLE 223-1 COMPARISON OF PHYSIOLOGIC EFFECTS OF FEEDING VERSUS STARVATION

	ENTERAL FEEDING	STARVATION
Intestinal contractility	Increased	Decreased
Release of secretory IgA from gut	Increased	Decreased
Release of trophic agents (bile salts, gastrin)	Increased	Decreased
Splanchnic intestinal blood flow	Increased	Decreased
Luminal microbiota Organisms Population	 Commensal Normal	 Pathogenic Overgrowth
Gut integrity and epithelial cell tight junctions	Intact	Permeable
Mass of GALT	Maintained	Diminished
Support of MALT at distant sites	Maintained	Diminished
Population of CD_4 helper lymphocytes emerging from gut into systemic circulation	T_H2 (Anti-Inflam)	T_H1 (Pro-Inflam)
Expression of adhesion molecules	MAdCAM	E-Selectin
Cell line affected (pass out of vascular space)	GALT cells	Neutrophils

GALT = gut-associated lymphoid tissue; IgA = Immunoglobulin A; MALT = mucosal-associated lymphoid tissue; MAdCAM = mucosal addressin adhesion molecule.

CONSEQUENCES OF NOT PROVIDING ENTERAL NUTRITION

For the critically ill patient, failure to provide enteral feeding generates a different physiologic response that is proinflammatory and is associated with worsened outcome. Increases in gut permeability allow activation of macrophages and neutrophils and upregulation of the innate immune responses. Engagement of the luminal bacteria by adherence to the gut epithelium with loss of barrier function adversely affects the acquired immune response, with stimulation and proliferation of T_H1 lymphocytes. Reduced contractility of the gut promotes bacterial overgrowth. Bacteria express virulent genes, which allow them to adhere to the epithelium. A contact-dependent activation of the epithelial cells results in the release of cytokines into the lymphatic channels. A gut-lung axis of inflammation is initiated, in which cytokines pass through the lymphatic channels and the thoracic duct to the systemic circulation and the capillary system of the lungs, promoting acute respiratory distress syndrome (ARDS) and pneumonia. The production of T_H1 cytokines stimulates the adhesion molecule E-selectin, which allows extravasation of activated neutrophils out of the vascular space and into the pulmonary alveoli. The same cytokines suppress the release of MAdCAM, which effectively traps GALT cells in the vascular space, preventing their return to the intestinal lamina propria. With the increases in gut permeability and the upregulation of immune responses, the gut becomes a proinflammatory organ and contributes its own component to the systemic inflammatory response syndrome (SIRS).

INITIATING ENTERAL FEEDING

In most cases, enteral access may be achieved quickly and easily by placing a nasogastric tube and initiating EN immediately after full volume resuscitation and attainment of hemodynamic stability. Although oral gastric feeding may reduce the incidence of sinusitis compared with nasogastric feeding, it may be more difficult to secure a tube adequately that is protruding from the patient's mouth. Surprisingly, more than 95% of critically ill patients will tolerate gastric feeding despite risk for ileus and aspiration. Compared with small bowel feeding, gastric feeding tends to be initiated almost 1 full day sooner. Small bowel feeding quickly "catches up" such that the overall mean provision of calories and time to advancement to goal calories is the same between the two levels of feeding. Small bowel feeding does reduce the risk for aspiration but may not significantly reduce the incidence of pneumonia. Small bowel feeds are perceived to be tolerated better because residual volumes are lower compared with gastric feeding. Percutaneous access is required only in those patients anticipated to require tube feeding for longer than 4 weeks.

With initiation of feeding, it is important to advance to goal as quickly as possible (within 24 to 36 hours). Accurate determination of caloric requirements helps avoid the danger of overfeeding. The caloric goal can be determined by weight-based equations, such as 25 kcal/kg/day, or by measuring requirements with indirect calorimetry. Protein requirements are best estimated again by weight-based equations, such as 1.2 to 1.5 g/kg/day, or by calculating nitrogen balance with a 24-hour urine-urea nitrogen (protein requirement = 1 g urine urea nitrogen × 6.25 g protein/1 g N).

Formula selection has been simplified with the advent of pharmaconutrient formulas. The initial decision in any critically ill patient is whether they are a candidate for an immune-modulating formula. Patients expected to benefit from a pharmaconutrient formula (compared with a standard formula) are those who require major elective gastrointestinal surgery (esophagectomy, gastrectomy, or pancreatectomy), patients who have experienced major trauma (with an Abdominal Trauma Index score >20, especially with head injury), burn patients (total body surface area >30%), patients with head and neck cancer, or critically ill patients on mechanical ventilation. If patients do not meet these criteria, a standard enteral formula providing 1.0 to 1.5 kcal/mL should be selected. The only other type of clinical scenario in which a specialty formula is required is when the patient demonstrates evidence of malassimilation (either maldigestion from pancreatic disease or malabsorption from compromise of small bowel absorption). In these patients, a formula composed of small peptides and medium-chain triglyceride oil or a fiber-containing formula should be initiated. Specialty formulas designed for specific organ failure are rarely indicated, owing to their increased expense and the fact that their use has not been shown to alter patient outcome.

Once feeds are initiated, the clinician must assess tolerance of EN (Table 223-2). Patients should be assessed to make sure they have achieved adequate volume resuscitation before initiation. Evaluating gut motility is important in selecting the proper tube, the level of feeding within the gastrointestinal tract, and whether there is need for simultaneous gastric decompression while feeding into the small bowel. Adequate gastric contractility is indicated by a nasogastric output of less than 1200 mL/day. Small bowel contractility may be assessed by bowel distention, bowel sounds on physical examination, and air-fluid levels on abdominal radiograph. Colonic contractility is evaluated by passage of stool and flatus. In the absence of risk for ischemia (such as a patient who is hypotensive on pressor agents), ileus is not a contraindication to feeding. In fact, feeding will stimulate promotility agents such as bombesin and motilin. Clinicians should be encouraged to "feed an ileus." Rapid ramp-up in the rate of feeding is tolerated better than slow ramp-up, and enteral feeding protocols should be in place to prevent inappropriate cessation of feeding. The head of the patient's bed should be elevated 35 to 45 degrees, and oral hygiene with chlorhexidine mouthwash twice a day should be used to decrease the bacterial count in oropharyngeal secretions. Physicians should have a low threshold for initiating prokinetic agents, should monitor laboratory tests to avoid the adverse effect of electrolyte abnormalities on motility, and may use the narcotic antagonist naloxone infused through the feeding tube to reverse the effects of any opioid narcotic in order to promote intestinal contractility.

Gastric residual volume (GRV) is a poor marker of gastric emptying and risk for aspiration. Raising the GRV cut-off level for cessation of feeds does not lead to increased aspiration, and lowering the number does not protect the patient from aspiration or pneumonia. Enteral feeding protocols should set the cut-off value for GRV somewhere between 400 and 500 mL, and feeds should not be stopped for the first GRV above this set point. After the first elevated GRV, the head of the bed should be elevated, the patient should be rolled over if possible into the right lateral decubitus position to promote gastric emptying, promotility agents should be considered, and the EN may be continued. In the absence of other signs of intolerance, the feedings should not be stopped for a single GRV above this cut-off point alone. Only after a second GRV is obtained above the cut-off level 4 hours later should feeds be stopped and the patient assessed further for evidence of intolerance.

TABLE 223-2 ENTERAL NUTRITION (EN) PROTOCOL FOR NASOGASTRIC FEEDING

1. Elevate head of bed 30-45 degrees at all times.
2. Scrutinize and correct electrolyte abnormalities (esp. K^+, Ca^{2+}, Mg^{2+}, and phosphorus)
3. Initiate proton pump inhibitor intravenously q8h
4. Place nasal bridle
   Place 12-French nasogastric tube into stomach
   Secure tube to bridle
   Confirm position by abdominal radiograph
5. Initiate EN feeds with small peptide/medium-chain triglycerides (MCT) oil formula full strength at 25 mL/hr
   Advance by 25 mL/hr q12h as tolerated to goal
   State Goal Feeds: _____ kcal/day, infused at final rate _____ mL/hr
6. Chlorhexidine mouthwash with good oral hygiene nursing care bid
7. Check Gastric Residual Volume (GRV) q4h
   Return all contents < 500 mL to the patient
8. If GRV > 400 mL, initiate the following:
   Continue EN at the current rate
   Turn patient to right lateral decubitus position if possible for 30 minutes
   Begin metoclopramide 10 mg IV q6h (if patient is receiving opioid narcotics)
   Begin naloxone 8 mg in 10 mL saline per tube q 6 hrs
   Recheck GRV in 4 hr
9. Only if second GRV 4 hr later is >400 mL, hold EN
   Recheck GRV q2h and restart EN when GRV is <400 mL
   If no other signs of intolerance, restart at same rate
   If other evidence of intolerance is present, consider reducing rate by 25 mL/hr when GRV <400 mL (or to baseline 25 mL/hr)
10. If tube in small bowel and GRV > 50 mL, recheck position of tube by abdominal radiograph. Consider switching to Aspirate/Feed nasojejunal tube.

COMPLICATIONS OF ENTERAL FEEDING

Aspiration is the most feared complication arising from provision of EN, but the ability of the clinician to monitor such events is limited. Studies using a very specific and very sensitive laboratory marker for aspiration (tracheal pepsin levels) have shown that most critically ill patients (>75%) show signs of aspiration, occurring at a frequency of 22 to 36% of bedside assessments done every 4 hours. These aspiration events are unwitnessed and unmeasurable by clinical parameters, but an increase in their frequency does correlate with increased risk for pneumonia. Ironically, aspiration of bacteria-laden oropharyngeal secretions is more likely to cause pneumonia than aspiration of bacteria-laden gastric contents. Likelihood for developing pneumonia may be reduced in the high-risk patient by elevating the head of the bed, switching from bolus to continuous infusion, displacing the levels of feeds lower in the gastrointestinal tract below the ligament of Treitz, adding a prokinetic agent, initiating oral hygiene twice daily with chlorhexidine mouthwash, and adding simultaneous gastric decompression.

Tube occlusion occurs when acid from the stomach comes in contact with the formula in the tube and forms a clot. The best declogging agent is a Viokase pancreatic enzyme preparation combined with sodium bicarbonate tablets mixed in warm water. This combination is more than twice as effective as soft drinks or papain meat tenderizer. Failure to declog the tube with these agents may necessitate mechanical declogging with some kind of cytology brush, stylette, or commercial corkscrew device.

Although diarrhea is a frequent complaint in the ICU for patients on tube feeding, most cases represent low-volume incontinence. Although diarrhea in the ICU represents a nursing problem, feeding does not need to be stopped. The most frequent cause of diarrhea in the ICU is the addition of sorbitol as a mixing agent for drugs infused through the feeding tube. Pseudomembranous colitis from *Clostridium difficile* occurs in less than 20% of patients (Chapter 304). Rarely, diarrhea is related to the osmolarity of the formula. Switching to a small peptide formula with medium-chain triglyceride oil or adding fiber to a formula often corrects the problem.

Bowel ischemia (Chapter 145) is a rare and unpredictable complication of enteral feeding. This complication is more often described in patients undergoing surgical placement of a small bowel feeding tube, but cases nonetheless have been shown to occur with nasoenteric feeding tubes. In the patient on EN who becomes hypotensive, feeds should be held if pressor therapy is being initiated, the dose of pressors are being increased, or a second or third agent is being added to the first. Feeds may be restarted in the hypotensive patient on pressor agents if they have been stable for 24 to 36 hours or the doses have already been reduced, or both. It is important to confirm adequate volume resuscitation, fiber should be avoided in these situations, and it may be safer to feed into the stomach than into the small bowel. Enteral feeding in the patient on pressor agents should be held for any sign of intolerance, such as increases in nasogastric output, sudden abdominal distention, new abdominal pain, or cessation of flatus and stool, because these may be the first signs of intestinal ischemia.

One other complication that is seen even today in modern urban university-based hospitals is the refeeding syndrome, a syndrome of sudden death associated with abrupt refeeding. Potential candidates for refeeding syndrome are patients who are severely malnourished, those who require mechanical ventilation and are prone to hypercapnia, and those with congestive heart failure. The mechanism of the refeeding syndrome is related to underlying cardiomyopathy and congestive heart failure, electrolyte shifts when the patient becomes anabolic, or volume overload from the feeding itself. Refeeding syndrome may be prevented by closely monitoring fluid volume, electrolytes, and caloric requirements, starting at a low rate of infusion with a mixed fuel substrate and advancing to goal slowly over 3 to 4 days.

CONCLUSION

The provision of early enteral feeding is one of the most important proactive therapeutic strategies that can favorably alter the outcome of critically ill patients through their course of hospitalization. A fairly narrow window of opportunity in time exists during which to initiate feeds in order to achieve attenuation of oxidative stress and modulate systemic immune responses. The timing, dose, and aspects of delivery of EN determine whether the patient receives the full benefit. The physiologic response seen from enteral feeding cannot be duplicated with parenteral nutrition or starvation. Instituting infusion protocols, improving clinician education (regarding issues such as ileus, GRVs, and perceived tolerance), and having the skills for deep jejunal placement of feeding tubes are all factors that promote the delivery of early EN in the ICU setting.

PARENTERAL NUTRITION

ALEXANDER WILMER AND GREET VAN DEN BERGHE

Malnutrition is a pathologic state resulting from unmet metabolic needs. It is associated with reduced body mass, reduced organ function, abnormalities in blood chemistries, and increased morbidity and mortality. On admission to the hospital, 30 to 60% of patients have some degree of malnutrition, and it may be severe in 10 to 25%. Many patients, especially elderly patients, those with prolonged hospitalization, and those with severe disease, are at increased risk for development of malnutrition in the hospital. Frequent reasons for malnutrition include increased catabolism, decreased calorie intake, or impaired anabolism.

Parenteral provision of nutritional support can modulate the catabolic response and correct or prevent nutritional deficits associated with disease. A state of malnutrition induced by starvation can usually be reversed by parenteral nutrition. However, in disease states associated with hypercatabolism, such as in critically ill patients, the provision of parenteral nutrients can at best be supportive. The use of parenteral nutrition is costly and associated with risks. It has grown into a standard of care despite a lack of objective evidence for a beneficial effect on outcome.

NUTRITIONAL SCREENING AND INDICATIONS

All patients who are malnourished or at risk for malnutrition should receive specialized nutritional care on the basis of the premise that this will improve outcome. A nutritional screening process should always precede the provision of artificial nutrition. This assessment should determine whether parenteral nutrition is truly necessary and whether nutritional treatment is likely to influence outcome. In the most recent practice guidelines of 2002, the American Society for Parenteral and Enteral Nutrition suggests that nutritional screening should incorporate data such as height, weight, weight change, primary diagnosis, and comorbidities for all patients in an ambulatory, hospital, home, or alternative site care setting. If nutritional screening identifies a patient to be at risk, a formal assessment should be performed, including a combination of clinical (history and physical examination) and biochemical parameters. However, there is no single method with sufficient sensitivity and specificity to screen for nutritional risk or to assess malnutrition, and none of the existing screening systems has been validated with respect to outcome. The Nutritional Risk Screening 2002 is a scoring system developed to detect the presence of malnutrition and the risk for development of malnutrition in the hospital (Tables 224-1 and 224-2). This system has good reliability, high practicability, and reasonably good predictive validity to identify patients who will benefit from nutritional support (likelihood ratio, 1.4 [1.9-1.0]).

TABLE 224-1 NUTRITIONAL RISK SCREENING (NRS 2002): INITIAL SCREENING

	YES	NO
1. Is BMI <20.5?		
2. Has the patient lost weight within the last 3 months?		
3. Has the patient had a reduced dietary intake in the last week?		
4. Is the patient severely ill (e.g., in intensive therapy)?		

Yes: If the answer is yes to any question, the screening in Table 224-2 is performed.
No: If the answer is no to all questions, the patient is rescreened at weekly intervals. If the patient is scheduled for a major operation, a preventive nutritional care plan is considered to avoid the associated risk status.
From Kondrup J, Allison SP, Elia M, et al. ESPEN guidelines for nutritional screening 2002. *Clin Nutr.* 2003;22:415-421.

There is no evidence that previously healthy patients without risk factors for malnutrition will benefit from enteral or parenteral feeding if the expected duration of insufficient provision of nutrients is less than 7 to 10 days. In those patients in whom nutritional assessment has revealed need for specialized nutritional support, parenteral nutrition should be initiated only in the presence of contraindications to the use of the gastrointestinal tract, such as perforation, proximal high-output fistulas, small-bowel necrosis, severe diarrhea or emesis, important abdominal distention, severe gastrointestinal bleeding, complete bowel obstruction, or severe hemodynamic instability. An indication for initiation of parenteral nutrition within 24 to 48 hours is commonly accepted if one or more of these conditions are likely to persist for more than 3 to 7 days.

Enteral nutrition frequently results in hypocaloric feeding. Even though the evidence for or against it is controversial, it seems reasonable to supplement enteral with parenteral nutrition as a safe and effective means to achieve earlier optimal caloric intake when the enteral approach does not deliver the targeted calories. It is recommended that in critically ill patients receiving less than their targeted enteral calories, supplemental parenteral nutrition should be initiated after 2 days (one guideline) or after 7 days (another guideline).

Frequently cited contraindications for parenteral nutrition include important risk for volume overloading, severe electrolyte disturbances, and major risks for catheter placement.

ORDERING PARENTERAL NUTRITION

Estimation of Fluid and Calorie Needs

Before parenteral nutrition is ordered, the fluid requirements of the patient should be evaluated. These will vary according to the age of the patient, the disease, and the impact of the disease on organ function. Fluid requirements will generally be met with 30 to 40 mL/kg per day or at 1 to 1.5 mL/kcal expended. A more accurate formula for patients with a body weight of 20 kg or more is 1500 mL + 20 mL/kg for each kilogram above 20 kg.

A second step in ordering parenteral nutrition is to estimate the calorie needs of a patient, which remains a difficult task. The total calorie intake should be determined in relation to the energy expenditure. Age, gender, body size, physical activity, fever, and severity of the disease are factors that modulate energy expenditure. Total energy expenditure is the amount of calories burned during 24 hours and can be measured directly by heat loss (direct calorimetry) or indirectly by the relation between oxygen consumption and carbon dioxide production (indirect calorimetry). Calorimetry is

TABLE 224-2 NUTRITIONAL RISK SCREENING (NRS 2002): FINAL SCREENING

IMPAIRED NUTRITIONAL STATUS		SEVERITY OF DISEASE (= INCREASE IN REQUIREMENTS)	
Absent **Score 0**	Normal nutritional status	Absent **Score 0**	Normal nutritional requirements
Mild **Score 1**	Weight loss >5% in 3 mo *or* Food intake below 50-75% of normal requirement in preceding week	Mild **Score 1**	Hip fracture* Chronic patients, in particular with acute complications: cirrhosis,* COPD* *Chronic hemodialysis, diabetes, oncology*
Moderate **Score 2**	Weight loss > 5% in 2 mo or BMI 18.5-20.5 + impaired general condition *or* Food intake 25-60% of normal requirement in preceding week	Moderate **Score 2**	Major abdominal surgery* Stroke* *Severe pneumonia, hematologic malignancy*
Severe **Score 3**	Weight loss >5% in 1 mo (>15% in 3 mo) or BMI <18.5 + impaired general condition *or* Food intake 0-25% of normal requirement in preceding week	Severe **Score 3**	Head injury* Bone marrow transplantation* *Intensive care patients (APACHE >10)*
		Sum of both scores	**= Total score**
Age	If ≥70 years: add 1 to total score above	**= age adjusted total score**	

Score ≥ 3: the patient is nutritionally at risk and a nutritional care plan is initiated.
Score < 3: weekly rescreening of the patient. If the patient is scheduled for a major operation, a preventive nutritional care plan is considered to avoid the associated risk status.
NRS 2002 is based on an interpretation of available randomized clinical trials.
*Indicates that a trial directly supports the categorization of patients with that diagnosis.
Nutritional risk is defined by the present **nutritional status** and risk for impairment of present status due to **increased requirements** caused by stress metabolism of the clinical condition.
A **nutritional care plan** is indicated in all patients who are (1) severely undernourished (score = 3), or (2) severely ill (score = 3), or (3) moderately undernourished + mildly ill (score 2 + 1), or (4) mildly undernourished + moderately ill (score 1 + 2).
Diagnoses shown in *italics* are based on the following prototypes:
Prototypes for severity of disease
Score = 1: a patient with chronic disease admitted to the hospital because of complications. The patient is weak but out of bed regularly. Protein requirement is increased but can be covered by oral diet or supplement in most cases.
Score = 2: a patient confined to bed because of illness (e.g., after major abdominal surgery). Protein requirement is substantially increased but can be covered, although artificial feeding is required in many cases.
Score = 3: a patient in intensive care with assisted ventilation, for example. Protein requirement is increased and cannot be covered even by artificial feeding. Protein breakdown and nitrogen loss can be significantly attenuated.
Modified from Kondrup J, Allison SP, Elia M, et al. ESPEN guidelines for nutritional screening 2002. *Clin Nutr.* 2003;22:415-421.

TABLE 224-3 MACRONUTRIENTS IN PARENTERAL NUTRITION

MACRONUTRIENT	MINIMUM NEED	MAXIMUM NOT TO BE EXCEEDED	TOTAL CALORIES
Carbohydrate	100-150 g/day	4-5 g/kg/day	40-70%
Protein	0.8 g/kg body weight	2 g/kg/day	15-20%
Lipids	2-4% of total calories	2.5 g/kg/day	15-40%

viewed as the "gold standard" in measuring energy expenditure. Unfortunately, time limitations and financial constraints preclude this method for everyday clinical practice. Total energy expenditure is the sum of cold- and diet-induced thermogenesis, energy consumed by physical activity, and resting energy expenditure. In hospitalized patients, resting energy expenditure is the most variable component and is highly influenced by body composition and degree of inflammation. The variability for the same disease can be as much as 100%, depending very much on the severity of the disease and the time course. This is why all of the frequently cited equations to predict energy expenditure are often inaccurate in patients with more acute and severe disease and can be associated with a substantial risk for overfeeding or underfeeding.

The Harris-Benedict equation, which was developed in normal individuals and calculates resting energy expenditure, is the most popular of these equations:

$$\text{Females: } 655 + (9.6 \times \text{weight in kg}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age in yr})$$

$$\text{Males: } 66.5 + (13.8 \times \text{weight in kg}) + (5.0 \times \text{height in cm}) - (6.8 \times \text{age in yr})$$

Stress and activity factors are added to this calculation. The predicted amount usually falls between 20 and 35 kcal/kg per day. A more practical method, for unstressed subjects, is to calculate calorie needs on the basis of an average value of 1 kcal/kg per hour for men; in women, subtract 5 to 10%. Yet another simple method is given by the following formulas (calculated for ideal body weight):

$$\text{Women} > 60 \text{ yr} = 20 \text{ kcal/kg/day}$$

$$\text{Women} < 60 \text{ yr} = 25 \text{ kcal/kg/day}$$

$$\text{Men} > 60 \text{ yr} = 25 \text{ kcal/kg/day}$$

$$\text{Men} < 60 \text{ yr} = 30 \text{ kcal/kg/day}$$

Forty percent to 50% of Americans are obese, and obesity makes accurate prediction of calorie needs even more difficult. Based on empirical data, a possible approach is to calculate the ideal body weight and to add a percentage (25 to 45%) of the excess body weight to the ideal weight. A formula to calculate ideal body weight is

$$\text{Women} = 45.5 + 0.91 \times (\text{length in cm} - 152.4)$$

$$\text{Men} = 50 + 0.91 \times (\text{length in cm} - 152.4)$$

Formulations

Total parenteral nutrition is the term used to describe a means of feeding whereby all or almost all of the estimated calorie needs are met solely by intravenous administration of nutrients. Supplementary parenteral nutrition refers to a patient who is receiving part of his or her nutritional needs through the gastrointestinal tract and the rest by parenteral infusion. Parenteral nutrition administered through a central vein is referred to as central parenteral nutrition (often also called total parenteral nutrition); when it is given through a peripheral vein, it is referred to as peripheral parenteral nutrition. The main difference is that formulations for peripheral parenteral nutrition need to be isotonic with blood to avoid phlebitis. Hypertonic parenteral formulas are given through a central vein, in which the high flow rapidly dilutes the contents. The main limitation of peripheral parenteral nutrition is that larger volumes are necessary for the nutritional needs of the patient to be met.

The products found in parenteral nutrition formulations typically include macronutrients (protein, carbohydrates, fat emulsions) and micronutrients (vitamins, minerals, and trace elements) (Table 224-3).

Carbohydrates

Carbohydrates are the main source of calories in almost all parenteral nutrition formulations. In the body, glucose is the main metabolic fuel. In the food industry, the natural form of glucose (D-glucose) is also frequently referred to as dextrose. Provision of parenteral glucose has a protein-sparing effect because it decreases the need for skeletal muscle breakdown to provide amino acid precursors for gluconeogenesis. Glucose also stimulates insulin release, thus decreasing lipolysis. The oxidation of 1 g of glucose yields 4 kcal. To meet the needs of the brain, the minimum daily amount of glucose is estimated to be 100 to 150 g. Parenteral nutrition formulations classically contain glucose concentrations ranging from 5 to 70%; the selection depends on the estimated calorie needs and the total volume requirement. In the stressed patient, the maximal oxidation rate of glucose is 4 to 7 mg/kg/minute (for a 70-kg patient, 400 to 700 g/day). To decrease the risk for

metabolic alterations, the maximal rate of glucose infusion should not exceed 5 mg/kg/minute.

Protein

In parenteral nutrition, nitrogen is administered as amino acids containing all essential and almost all nonessential amino acids. Amino acids are a source of calories and precursors for the biosynthesis of proteins involved in almost every body function. Protein can be oxidized and yields 4 kcal/g. In steady-state conditions, protein oxidation equals protein intake, and under such conditions, exogenous protein serves as an energy supply. However, in Europe, it is generally assumed that in critically ill patients, the structural or biosynthetic function of amino acids outweighs their function as a metabolic fuel. Therefore, parenteral protein in that part of the world is usually not included in the calculation of calorie needs. The dietary reference intake for healthy adults is 0.8 g per kilogram of body weight per day, assuming that total calorie intake is adequate. In patients with more severe disease, such as critically ill patients, 1.2 to 1.5 g/kg may seem more appropriate. Burn patients and patients with important gastrointestinal losses presumably fare better with high-protein regimens (>1.5 g/kg).

The standard formulations for amino acids include solutions containing amino acids only or combinations of amino acids with glucose. Standard amino acid solutions are also available with or without electrolytes. Within the amino acid solutions, different formulations have been tailored to specific disease states. For example, patients with hepatic encephalopathy may benefit from solutions with increased amounts of branched-chain amino acids (valine, leucine, and isoleucine) and reduced amounts of aromatic amino acids. Branched-chain amino acids are oxidized in muscle tissue and therefore may decrease the metabolic burden on the liver. Standard amino acid solutions do not contain glutamine because crystalline L-glutamine is poorly soluble and degrades during heat stabilization. However, glutamine participates intimately in many metabolic processes, including protein synthesis and acid-base balance. Under normal conditions, glutamine is not an essential amino acid, but in critically ill patients, plasma levels fall because endogenous production does not meet increased demand. In critically ill patients, supplemental glutamine in the form of intravenous alanyl-glutamine dipeptide has been shown to improve morbidity and to reduce mortality. However, the interpretation of the available evidence differs, with one guideline recommending the routine use of supplemental glutamine in all patients receiving parenteral nutrition (independent of the concomitant use of enteral nutrition) and another guideline recommending the use only for patients who are exclusively fed with parenteral nutrition.

There is no convincing evidence for specific amino acid compositions in patients with acute renal failure, who may need as much as 1.5 g/kg/day of protein when undergoing renal replacement therapies. This is in contrast to stable patients and those with chronic renal failure, for whom a moderate protein restriction (0.7 to 1.0 g/kg/day) is recommended.

Lipids

Lipids are fat emulsions used for provision of energy and to supply linoleic acid and linolenic acid, which are essential, polyunsaturated fatty acids. Linoleic acid is the basic substance of the long-chain ω-6 fatty acids, and linolenic acid is the equivalent of the ω-3 fatty acid family. Lipid emulsions are iso-osmolar and contain a core made essentially of triglycerides stabilized by a layer of phospholipids. Phospholipids serve as an emulsifying agent; glycerol is used to make the emulsion isotonic. Fat emulsions are available in concentrations of 10%, 20%, and 30%. Conventional lipid emulsions use soybean oil or safflower oil or a mixture of both containing only long-chain triglycerides. More recent emulsions contain a mixture of both medium- and long-chain triglycerides. Medium-chain triglycerides are derived from coconut oil and contain mainly saturated fatty acids. They have a number of advantages, such as faster clearance from the blood stream, faster oxidation for energy production, no accumulation in liver tissue, and no storage in adipose tissue. However, hepatic metabolism results in ketogenesis and may lead to acidosis. Olive oil has recently been introduced into fat emulsions. Olive oil is rich in monounsaturated oleic acid and, compared with safflower or soybean oil, may have beneficial influences on inflammatory and immunologic mechanisms. Research on the importance of ω-6 and ω-3 fatty acids in the standard Western diet has led to the development of lipid emulsions based on fish oil. Deep-sea fish oil is an important source of the very long chain, polyunsaturated ω-3 fatty acids eicosapentaenoic acid and docosahexaenoic acid. An increased incorporation of ω-3 fatty acids into plasma membranes derived from fish oil, compared with ω-6 fatty acids derived from vegetable oils and animal fats, increases the release of eicosapentaenoic acid rather than arachidonic acid. The lipid mediators derived from these substances differ markedly. Those derived from eicosapentaenoic acid are mainly anti-inflammatory; those derived from arachidonic acid are more pro-inflammatory. The ratio of ω-6 to ω-3 fatty acids in soybean emulsions and in mixtures of long- and medium-chain triglycerides is 7 : 1; in olive oil emulsions, it is 9 : 1. Outside the United States, manufacturers are marketing lipid emulsions with a ratio of ω-6 to ω-3 fatty acids of less than 4 : 1 with the hope of improved nutritional immunomodulation.

Use of lipids as an energy source can have important benefits. Oxidation of 1 g of intravenous fat supplies 9 kcal. It allows a reduced prescription of parenteral glucose and can thereby reduce the risk or severity of hyperglycemia, especially in stressed patients with insulin resistance. Because of a lower respiratory quotient of 0.7, less carbon dioxide is produced during oxidation of 1 g of lipids compared with 1 g of glucose, although substrate oxidation of glucose is probably not decreased. Only 10% of parenteral nutrition is needed as fat to meet essential fatty acid needs. However, most parenteral nutrition formulations now contain 15 to 40% as lipids. Adults usually receive 0.5 to 1.5 g/kg/day. In patients with hypertriglyceridemia (more than 4 to 5 mmol/L or 350 to 400 mg/dL), lipid emulsions should not be started or should be temporarily interrupted.

Micronutrients

Vitamins are essential organic micronutrients, and most of them are used as necessary precursors of coenzymes. Thirteen different vitamins are required in the diet of human beings; nine of these are water soluble, and four are fat soluble. The essential trace elements include iron, iodine, copper, manganese, zinc, cobalt, molybdenum, selenium, vanadium, and nickel. These trace elements are needed as enzyme cofactors or prosthetic groups.

Vitamins and trace elements are usually administered as combination products; some are also commercially available as single-item injection. The ideal amount of micronutrients remains poorly defined. It is commonly recommended and accepted that all patients should receive daily micronutrient supplementation in standard doses routinely with parenteral nutrition. In critically ill patients, it may be advantageous to increase the dose of vitamins C and E and of selenium because of their role as nonenzymatic reactive oxygen species scavengers. Unless there is clear clinical suggestion of potential deficiency, routine monitoring of serum levels of vitamins or trace elements is not recommended.

PARENTERAL NUTRITION DELIVERY

Total parenteral nutrition can be given in different ways: as separate solutions for carbohydrates, amino acids, and lipids; as a primary amino acid and glucose solution (two-in-one) with the lipid component as piggyback; or as a three-in-one admixture (all-in-one infusion). Several manufacturers now make all-in-one infusions of varying volumes and varying but predefined contents of lipids, glucose, and protein. These have become popular in many institutions because pharmacy and handling costs are decreased and potential breaks in sterility are avoided. However, compared with prescriptions tailored specifically to an individual patient, these all-in-one infusions are less precise in meeting individual nutritional needs.

Because faster infusion rates are associated with a higher incidence of acute adverse effects, during the first days, lipid emulsions should not be infused at a rate faster than 0.1 g/kg/hour with long-chain triglycerides and 1.5 g/kg/hour with mixed medium- and long-chain triglycerides.

Vascular Access

Solutions for peripheral parenteral nutrition are hypertonic to blood, and their osmolality should not exceed 900 mOsm/L. When solution osmolality exceeds 900 mOsm/L, the incidence of phlebitis, inflammation, and pain is clearly increased. Adding 5000 units of heparin to a peripheral parenteral nutrition solution may prolong the duration of the peripheral line.

In most cases, parenteral nutrition is delivered through a central venous access. The selection of the site for catheter insertion and the type of catheter needs to be individualized. If the aim of the intervention is to provide an access for parenteral nutrition only, a single-lumen catheter is preferred. In general, the favored site for insertion is the subclavian vein. Placement in the internal jugular vein, compared with the subclavian vein, appears to be associated with a slightly higher risk of infection and a clearly higher risk of thrombosis. It is also less comfortable for mobile patients. Placement in the subclavian vein is associated with a small risk of pneumothorax and a slightly higher risk of stenosis. The femoral vein should be used only when placement

in the jugular or subclavian vein is contraindicated or not possible. A femoral vein access is associated with the highest risk of infection or thrombosis. Most catheters are introduced by skin puncture; catheters intended for long-term use are placed surgically. Peripherally inserted catheters are inserted through a peripheral, usually antecubital, vein and then advanced into a central vein. They can be placed if the intended duration of parenteral nutrition is more than 2 weeks, and they can be used for up to 6 months in stable patients. The main advantage of these catheters is the avoidance of the risks associated with the puncture of a central vein, but they may lead to a higher rate of phlebitis.

Before placement of a vascular access, patients should be well hydrated and the coagulation status checked. Strict aseptic technique is necessary, and correct positioning of the catheter should be controlled by a chest radiograph before central parenteral nutrition is initiated. Proper catheter care includes regular inspection of the insertion site and dressing with gauze or transparent, semipermeable dressings.

Mechanical complications during placement include arterial puncture, pneumothorax, and hematoma. Infectious complications related to a central venous access occur in 4 to 20% of hospitalized patients, especially in immunocompromised patients and in critically ill patients. In patients with central parenteral nutrition, any sign of fever or sepsis should prompt the thought of catheter-related septicemia or catheter infection. Thrombosis detected by ultrasound examination is frequent, but its clinical relevance remains unclear.

METABOLIC COMPLICATIONS AND MONITORING OF PARENTERAL NUTRITION

The metabolic complications related to parenteral nutrition are numerous. Acute metabolic complications include electrolyte deficiencies, particularly potassium, magnesium, phosphorus, and calcium. These deficiencies are common but can be prevented by adequate monitoring of plasma levels and treated. The same is true for trace elements and vitamin deficiencies, particularly thiamine.

Glucose infused by parenteral nutrition can aggravate illness-induced *hyperglycemia*. Hyperglycemia is common during critical illness and associated with adverse outcome. Large observational studies have revealed a J-curved relationship between blood glucose level and the risk for mortality, with the lowest risk roughly at the "normal for age" blood glucose level. The first randomized controlled trial of "intensive insulin therapy" (IIT) using aggressive parenteral nutrition and central venous continuous insulin infusion targeted a "strictly normal level for fasting blood glucose," compared with tolerating hyperglycemia as an adaptive response and thus starting insulin only when blood glucose levels exceeded the renal threshold (12 mmol/L or 215 mg/dL).■ This study of cardiac and high-risk noncardiac surgery patients in a Surgical Intensive Care Unit (SICU) setting showed reduced mortality with the use of IIT. A number of other trials have demonstrated no effect of IIT on mortality in different ICU settings and other hospitalized patients, and a meta-analysis of 21 trials found no benefit associated with IIT on short-term hospital or ICU mortality.■ The recently reported, multicenter NICE-SUGAR (Normoglycemia in Intensive Care Evaluation—Survival Using Glucose Algorithm Regulation) study showed an actual increase in mortality with target glucose levels of 80 to 108 mg/dL, compared with a target of <180 mg/dL.■ Recent American College of Physicians (ACP) clinical practice guidelines regarding the use of intensive insulin therapy for the management of glycemic control in hospitalized patients have recommended not using IIT to strictly control blood glucose in either non-SICU/medical ICU (MICU) patients or in SICU/MICU patients, with or without diabetes mellitus.

Hypertriglyceridemia is another complication of parenteral nutrition that can increase the risk for liver steatosis. Infusion of lipids over a period of 4 to 8 hours can result in pulmonary hypertension (Chapter 68). Serum triglyceride levels should be determined before starting parenteral nutrition and once a week thereafter. When instituting parenteral nutrition, patients with renal failure are more susceptible to uremia and those with volume depletion to metabolic acidosis. Prevention of hyperglycemia with insulin in intensive care unit patients has been shown to reduce the risk and the severity of hypertriglyceridemia.

Liver steatosis is usually caused by overfeeding and may give rise to elevated aminotransferases and parenchymal abnormalities on ultrasound. *Cholestatic liver disease* may be serious and should be suspected in the setting of elevated γ-glutamyl transferase and alkaline phosphatase, often also in combination with hyperbilirubinemia. The etiology remains unclear, and early reinstitution of enteral feeding and the insulin-titrated prevention of hyperglycemia have been shown to reduce its occurrence. Other complications of the hepatobiliary tract associated with parenteral nutrition are *gallbladder stasis,* which leads to increased risk for gallbladder sludge, gallstones, and acalculous cholecystitis.

Finally, the *refeeding syndrome* is a potentially life-threatening complication of parenteral nutrition. This syndrome comprises a series of metabolic and physiologic derangements resulting from reinstitution of nutrition, possibly because the provision of full specialized nutritional support is initiated too rapidly. Patients who have lost a large amount of weight or who are chronically malnourished are at greatest risk for this syndrome. Usually, this syndrome manifests within the first 2 weeks after start of parenteral nutrition with malaise, edema, weakness, and cardiac arrhythmias. Typical metabolic features are hypophosphatemia, hypokalemia, hypomagnesemia, thiamine deficiency, and fluid overload. Refeeding syndrome is further discussed in Chapter 222.

VITAMINS, TRACE MINERALS, AND OTHER MICRONUTRIENTS

JOEL B. MASON

MICRONUTRIENTS IN NUTRITIONAL SCIENCE

Dietary Requirements

Micronutrients are a diverse array of dietary components necessary to sustain health. The physiologic roles of micronutrients are as varied as their composition; some micronutrients are used in enzymes as either coenzymes or prosthetic groups, others as biochemical substrates or hormones; in some instances, the functions are not well defined. Under normal circumstances, the average daily dietary intake for each micronutrient that is required to sustain normal physiologic functions is measured in milligrams or smaller quantities. In this manner, micronutrients are distinguished from macronutrients, which encompass carbohydrates, fats, and proteins, as well as the macrominerals calcium, magnesium, and phosphorus.

Optimal Intake

For orderly homeostasis to proceed, most dietary nutrients must be ingested in quantities that are neither too small nor too great. Disorders may arise, therefore, when intake regularly falls outside of this physiologic window. The size of this physiologic window varies for each micronutrient and should be kept in mind, particularly in this era when the administration of large quantities of certain micronutrients is increasingly explored for possible therapeutic implications. The dietary requirement for a particular micronutrient is determined by many factors, only one of which is the amount needed to sustain those physiologic functions for which it is used (Table 225-1). The U.S. Institute of Medicine Food and Nutrition Board regularly updates dietary guidelines that define the quantity of each micronutrient that is "adequate to meet the known nutrient needs of practically all healthy persons." These *recommended dietary allowances* (RDAs) were most recently revised between 1998 and 2001, and the values for adults appear in Tables 225-2 and 225-3. Also established for the first time for each micronutrient were *tolerable upper limits* (TULs), which are the "maximal daily levels of oral intake likely to pose no adverse health risks" (see Tables 225-2 and 237-3). *Adequate intake,* the amount necessary to prevent a deficiency state, is not necessarily synonymous with *optimal intake*.

TYPES AND FUNCTION OF MICRONUTRIENTS

Vitamins

Vitamins are categorized as either fat soluble (A, D, E, K) or water soluble (all the others), as shown in Table 225-2. This categorization remains physiologically meaningful. None of the fat-soluble vitamins appear to serve as coenzymes. Intestinal absorption of the fat-soluble vitamins is primarily through a micellar phase, and pathophysiologic conditions associated with fat malabsorption frequently are associated with selective deficiencies of the fat-soluble vitamins. Most of the functions of the water-soluble vitamins are as coenzymes, and they are not absorbed through the lipophilic phase in the intestine.

Trace Elements

Fifteen trace elements have been identified as essential for health: iron, zinc, copper, chromium, selenium, iodine, fluorine, manganese, molybdenum, cobalt, nickel, tin, silicon, vanadium, and arsenic (see Table 225-3), but only for the first 10 of these has compelling evidence indicated that they are essential nutrients in humans. Cobalt appears to be essential solely as a component of vitamin B_{12}, but an isolated deficiency state has never been described. Deficiency syndromes for several of the essential trace elements were not recognized until recently because of their exceedingly small requirements and because of the ubiquitous nature of these elements in foodstuffs. Only under exceptional circumstances, such as long-term reliance on total parenteral nutrition lacking these elements, have some of the deficiency syndromes been observed.

The biochemical functions of trace elements appear to be as components of prosthetic groups or as cofactors for enzymes. Determination of essential trace element status is problematic with the exception of iron. The low concentrations of these elements in bodily fluids and tissues, the finding that blood levels frequently do not correlate well with levels in the target tissues, and the fact that functional tests cannot be devised until their biochemical functions are better understood preclude an accurate laboratory method of assessing the adequacy of most trace elements.

Additional Compounds with Nutritional Relevance

Evidence indicates that humans also have an absolute requirement for the dietary component choline, which is a necessary precursor for acetylcholine and phospholipids and is needed to sustain normal levels of biologic methylation. To date, the most significant adverse effect of dietary inadequacy has been hepatic inflammation. Deficiency is nevertheless thought to be extremely rare, although pregnancy, and particularly lactation, increases the apparent requirement. Individuals whose long-term nutritional requirements are solely derived from total parenteral nutrition appear to be susceptible to choline deficiency. Both an RDA (425 mg, women; 550 mg, men) and a TUL (3.5 g) have now been established.

L-Carnitine is a dietary component that participates in fatty acid metabolism in mitochondria. Although no evidence exists for a dietary requirement in children or adults, premature infants have very low stores of skeletal muscle carnitine. Therefore, preterm infants receiving parenteral nutrition without carnitine supplements appear to be the group at high risk for deficiency. Parenteral supplementation of carnitine in such infants may increase serum carnitine concentration and improve lipid tolerance, weight gain, and nitrogen retention.

CONDITIONS THAT INCREASE REQUIRED DIETARY INTAKE

Many physiologic, pathophysiologic, and pharmacologic factors increase the dietary requirements for micronutrients (see Table 225-1), thereby enhancing the risk of developing a deficiency state.

Physiologic Factors

Stages of the life cycle frequently have a significant impact on the requirements of nutrients. Phases of rapid growth and development, such as in utero development, infancy, adolescence, and pregnancy, are associated with increases in the utilization of certain micronutrients on a per-kilogram basis.

Pregnancy

Requirements for most micronutrients are increased in pregnancy, but, proportionately, the observed increases in the maternal requirements for iron and folate are particularly great and are related to the rapid proliferation of the placental and fetal tissues. Periods of lactation are similarly associated with remarkable increases in requirements; a lactating woman experiences disproportionately large increases in her requirements for zinc and vitamins A, E, and C to meet the metabolic demands incurred by milk production in addition to the aforementioned needs observed in pregnancy.

Aside from its general role in supporting the rapid proliferation of placental and fetal tissues, folate plays a specific role in the prevention of particular birth defects. A 20 to 85% reduction in births complicated by neural tube defects (NTDs, i.e., spina bifida and anencephaly) has been realized by providing women with a daily supplement of folic acid in the form of supplements or fortified foods. The optimal dose is not well defined, but 200 to 400 μg/day clearly affords a substantial degree of protection. Populations with a high background rate of NTD births attain the largest reductions in NTDs from supplemental folate. However, because the nascent neural tube closes about day 20 after conception, the additional folate must be provided before this time in order to be effective.

Infancy

Infancy carries particular vulnerabilities to specific micronutrient inadequacies. Healthy infants in the United States are typically supplemented with vitamin K at birth and with iron and vitamin D during the course of the first year because of their particular susceptibility to deficiencies of these nutrients.

Women of Childbearing Age

The ability to maintain adequate iron status from menarche through menopause is compromised in women by the additional losses incurred by

TABLE 225-1 FACTORS THAT DETERMINE DIETARY REQUIREMENT OF A MICRONUTRIENT

PHYSIOLOGIC FACTORS
Bioavailability: the proportion of a micronutrient that is ingested and is capable of being assimilated and used for physiologic purposes
Quantity required to fulfill physiologic roles
Extent to which the body can reuse the micronutrient
Distribution of nutrient in the body: storage compartments
Gender
Stage of life cycle: intrauterine development, childhood, adulthood, elder adulthood, pregnancy, lactation
PATHOPHYSIOLOGIC AND PHARMACOLOGIC FACTORS
Inborn errors of metabolism: variously affect assimilation, utilization, or excretion of micronutrients
Acquired disease states that alter the amounts required to sustain homeostasis (e.g., malabsorption, maldigestion, states that increase use)
Lifestyle habits: smoking, ethanol consumption
Drugs: may alter bioavailability and/or utilization

menstruation, pregnancy, and lactation. Therefore, it is not surprising that the population subset that almost invariably displays the highest rate of iron deficiency is women of childbearing age.

Elderly Persons

Specific dietary recommendations for elderly people have been formally incorporated into the RDAs because aging has an impact on the need for certain micronutrients. Vitamin B_{12} status declines significantly with aging, in large part because of the high prevalence of atrophic gastritis and its associated impairment in protein-bound vitamin B_{12} absorption. Estimates suggest that 10 to 20% of the elderly population is at risk for clinically significant vitamin B_{12} deficiency. Consequently, elderly persons should consume some of their vitamin B_{12} requirement in the crystalline form rather than solely from the naturally occurring protein-bound forms found in food because absorption of the former is not impaired by atrophic gastritis. Elderly people also require greater quantities of vitamins B_6 and D to maintain health compared with younger adults, as reflected in the new RDAs (see Table 225-3). For instance, the RDA of vitamin D in persons over the age of 70 is now set at 20 μg/day (800 international units), as opposed to adults who are 70 or

TABLE 225-2 VITAMINS AND THEIR FUNCTIONS

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
FAT-SOLUBLE VITAMINS				
Vitamin A	A family of the retinoid compounds, each member having biologic activity qualitatively similar to retinol. Carotenoids are structurally related to retinoids. Some carotenoids, most notably β-carotene, are metabolized into compounds with vitamin A activity and are therefore considered to be provitamin A compounds. Vitamin A is an integral component of rhodopsin and iodopsins, light-sensitive proteins in rod and cone cells in the retina. *Additional functions:* induction and maintenance of cellular differentiation in certain tissues; signal for appropriate morphogenesis in the developing embryo; maintenance of cell-mediated immunity. One microgram of retinol = 3.33 IU of vitamin A.	Follicular hyperkeratosis and night blindness are early indicators. Conjunctival xerosis, degeneration of the cornea (keratomalacia), and de-differentiation of rapidly proliferating epithelia are later indications of deficiency. *Bitot spots* (focal areas of the conjunctiva or cornea with foamy appearance) are an indication of xerosis. Blindness, due to corneal destruction and retinal dysfunction, ensues if left uncorrected. Increased susceptibility to infection is also a consequence. [F: 700 μg; M: 900 μg]	In adults, >150,000 μg may cause *acute* toxicity: fatal intracranial hypertension, skin exfoliation, and hepatocellular necrosis. *Chronic* toxicity may occur with habitual daily intake of >10,000 μg: alopecia, ataxia, bone and muscle pain, dermatitis, cheilitis, conjunctivitis, pseudotumor cerebri, hepatocellular necrosis, hyperlipidemia, and hyperostosis are common. Single, large doses of vitamin A (30,000 μg), or habitual intake of >4500 μg/day in early pregnancy can be teratogenic. Excessive intake of carotenoids causes a benign condition characterized by yellowish discoloration of the skin. Habitually large doses of canthaxanthin, a carotenoid, have the additional capability of inducing a retinopathy. [3000 μg]	Retinol concentration in the plasma and vitamin A concentrations in the milk and tears are reasonably accurate measures of adequate status. Toxicity is best assessed by elevated levels of retinyl esters in plasma. A quantitative measure of dark adaptation for night vision or an electroretinogram are useful functional tests.
Vitamin D	A group of sterol compounds whose parent structure is cholecalciferol (vitamin D_3). Cholecalciferol is formed in the skin from 7-dehydrocholesterol (provitamin D_3) by exposure to UVB radiation. A plant sterol, ergocalciferol (provitamin D_2) can be similarly converted into vitamin D_2 and has similar vitamin D activity. The vitamin undergoes sequential hydroxylations in the liver and kidney at the 25 and 1 positions, respectively, producing the most bioactive form of the vitamin, 1,25-dihydroxy vitamin D. Maintains intracellular and extracellular concentrations of calcium and phosphate by enhancing intestinal absorption of the two ions and, in conjunction with PTH, promoting their mobilization from bone mineral. Retards proliferation and promotes differentiation in certain epithelia. One microgram is = 40 IU.	Deficiency results in disordered bone modeling called *rickets* in childhood and *osteomalacia* in adults. Expansion of the epiphyseal growth plates and replacement of normal bone with unmineralized bone matrix are the cardinal features of rickets; the latter feature also characterizes osteomalacia. Deformity of bone and pathologic fractures occur. Decreased serum concentrations of calcium and phosphate may occur. [15 μg, ages 19-70 yr; 20 μg, age >70 yr]	Excess amounts result in abnormally high concentrations of calcium and phosphate in the serum: metastatic calcifications, renal damage, and altered mentation may occur. [50 μg]	The serum concentration of the major circulating metabolite, 25-hydroxyvitamin D, is an excellent indicator of systemic status except in chronic renal failure, in which the impairment of renal L-hydroxylation results in disassociation of the mono- and dihydroxyvitamin concentrations. Measuring the serum concentration of 1,25-dihydroxyvitamin D is then necessary.

TABLE 225-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Vitamin E	A group of at least 8 naturally occurring compounds, some of which are tocopherols and some of which are tocotrienols. At present, the only dietary form that is thought to be biologically active in humans is α-tocopherol. Acts as an antioxidant and free radical scavenger in lipophilic environments, most notably in cell membranes. Acts in conjunction with other antioxidants such as selenium.	Deficiency due to dietary inadequacy rare. Usually seen in (1) premature infants, (2) individuals with fat malabsorption, and (3) individuals with abetalipoproteinemia. Red blood cell fragility occurs and can produce a hemolytic anemia. Neuronal degeneration produces peripheral neuropathies, ophthalmoplegia, and destruction of posterior columns of spinal cord. Neurologic disease is frequently irreversible if deficiency is not corrected early enough. May contribute to the hemolytic anemia and retrolental fibroplasia seen in premature infants. Reported to suppress cell-mediated immunity. [15 mg]	Depressed levels of vitamin K-dependent procoagulants and potentiation of oral anticoagulants has been reported, as has impaired WBC function. Doses of 800 mg/day have been reported to increase slightly the incidence of hemorrhagic stroke. [1000 mg]	Plasma or serum concentration of α-tocopherol is most commonly used. Additional accuracy is obtained by expressing this value per mg of total plasma lipid. RBC peroxide hemolysis test is not entirely specific but is a useful functional measure of the antioxidant potential of cell membranes.
Vitamin K	A family of naphthoquinone compounds with similar biologic activity. Phylloquinone (vitamin K_1) is derived from plants; a variety of menaquinones (vitamin K_2) is derived from bacterial sources. Serves as an essential cofactor in the post-translational γ-carboxylation of glutamic acid residues in many proteins. These proteins include several circulating procoagulants and anticoagulants as well as proteins in a variety of tissues.	Deficiency syndrome, uncommon except in (1) breast-fed newborns, in whom it may cause "hemorrhagic disease of the newborn," (2) adults with fat malabsorption or who are taking drugs that interfere with vitamin K metabolism (e.g., coumarin, phenytoin, broad-spectrum antibiotics), and (3) individuals taking large doses of vitamin E and anticoagulant drugs. Excessive hemorrhage is the usual manifestation. [F: 90 μg; M: 120 μg]	Rapid intravenous infusion of K_1 has been associated with dyspnea, flushing, and cardiovascular collapse; this is likely related to the dispersing agents in the solution. Supplementation may interfere with coumarin-based anticoagulation. Pregnant women taking large amounts of the provitamin menadione may deliver infants with hemolytic anemia, hyperbilirubinemia, and kernicterus. [no TUL established]	Prothrombin time is typically used as a measure of functional K status; it is neither sensitive nor specific for vitamin K deficiency. Determination of undercarboxylated prothrombin in the plasma is more accurate but less widely available.
WATER-SOLUBLE VITAMINS				
Thiamin (vitamin B_1)	A water-soluble compound containing substituted pyrimidine and thiazole rings and a hydroxyethyl side chain. The coenzyme form is thiamin pyrophosphate (TPP). Serves as a coenzyme in many α-ketoacid decarboxylation and transketolation reactions. Inadequate thiamin availability leads to impairments of above reactions, resulting in inadequate adenosine triphosphate synthesis and abnormal carbohydrate metabolism, respectively. May have an additional role in neuronal conduction independent of aforementioned actions.	Classic deficiency syndrome ("beriberi") described in Asian populations consuming polished rice diet. Alcoholism and chronic renal dialysis are also common precipitants. High carbohydrate intake increases need for B_1. *Mild deficiency*: irritability, fatigue, and headaches. *More severe deficiency*: combinations of peripheral neuropathy, cardiovascular dysfunction, and cerebral dysfunction. Cardiovascular involvement ("wet beriberi"): congestive heart failure and low peripheral vascular resistance. Cerebral disease: nystagmus, ophthalmoplegia, and ataxia (Wernicke's encephalopathy); hallucinations, impaired short-term memory, and confabulation ("Korsakoff's psychosis"). Deficiency syndrome responds within 24 hr to parenteral thiamin but is partially or wholly irreversible after a certain stage. [F: 1.1 mg; M: 1.2 mg]	Excess intake is largely excreted in the urine, although parenteral doses of >400 mg/day are reported to cause lethargy, ataxia, and reduced tone of the gastrointestinal tract. [TUL not established]	The most effective measure of B_1 status is the erythrocyte transketolase activity coefficient, which measures enzyme activity before and after addition of exogenous TPP: RBCs from a deficient individual express a substantial increase in enzyme activity with addition of TPP. Thiamin concentrations in blood or urine are also used.
Riboflavin (vitamin B_2)	Consists of a substituted isoalloxazine ring with a ribitol side chain. Serves as a coenzyme for a diverse array of biochemical reactions. The primary coenzymatic forms are flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). Riboflavin holoenzymes participate in oxidation-reduction reactions in a myriad of metabolic pathways.	Deficiency is usually seen in conjunction with deficiencies of other B vitamins. Isolated deficiency of riboflavin produces hyperemia and edema of nasopharyngeal mucosa, cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, and a normochromic, normocytic anemia. [F: 1.1; M: 1.3]	Toxicity not reported in humans. [TUL not established]	The most common method of assessment is determining the activity coefficient of glutathione reductase in RBCs (the test is invalid for individuals with glucose-6-phosphate dehydrogenase [G6PD] deficiency). Measurements of blood and urine concentrations are less desirable methods.

TABLE 225-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Niacin (vitamin B_3)	Refers to nicotinic acid and the corresponding amide, nicotinamide. The active coenzymatic forms are composed of nicotinamide affixed to adenine dinucleotide, forming NAD or NADP. More than 200 apoenzymes use these compounds as electron acceptors or hydrogen donors, either as a coenzyme or as a co-substrate. The essential amino acid tryptophan is a precursor of niacin; 60 mg of dietary tryptophan yields approximately 1 mg of niacin. Dietary requirements thus depend partly on tryptophan intake. Requirement is often determined on basis of caloric intake (i.e., niacin equivalents/1000 kcal). Large doses of nicotinic acid (1.5-3 g/day) effectively lower low-density lipoprotein cholesterol and elevate high-density lipoprotein cholesterol.	*Pellagra* is the classic deficiency syndrome and is often seen in populations in which corn is the major source of energy. Still endemic in parts of China, Africa, and India. Diarrhea, dementia (or associated symptoms of anxiety or insomnia), and a pigmented dermatitis that develops in sun-exposed areas are typical features. Glossitis, stomatitis, vaginitis, vertigo, and burning dysesthesias are early signs. Reported to occasionally occur in carcinoid syndrome because tryptophan is diverted to other synthetic pathways. [F: 14 mg; M: 16 mg]	Human toxicity known largely through studies examining hypolipidemic effects. Includes vasomotor phenomenon (flushing), hyperglycemia, parenchymal liver damage, and hyperuricemia. [35 mg]	Assessment of status is problematic: blood levels of vitamin not reliable. Measurement of urinary excretion of the niacin metabolites, *N*-methylnicotinamide and 2-pyridone, is thought to be the most effective means of assessment at present.
Vitamin B_6	Refers to several derivatives of pyridine, including pyridoxine (PN), pyridoxal (PL), and pyridoxamine (PM), which are interconvertible in the body. The coenzymatic forms are pyridoxal-5-phosphate (PLP) and pyridoxamine-5-phosphate (PMP). As a coenzyme, B_6 is involved in many transamination reactions (and thereby in gluconeogenesis), in the synthesis of niacin from tryptophan, in the synthesis of several neurotransmitters, and in the synthesis of δ-aminolevulinic acid (and therefore in heme synthesis). It also has functions unrelated to coenzymatic activity: PL and PLP bind to hemoglobin and alter O_2 affinity; PLP also binds to steroid receptors, inhibiting receptor affinity to DNA and thereby modulating steroid activity.	Deficiency usually seen in conjunction with other water-soluble vitamin deficiencies. Stomatitis, angular cheilosis, glossitis, irritability, depression, and confusion occur in moderate to severe depletion; normochromic, normocytic anemia has been reported in severe deficiency. Abnormal electroencephalograms and, in infants, convulsions have also been observed. Some sideroblastic anemias respond to B_6 administration. Isoniazid, cycloserine, penicillamine, ethanol, and theophylline can inhibit B_6 metabolism. [Ages 19-50 yr: 1.3 mg; >50 yr: 1.5 mg for women, 1.7 mg for men]	Long-term use with doses exceeding 200 mg/day (in adults) may cause peripheral neuropathies and photosensitivity. [100 mg]	Many useful laboratory methods of assessment exist. The plasma or erythrocyte PLP levels are most common. Urinary excretion of xanthurenic acid after an oral tryptophan load or activity indices of RBC alanine or aspartic acid transaminases (ALT and AST, respectively) are all functional measures of B_6-dependent enzyme activity.
Folate	A group of related pterin compounds. More than 35 forms of the vitamin are found naturally. The fully oxidized form, folic acid, is not found in nature but is the pharmacologic form of the vitamin. All folate functions relate to its ability to transfer one-carbon groups. It is essential in the de novo synthesis of nucleotides and in the metabolism of several amino acids, and is an integral component for the regeneration of the "universal" methyl donor, *S*-adenosylmethionine. Inhibition of bacterial and cancer cell folate metabolism is the basis for the sulfonamide antibiotics and chemotherapeutic agents such as methotrexate and 5-fluorouracil, respectively.	Women of childbearing age are most likely to be deficient. *Classic deficiency syndrome:* megaloblastic anemia, diarrhea. The hematopoietic cells in bone marrow become enlarged and have immature nuclei, reflecting ineffective DNA synthesis. The peripheral blood smear demonstrates macro-ovalocytes and polymorphonuclear leukocytes with an average of more than 3.5 nuclear lobes. Megaloblastic changes also occur in other epithelia that proliferate rapidly (e.g., oral mucosa, gastrointestinal tract), producing glossitis and diarrhea, respectively. Sulfasalazine and diphenytoin inhibit absorption and predispose to deficiency. [400 μg of dietary folate equivalents (DFE); 1 DFE = 1 μg food folate = 0.6 μg folic acid]	Doses >1000 μg/day may partially correct the anemia of B_{12} deficiency and may therefore mask (and perhaps exacerbate) the associated neuropathy. Large doses also reported to lower seizure threshold in individuals prone to seizures. Parenteral administration is rarely reported to cause allergic phenomena, which is probably due to dispersion agents. [1000 μg]	Serum folate measures short-term folate balance, whereas RBC folate is a better reflection of tissue status. Serum homocysteine rises early in deficiency but is nonspecific because B_{12} or B_6 deficiency, renal insufficiency, and older age may also cause elevations.

TABLE 225-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Vitamin C (ascorbic and dehydroascorbic acid)	Ascorbic acid readily oxidizes to dehydroascorbic acid in aqueous solution. The latter can be reduced in vivo, so it possesses vitamin C activity. Total vitamin C is therefore the sum of ascorbic and dehydroascorbic acid content. It serves primarily as a biologic antioxidant in aqueous environments. Biosyntheses of collagen, carnitine, bile acids, and norepinephrine, as well as proper functioning of the hepatic mixed-function oxygenase system, depend on this property. Vitamin C in foodstuffs increases the intestinal absorption of nonheme iron.	Overt deficiency is uncommon in developed countries. The classic deficiency syndrome is *scurvy*: fatigue, depression, and widespread abnormalities in connective tissues, such as inflamed gingivae, petechiae, perifollicular hemorrhages, impaired wound healing, coiled hairs, hyperkeratosis, bleeding into body cavities. In infants, defects in ossification and bone growth may occur. Tobacco smoking lowers plasma and leukocyte vitamin C levels. [F: 75 mg; M: 90 mg; increase requirement for cigarette smokers by 35 mg/day]	≥500 mg/day (in adults) may cause nausea and diarrhea. >1 g/day modestly increases risk for oxalate kidney stones. Supplementation may interfere with laboratory tests based on redox potential (e.g., fecal occult blood testing, serum cholesterol, and glucose). Withdrawal from chronic ingestion of high doses of vitamin C supplements should be done gradually because accommodation appears to occur, raising a concern of "rebound scurvy." [2 g]	Plasma ascorbic acid concentration reflects recent dietary intake, whereas WBC levels more closely reflect tissue stores. Women's plasma levels are approximately 20% higher than men's for any given dietary intake.
Vitamin B_{12}	A group of closely related cobalamin compounds composed of a corrin ring (with a cobalt atom in its center) connected to a ribonucleotide through an aminopropanol bridge. Microorganisms are the ultimate source of all naturally occurring B_{12}. The two active coenzyme forms are deoxyadenosylcobalamin and methylcobalamin. These coenzymes are needed for the synthesis of succinyl coenzyme A (CoA), which is essential in lipid and carbohydrate metabolism, and for the synthesis of methionine. The latter reaction is essential for amino acid metabolism, for purine and pyrimidine synthesis, for many methylation reactions, and for the intracellular retention of folates.	Dietary inadequacy is a rare cause of deficiency except in strict vegetarians. Most deficiencies arise from loss of intestinal absorption, which may occur with pernicious anemia, pancreatic insufficiency, atrophic gastritis, small bowel bacterial overgrowth, or ileal disease. Megaloblastic anemia and megaloblastic changes in other epithelia (see "Folate") are the result of sustained depletion. Demyelination of peripheral nerves, posterior and lateral columns of spinal cord, and nerves within the brain may occur. Altered mentation, depression, and psychoses occur. Hematologic and neurologic complications may occur independently. Folate supplementation, in doses of 1000 μg/day, may partly correct the anemia, thereby masking (or perhaps exacerbating) the neuropathic complication. [2.4 μg]	A few allergic reactions have been reported to crystalline B_{12} preparations and are probably due to impurities, not the vitamin. [TUL not established]	Serum, or plasma, concentrations are generally accurate. Subtle deficiency with neurologic complications, as described in the "Deficiency" column, can best be established by concurrently measuring the concentration of plasma B_{12} and serum methylmalonic acid because the latter is a sensitive indicator of cellular deficiency.
Biotin	A bi-cyclic compound consisting of a ureido ring fused to a substituted tetrahydrothiophene ring. Endogenous synthesis by intestinal flora may contribute significantly to biotin nutriture. Most dietary biotin is linked to lysine, a compound called biotinyl lysine, or biocytin. The lysine must be hydrolyzed by an intestinal enzyme called biotinidase before intestinal absorption occurs. Acts primarily as a coenzyme for several carboxylases; each holoenzyme catalyzes an ATP-dependent CO_2 transfer. The carboxylases are critical enzymes in carbohydrate and lipid metabolism.	Isolated deficiency is rare. Deficiency in humans has been produced by prolonged total parenteral nutrition lacking the vitamin and by ingestion of large quantities of raw egg white, which contains avidin, a protein that binds biotin with such high affinity that it renders it biounavailable. Alterations in mental status, myalgias, hyperesthesias, and anorexia occur. Later, a seborrheic dermatitis and alopecia develop. Deficiency is usually accompanied by lactic acidosis and organic aciduria. [30 μg]	Toxicity has not been reported in humans with doses as high as 60 mg/day in children. [TUL not established]	Plasma and urine concentrations of biotin are diminished in the deficient state. Elevated urine concentrations of methyl citrate, 3-methylcrotonylglycine, and 3-hydroxyisovalerate are also observed in deficiency.
Pantothenic acid	Consists of pantoic acid linked to β-alanine through an amide bond. An essential component of CoA and phosphopantetheine, which are essential for synthesis and β-oxidation of fatty acids, as well as synthesis of cholesterol, steroid hormones, vitamins A and D, and other isoprenoid derivatives. CoA is also involved in the synthesis of several amino acids and δ-aminolevulinic acid, a precursor for the corrin ring of vitamin B_{12}, the porphyrin ring of heme, and of cytochromes. CoA is also necessary for the acetylation and fatty acid acylation of a variety of proteins.	Deficiency rare: only reported as a result of feeding semisynthetic diets or an antagonist to the vitamin. Experimental, isolated deficiency in humans produces fatigue, abdominal pain, vomiting, insomnia, and paresthesias of the extremities. [5 mg]	In doses of 10 g/day, diarrhea is reported to occur. [TUL not established]	Whole blood and urine concentrations of pantothenate are indicators of status; serum levels are not thought to be accurate.

*Recommended daily allowance (RDA) established for female (F) and male (M) adults by the U.S. Food and Nutrition Board, 1999-2001. In some instances, insufficient data exist to establish an RDA, in which case the adequate intake (AI) established by the board is listed.
†Tolerated upper intake (TUL) established for adults by the U.S. Food and Nutrition Board, 1999-2001.
PTH = parathyroid hormone; UVB = ultraviolet B.

TABLE 225-3 NUTRITIONAL TRACE ELEMENTS AND THEIR CLINICAL IMPLICATIONS

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Chromium	Dietary chromium consists of both inorganic and organic forms. Its primary function in humans is to potentiate insulin action. It accomplishes this function as a circulating complex called *glucose tolerance factor*, thereby affecting carbohydrate, fat, and protein metabolism.	Deficiency in humans only described in long-term total parenteral nutrition (TPN) patients receiving insufficient chromium. Hyperglycemia or impaired glucose tolerance occurs. Elevated plasma free fatty acid concentrations, neuropathy, encephalopathy, and abnormalities in nitrogen metabolism are also reported. Whether supplemental chromium may improve glucose tolerance in glucose-intolerant individuals remains controversial. [F: 25 µg; M: 35 µg]	Toxicity after oral ingestion is uncommon and seems confined to gastric irritation. Airborne exposure may cause contact dermatitis, eczema, skin ulcers, and bronchogenic carcinoma. [no TUL established]	Plasma or serum concentration of chromium is a crude indicator of chromium status; it appears to be meaningful when the value is markedly above or below the normal range.
Copper	Copper is absorbed by a specific intestinal transport mechanism. It is carried to the liver where it is bound to ceruloplasmin, which circulates systemically and delivers copper to target tissues in the body. Excretion of copper is largely through bile, and then into the feces. Absorptive and excretory processes vary with the levels of dietary copper, providing a means of copper homeostasis. Copper serves as a component of many enzymes, including amine oxidases, ferroxidases, cytochrome c oxidase, dopamine β-hydroxylase, superoxide dismutase, and tyrosinase.	Dietary deficiency is rare; it has been observed in premature and low-birthweight infants fed exclusively a cow's milk diet and in individuals on long-term TPN without copper. Clinical manifestations include depigmentation of skin and hair, neurologic disturbances, leukopenia, hypochromic microcytic anemia, and skeletal abnormalities. Anemia arises from impaired utilization of iron and is therefore a conditioned form of iron deficiency anemia. The deficiency syndrome, except the anemia and leukopenia, is also observed in Menkes' disease, a rare inherited condition associated with impaired copper utilization. [900 µg]	Acute copper toxicity has been described after excessive oral intake and with absorption of copper salts applied to burned skin. Milder manifestations include nausea, vomiting, epigastric pain, and diarrhea; coma and hepatic necrosis may ensue in severe cases. Toxicity may be seen with doses as low as 70 µg/kg/day. Chronic toxicity is also described. Wilson's disease is a rare, inherited disease associated with abnormally low ceruloplasmin levels and accumulation of copper in the liver and brain, eventually leading to damage to these two organs. [10 mg]	Practical methods for detecting marginal deficiency are not available. Marked deficiency is reliably detected by diminished serum copper and ceruloplasmin concentrations as well as low red blood cell (RBC) superoxide dismutase activity.
Fluorine	Known more commonly by its ionic form, fluoride. It is incorporated into the crystalline structure of bone, thereby altering its physical characteristics.	Intake of <0.1 mg/day in infants and <0.5 mg/day in children is associated with an increased incidence of dental caries. Optimal intake in adults is between 1.5 and 4 mg/day. [F: 3 mg; M: 4 mg]	Acute ingestion of >30 mg/kg body weight is likely to cause death. Excessive chronic intake (0.1 mg/kg/day) leads to mottling of teeth (dental fluorosis), calcification of tendons and ligaments, and exostoses and may increase the brittleness of bones. [10 mg]	Estimates of intake or clinical assessment are used because no good laboratory test exists.
Iodine	Readily absorbed from the diet, concentrated in the thyroid, and integrated into the thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3). These hormones circulate largely bound to thyroxine-binding globulin. They modulate resting energy expenditure and, in the developing human, growth and development.	In the absence of supplementation, populations relying primarily on food from soils with low iodine content have endemic iodine deficiency. Maternal iodine deficiency leads to fetal deficiency, which produces spontaneous abortions, stillbirths, hypothyroidism, cretinism, and dwarfism. Permanent cognitive deficits may result from iodine deficiency during first 2 years of life. In the adult, compensatory hypertrophy of the thyroid goiter occurs along with varying degrees of hypothyroidism. [150 µg]	Large doses (>2 mg/day in adults) may induce hypothyroidism by blocking thyroid hormone synthesis. Supplementation with >100 mg/day to an individual who was formerly deficient occasionally induces hyperthyroidism. [1.1 mg]	Iodine status of a population can be estimated by the prevalence of goiter. Urinary excretion of iodine is an effective laboratory means of assessment. Thyroid-stimulating hormone (TSH) blood level is an indirect, and therefore not entirely specific, means of assessment.
Iron	Conveys the capacity to participate in redox reactions to a number of metalloproteins such as hemoglobin, myoglobin, cytochrome enzymes, and many oxidases and oxygenases. Primary storage form is ferritin and, to a lesser degree, hemosiderin. Intestinal absorption is 15-20% for "heme" iron and 1-8% for iron contained in vegetables. Absorption of the latter form is enhanced by the ascorbic acid in foodstuffs; by poultry, fish, or beef; and by an iron-deficient state. It is decreased by phytate and tannins.	The most common micronutrient deficiency in the world. Women of childbearing age are the highest-risk group because of menstrual blood losses, pregnancy, and lactation. The classic deficiency syndrome is hypochromic, microcytic anemia. Glossitis and koilonychia ("spoon" nails) are also observed. Easy fatigability often is an early symptom, before anemia appears. In children, mild deficiency of insufficient severity to cause anemia is associated with behavioral disturbances and poor school performance. [postmenopausal F and M: 8 mg; premenopausal F: 18 mg]	Iron overload typically occurs when habitual dietary intake is extremely high, intestinal absorption is excessive, repeated parenteral administration occurs, or a combination of these factors exists. Excessive iron stores usually accumulate in the reticuloendothelial tissues and cause little damage ("hemosiderosis"). If overload continues, iron eventually begins to accumulate in tissues such as the hepatic parenchyma, pancreas, heart, and synovium, causing hemochromatosis (Chapter 219). Hereditary hemochromatosis results from homozygosity of a common recessive trait. Excessive intestinal absorption of iron is seen in homozygotes. [45 mg]	Negative iron balance initially leads to depletion of iron stores in the bone marrow: a bone marrow biopsy and the concentration of serum ferritin are accurate indicators of early depletion. As the severity of deficiency proceeds, serum iron (SI) decreases and total iron-binding capacity (TIBC) increases: an iron saturation (SI/TIBC) of <16% suggests iron deficiency. Microcytosis, hypochromia, and anemia ensue. Elevated levels of serum ferritin or an iron saturation of >60% suggest iron overload, although systemic inflammation elevates serum ferritin regardless of iron status.

TABLE 225-3 NUTRITIONAL TRACE ELEMENTS AND THEIR CLINICAL IMPLICATIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Manganese	A component of several metalloenzymes. Most manganese is in mitochondria, where it is a component of manganese superoxide dismutase.	Manganese deficiency in the human has not been conclusively demonstrated. It is said to cause hypocholesterolemia, weight loss, hair and nail changes, dermatitis, and impaired synthesis of vitamin K–dependent proteins. [F: 1.8 mg; M: 2.3 mg]	Toxicity by oral ingestion is unknown in humans. Toxic inhalation causes hallucinations, other alterations in mentation, and extrapyramidal movement disorders. [11 mg]	Until the deficiency syndrome is better defined, an appropriate measure of status will be difficult to develop.
Molybdenum	A cofactor in several enzymes, most prominently xanthine oxidase and sulfite oxidase.	A probable case of human deficiency is described as being secondary to parenteral administration of sulfite and resulted in hyperoxypurinemia, hypouricemia, and low sulfate excretion. [45 µg]	Toxicity not well described in humans, although it may interfere with copper metabolism at high doses. [2 mg]	Laboratory means of assessment not meaningful until deficiency syndrome is better described.
Selenium	Most dietary selenium is in the form of an amino acid complex. Nearly complete absorption of such forms occurs. Homeostasis is largely performed by the kidney, which regulates urinary excretion as a function of selenium status. Selenium is a component of several enzymes, most notably glutathione peroxidase and superoxide dismutase. These enzymes protect against oxidative and free radical damage of various cell structures. The antioxidant protection conveyed by selenium apparently operates in conjunction with vitamin E because deficiency of one seems to potentiate damage induced by a deficiency of the other. Selenium also participates in the enzymatic conversion of thyroxine to its more active metabolite, triiodothyronine.	Deficiency is rare in North America but has been observed in individuals on long-term TPN lacking selenium. Such individuals have myalgias and/or cardiomyopathies. Populations in some regions of the world, most notably some parts of China, have marginal intake of selenium. In these regions *Keshan's disease*, a condition characterized by cardiomyopathy, is endemic; it can be prevented (but not treated) by selenium supplementation. [55 µg]	Toxicity is associated with nausea, diarrhea, alterations in mental status, peripheral neuropathy, loss of hair and nails: such symptoms were observed in adults who inadvertently consumed 27-2400 mg. [400 µg]	Erythrocyte glutathione peroxidase activity and plasma, or whole blood, selenium concentrations are the most commonly used methods of assessment. They are moderately accurate indicators of status.
Zinc	Intestinal absorption occurs by a specific process that is enhanced by pregnancy and corticosteroids and diminished by coingestion of phytates, phosphates, iron, copper, lead, or calcium. Diminished intake of zinc leads to an increased efficiency of absorption and decreased fecal excretion, providing a means of zinc homeostasis. Zinc is a component of more than 100 enzymes, among which are DNA polymerase, RNA polymerase, and transfer RNA synthetase.	Zinc deficiency has its most profound effect on rapidly proliferating tissues. *Mild deficiency:* growth retardation in children. *More severe deficiency:* growth arrest, teratogenicity, hypogonadism and infertility, dysgeusia, poor wound healing, diarrhea, dermatitis on the extremities and around orifices, glossitis, alopecia, corneal clouding, loss of dark adaptation, and behavioral changes. Impaired cellular immunity is observed. Excessive loss of gastrointestinal secretions through chronic diarrhea and fistulas may precipitate deficiency. *Acrodermatitis enteropathica* is a rare, recessively inherited disease in which intestinal absorption of zinc is impaired. [F: 8 mg; M: 11 mg]	Acute zinc toxicity can usually be induced by ingestion of >200 mg of zinc in a single day (in adults). It is manifested by epigastric pain, nausea, vomiting, and diarrhea. Hyperpnea, diaphoresis, and weakness may follow inhalation of zinc fumes. Copper and zinc compete for intestinal absorption: long-term ingestion of >25 mg/day of zinc may lead to copper deficiency. Long-term ingestion of >150 mg/day has been reported to cause gastric erosions, low high-density lipoprotein cholesterol levels, and impaired cellular immunity. [40 mg]	No accurate indicators of zinc status exist for routine clinical use. Plasma, RBC, and hair zinc concentrations are often misleading. Acute illness, in particular, is known to diminish plasma zinc levels, in part by inducing a shift of zinc out of the plasma compartment and into the liver. Functional tests that determine dark adaptation, taste acuity, and rate of wound healing lack specificity.

*Recommended daily allowance (RDA) established for female (F) and male (M) adults by the U.S. Food and Nutrition Board, 1999-2001. In some instances, insufficient data exist to establish an RDA, in which case the adequate intake (AI) established by the board is listed.
†Tolerated upper limit (TUL) established for adults by the U.S. Food and Nutrition Board, 1999-2001.

younger, whose RDA is 15 µg/day. This increase appears to result from diminished cutaneous synthesis of vitamin D by senile skin and from decreased sun exposure, which is particularly important in elderly patients in institutional facilities. The need for crystalline vitamin B_{12} and for a quantity of vitamin D that is difficult to achieve without resorting to a supplement suggests that universal use of a daily supplement pill containing these nutrients would benefit elderly people. Widespread use among elders of a multivitamin that contains a wide spectrum of micronutrients is more controversial, in part because of concerns regarding subtle toxicity. For example, elders with chronic renal failure appear to have a vulnerability to vitamin A toxicity, suggesting that use of supplements containing this vitamin is contraindicated.

PATHOPHYSIOLOGIC AND PHARMACOLOGIC FACTORS

Diseases of the Gastrointestinal Tract

Intestinal malabsorptive and maldigestive states predispose to multiple micronutrient deficiencies. Both fat-soluble and water-soluble micronutrients (except vitamin B_{12}) are absorbed predominantly in the proximal small intestine. Therefore, diffuse mucosal diseases affecting the proximal portion of the gastrointestinal tract are likely to result in deficiencies. Even in the absence of mucosal disease of the proximal small intestine, extensive ileal disease, small bowel bacterial overgrowth, and chronic cholestasis can each interfere with the maintenance of adequate intraluminal conjugated bile acid

concentrations and can thereby impair absorption of fat-soluble vitamins. Maldigestion is usually the result of chronic pancreatitis. Untreated, it frequently causes malabsorption and deficiencies of fat-soluble vitamins. Vitamin B_{12} malabsorption can often be demonstrated in this setting, a result of inadequate R-protein digestion, but clinical vitamin B_{12} deficiency is rarely reported.

Inborn Errors of Metabolism

Myriad rare inborn errors of metabolism have been described for vitamins and minerals that impair an individual's ability to assimilate, utilize, or retain a particular micronutrient (Chapter 212). Such defects are usually partial and can often be overcome, to a certain extent, by administering doses of the nutrient that are several degrees of magnitude greater than usually required. Suspicion for such defects should be entertained if (1) a known defect exists in the family, (2) a deficiency syndrome arises at birth or during infancy, or (3) the deficiency syndrome is present despite adequate dietary intake and the absence of any disease that would impair the ability to assimilate the nutrient.

Medications

Long-term administration of many drugs may adversely affect micronutrient status. The manner in which drug-nutrient interactions occur varies; some of the more common mechanisms are outlined in Table 225-4. Some drugs exert their therapeutic effects by specifically inhibiting the actions of a micronutrient. Examples include coumarin, which inhibits γ-carboxylation reactions mediated by vitamin K, and methotrexate, which binds tightly to dihydrofolate reductase, thereby inhibiting folate metabolism.

Toxins

Tobacco smoking alters the metabolism of several vitamins, including folate and vitamins C and E. In large surveys, diminished plasma levels of folate and ascorbic acid have been observed in chronic smokers. Smoking is also associated with diminished levels of folate in cells of the oral mucosa, diminished ascorbic acid levels in leukocytes, and decreased concentrations of vitamin E in the alveolar fluid, findings providing evidence that many tissues can be affected by smoking and that the effect does not simply represent a shift of these micronutrients out of the plasma compartment.

ADVANCES IN NUTRITIONAL SCIENCE

New Frontiers in Marginal Deficiency States of Micronutrients

Does Optimal Intake of Micronutrients Optimize Health?

Updating the definition of a micronutrient deficiency and establishing recommended daily intakes that are consistent with the most recent evidence has proved difficult for several reasons. In some instances, a novel biochemical or physiologic role for a nutrient has been identified, but an appropriate question that arises is whether optimization of such functions translates into optimization of health. For example, providing supplemental vitamin E to elderly individuals who are vitamin E replete enhances T-lymphocyte responsiveness; nevertheless, it is unclear whether this translates into diminished infection rates. Another difficult problem pertains to the use of micronutrients in supraphysiologic quantities that exceed all conventional concepts of what is necessary for health. Some micronutrients, when taken in such large quantities, have effects on physiologic functions that impart apparent health benefits. The ingestion of gram quantities of niacin to reduce low-density lipoprotein (LDL) cholesterol is an example. Such physiologic effects are not observed at more conventional levels of intake and are therefore usually considered pharmacologic effects of the nutrient. Thus, the determination of optimal nutrient intake is highly dependent on which physiologic effect is sought. Furthermore, if only a segment of the population will benefit from supraphysiologic quantities of a nutrient, should dietary guidelines for the remainder of the population be established according to this effect?

Determining an adequate level of intake implies the existence of a means of measuring nutrient status. In seeking an appropriate measure of nutrient status, the diversity of function often makes it difficult to decide which measurement is the most germane. Tobacco smoking, for example, diminishes vitamin E levels in alveolar fluid but not in the serum. Thus, the concepts of localized nutrient deficiencies and tissue-specific requirements add an additional level of complexity to the determination of nutrient status.

TABLE 225-4 DRUG-MEDIATED EFFECTS ON MICRONUTRIENT STATUS: EXAMPLES

DRUG	NUTRIENT	MECHANISM OF INTERACTION
Dextroamphetamine, fenfluramine, levodopa	Potentially all micronutrients	Induces anorexia
Cholestyramine	Vitamin D, folate	Adsorbs nutrient, decreases absorption
Omeprazole	Vitamin B_{12}	Modest bacterial overgrowth, decreases gastric acid, impairs absorption
Sulfasalazine	Folate	Impairs absorption and inhibits folate-dependent enzymes
Isoniazid	Pyridoxine	Impairs utilization of B_6
Nonsteroidal anti-inflammatory drugs	Iron	Gastrointestinal blood loss
Penicillamine	Zinc	Increases renal excretion

Redefinition of Nutritional Requirements

Folate

An example of the complexities that have arisen in redefining the criteria for vitamin deficiencies and vitamin requirements is the water-soluble vitamin, folate. In the past, guidelines regarding its necessary intake were straightforward because they were based solely on the prevention of megaloblastic anemia. Measuring serum and erythrocyte folate concentrations were the most common means of assessing status, and maintaining these levels within accepted normative ranges provided assurance that folate status was adequate to prevent anemia. However, degrees of deficiency that are insufficient to cause anemia may still disturb normal biochemical and physiologic homeostasis and, in some instances, cause clinical disease. Clinical trials have demonstrated that women taking folic acid supplements at the time of conception have a markedly lower chance of delivering a baby with an NTD compared with women who are not folate supplemented but whose folate status falls within a conventionally accepted range. This observation compelled the U.S. government to mandate the fortification of flour, beginning in 1998. Present recommendations are that women of childbearing age consume 400 μg/day of folic acid in the form of supplements or fortified foods, although the dose-response curve of this effect is ill defined.

Less than optimal intake of folate is also evidenced by an increase in serum homocysteine, an amino acid that is normally metabolized by a folate-dependent pathway. Before the federally mandated fortification of flour, the median intake of folate among adults was one half of the present RDA, and a substantial minority of Americans had significantly elevated serum homocysteine levels. Elevated homocysteine has been associated with the development of occlusive vascular disease and accelerated cognitive decline. In randomized clinical trials, however, supplementation with folate, vitamin B_{12}, and vitamin B_6 has shown no benefit against cardiovascular disease despite its ability to lower homocysteine levels.[1] Such supplementation also has no clear benefit for cognitive function, except perhaps in patients with low baseline folate levels.[2]

A compelling body of observations in both humans and animals has demonstrated that habitually low consumption of folate is also associated with a substantial increase in the risk for colorectal cancer, and perhaps cancers of other organs such as those of the breast and pancreas. This inverse relationship is observed even when folate status (or dietary intake) falls within the range of conventionally accepted normative values. This relationship has further complicated the determination of what constitutes an optimal intake of folate. The issue is further confounded by newer observations suggesting that an exceptionally high intake of folate among those who unknowingly harbor precancerous or cancerous lesions may paradoxically enhance the progression of these neoplasms, thereby underscoring the potential for harm produced by taking a nutrient outside of its physiologic window.

The most recent update of the U.S. RDA for folate, which occurred in 1998, raised the value from 200 to 400 μg/day, citing both the prevention of anemia and optimization of serum homocysteine as criteria, and recommended that women capable of becoming pregnant consume an additional 400 μg/day in the form of supplements or fortified food. The issues surrounding the prevention of cardiovascular disease, cancer, and cognitive decline were not incorporated into the 1998 determination because the existing data at the time were thought to be inconclusive. However, it may prove appropriate to integrate some of the knowledge surrounding these issues in future revisions of the RDAs. The potential for toxicity, the criterion

for which was primarily linked to its ability to mask vitamin B_{12} deficiency, was dealt with by setting the TUL at 1000 μg/day of folic acid obtained from supplements and fortified foods in addition to that obtained from natural food sources (see Table 225-2).

The electronic version of this chapter describes two other instances that exemplify how our expanding understanding of the biologic effects of micronutrients has complicated the process of determining guidelines for optimal intake.[3-5]

Antioxidant and Free Radical Scavenging Vitamins and Provitamins

Vitamins A, C, and E, as well as many of the carotenoids, are effective antioxidants. In addition, vitamins C and E and some of the carotenoids can scavenge free radicals when these nutrients are taken in adequate quantities. Oxidation and free radical damage have been implicated as important contributors to common degenerative illnesses such as atherosclerosis, cancer, cataracts, and retinal degeneration. Clinical trials to test the efficacy of antioxidant supplements have shown no benefit and oftentimes harm, although growing evidence indicates that the adverse effects of the large doses used in many trials may have obscured the health benefits of these nutrients and that populations with marginal antioxidant status may benefit from such supplements.[3] Two large-scale clinical intervention trials with β-carotene supplements conducted in the 1990s reported increased rates of lung cancer among the recipients of the carotenoid. Subsequent mechanistic studies indicated that the large doses administered (~30 mg/day) result in asymmetrical cleavage of the carotenoid into unnatural products that antagonize normal signaling pathways in the lung epithelium, whereas lower supplemental doses undergo symmetrical cleavage into two molecules of vitamin A, thereby protecting against neoplastic transformation.

LDL oxidized in vivo is atherogenic. Prevention of LDL oxidation, at least in animal models, retards the process of atherogenesis. Supplementation of human subjects with several times the RDA of α-tocopherol, and perhaps some of the other antioxidant micronutrients, is an effective means of preventing LDL oxidation. Human intervention trials with vitamin E or other antioxidant nutrients, however, have generally been unable to demonstrate clinical benefits in the reduction of cardiovascular events. There nevertheless has been a sizeable reduction in cardiovascular events observed with vitamin E supplementation among populations of patients who are under exceptional oxidative stress, such as those with chronic renal failure and certain classes of diabetes, suggesting that it is only among select groups of individuals that a clinical benefit may be realized.

Nonalcoholic steatohepatitis (NASH) (Chapter 155), a disease that is closely associated with features of the metabolic syndrome (Chapter 237), can progress to cirrhosis in up to 15% of patients. Oxidative stress (as well as insulin resistance) has been implicated as a key factor contributing to hepatic injury in NASH. In a recent study of 247 nondiabetic patients with NASH, vitamin E at a dose of 800 IU daily for 96 weeks was associated with a significantly higher rate of improvement in NASH than placebo (43% vs. 19%, $P = .001$).[4]

Epidemiologic studies indicate that occurrence of cancers of the oral cavity, lung, esophagus, and stomach (and perhaps the colorectum) is inversely related to dietary intake of fresh vegetables and fruits. Careful dissection of dietary data suggests that β-carotene and vitamin E content are strongly predictive components of these foodstuffs. High doses of vitamin A and some of its synthetic analogues (e.g., 13-*cis*-retinoic acid) can effectively reduce the recurrence of head and neck cancers, although hepatic toxicity is sometimes a limiting factor in such cancer preventive therapy. Similarly, these agents, as well as β-carotene or vitamin E, when taken in large doses have been shown significantly to promote the regression of oral leukoplakia, a premalignant lesion. Daily supplementation with one to three times the U.S. RDA of β-carotene, selenium, and vitamin E has been shown to reduce the incidence of adenocarcinoma of the stomach in a region of China where the disease, as well as marginal vitamin status, is particularly prevalent. However, as mentioned earlier, trials conducted in developed Western countries have observed no diminution of lung cancer among smokers with daily supplementation of β-carotene and vitamin E.

Epidemiologic associations also suggest an inverse relationship between lens cataract or macular degeneration and the intake of vitamins C, E, and β-carotene. These common degenerative conditions of the eye are caused, at least in part, by photo-oxidation. Some evidence in animal models indicates that they can be retarded by supraphysiologic supplementation with vitamins C or E. When tested under the conditions of a rigorously conducted multicenter, controlled trial, daily supplementation with a combination of vitamins C, E, and β-carotene (with or without zinc) had no effects compared with placebo on the likelihood of developing cataracts. However, the combination that included zinc produced about a 30% decline in the progression of early macular degeneration to an advanced stage and the likelihood of moderate visual acuity loss.[4]

Further investigation is necessary to define the circumstances more clearly under which antioxidant nutrients can be used to prevent or treat chronic degenerative diseases.

TABLE 225-5 NEWLY IDENTIFIED ROLES FOR VITAMINS

VITAMIN OR PROVITAMIN	CLASSIC ROLE	NEW ROLE
β-Carotene	Pro-vitamin A	Antioxidant, free radical
Niacin	NAD/NADP coenzyme	Reduction of LDL, elevation of HDL and cholesterol
Folate	Hemopoietic factor	Diminishes homocysteinemia
Vitamin A	Transduction of visual input in retina	Induction and maintenance of epithelial differentiation, signal in embryogenesis
Vitamin D	Regulator of calcium	Retards epithelial proliferation; promotes differentiation
Vitamin B_6	Coenzyme for transamination	Modulation of steroid activity

HDL = high-density lipoprotein; LDL = low-density lipoprotein; NAD = nicotinamide adenine dinucleotide; NADP = nicotinamide-adenine dinucleotide phosphate.

Vitamin B_{12} and Neuropsychiatric Disease

Plasma vitamin B_{12} concentrations are considered an accurate indication of vitamin B_{12} status. The normative range for a healthy population has typically been reported to be 150 (or 200) to 900 pg/mL. Values greater than 150 pg/mL were thought, until recently, to exclude vitamin B_{12} deficiency as a cause of neurologic or psychiatric syndromes. Recent observations now indicate that 7 to 10% of individuals who have plasma vitamin B_{12} values between 150 and 400 pg/mL may develop neuropsychiatric complications of vitamin B_{12} deficiency in the absence of any indications of megaloblastic anemia. Such individuals can be identified by the demonstration of an elevated level of methylmalonic acid in the blood that decreases to normal levels with parenteral vitamin B_{12} administration. An elevation in serum methylmalonic acid is both a sensitive and a specific indication of cellular vitamin B_{12} deficiency. An alternative approach is to administer several parenteral injections of vitamin B_{12} to an individual who has an otherwise unexplained neuropsychiatric syndrome and whose plasma vitamin B_{12} level falls in the range of 150 to 400 pg/mL. Awareness of this phenomenon is particularly important because it is has become clear that atrophic gastritis, an asymptomatic condition that affects approximately 30% of the elderly population, frequently produces a modest decrease in vitamin B_{12} status.

Table 225-5 lists several examples of biochemical functions of vitamins that have only recently been identified. As the clinical significance of each of these new roles is defined and as quantities of each vitamin needed to optimize such functions are determined, redefinition of the desirable range of vitamin status is likely to occur. Future efforts to refine appropriate dietary goals further for each micronutrient will, however, need to take into consideration an important theme that is underscored by the previous discussion: that the level of consumption of a particular micronutrient that conveys health benefits to one segment of the population is not necessarily beneficial, or even appropriate, for all segments of society.

EATING DISORDERS

MARSHA D. MARCUS AND JENNIFER E. WILDES

DEFINITION

The eating disorders are psychiatric syndromes characterized by abnormal eating behaviors and maladaptive thoughts or beliefs about eating, shape, or weight. The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) describes two primary eating disorders, anorexia nervosa (AN) and bulimia nervosa (BN). A third disorder, binge-eating disorder (BED), also is included as a diagnosis requiring further study. All other presentations of clinically significant eating problems are represented by the residual diagnosis, eating disorder not otherwise specified (EDNOS).

ANOREXIA NERVOSA

The hallmark features of AN are persistent unwillingness or inability to maintain a minimally adequate body weight, which is defined in DSM-IV-TR as less than 85% of that expected, coupled with an intense fear of gaining weight

TABLE 226-1 DSM-IV-TR* DIAGNOSTIC CRITERIA FOR ANOREXIA NERVOSA

A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
B. Intense fear of gaining weight or becoming fat, even though underweight.
C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
D. In postmenarchal females, amenorrhea, that is, the absence of at least three consecutive menstrual cycles (a woman is considered to have amenorrhea if her periods occur following only hormone, e.g., estrogen, administration).

Specify type:

Restricting type: During the current episode of anorexia nervosa, the person has not regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Binge-eating/purging type: During the current episode of anorexia nervosa, the person has regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

**Diagnostic and Statistical Manual of Mental Disorders*. 4th ed., text revision. Copyright 2000 American Psychiatric Association.

TABLE 226-2 DSM-IV-TR* DIAGNOSTIC CRITERIA FOR BULIMIA NERVOSA

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
   2. A sense of lack of control over eating during the episodes (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
D. Self-evaluation is unduly influenced by body shape and weight.
E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify type:

Purging type: During the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

Nonpurging type: During the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

**Diagnostic and Statistical Manual of Mental Disorders*. 4th ed., text revision. Copyright 2000 American Psychiatric Association.

or becoming fat. There is no clear definition for the 85% weight cutoff in AN. In the United States, this criterion often is applied with respect to the Metropolitan Life Insurance Tables, while guidelines specified by the International Classification of Diseases (ICD-10) suggest a body mass index (BMI) of less than or equal to 17.5 as a threshold for AN diagnosis. AN has two subtypes, binge-eating/purging and restricting. DSM-IV-TR criteria for AN are presented in Table 226-1.

BULIMIA NERVOSA

BN is characterized by recurrent episodes of binge eating (i.e., the intake of an exceptionally large amount of food given the context accompanied by a sense of loss of control over eating) that are coupled with compensatory behaviors (e.g., self-induced vomiting, fasting) intended to undo the effects of binge episodes. BN also has two subtypes, purging and nonpurging. Diagnostic criteria are detailed in Table 226-2.

BINGE-EATING DISORDER

BED is characterized by recurrent binge eating in the absence of regular, inappropriate compensatory behaviors. Although classified in DSM-IV-TR as an example of EDNOS, BED is likely to be included as an official diagnosis in the next version of the DSM because there now is substantial evidence documenting the disorder's conceptual validity and clinical utility.

EATING DISORDER NOT OTHERWISE SPECIFIED

A complete discussion of the residual category of eating disorders, EDNOS, is beyond the scope of this chapter. However, it is important to note that EDNOS is the most common diagnosis at many eating disorders programs, reflecting considerable fluidity in the presentation of disordered eating over time and the limitations of current diagnostic criteria. For example, there is little evidence to support the frequency criteria for binge eating or purging in the diagnosis of BN or the utility of the amenorrhea criterion for a diagnosis of AN. Consequently, many cases of EDNOS are subsyndromal variants of AN or BN, but there also are other patterns of disordered eating. For example, purging disorder, or recurrent purging behaviors in the absence of binge eating, has been described.

EPIDEMIOLOGY

Epidemiologic data on the incidence and prevalence of eating disorders are limited. Available evidence indicates that AN is relatively uncommon, with lifetime prevalence estimates ranging from 0.3% to 2.2% in women. Lifetime prevalence estimates for BN range from 1% to 4.6%, whereas estimates for BED range from 0.6 to 3.5% in community samples and are higher among overweight individuals, especially those seeking weight-loss treatment.

AN and BN are more common among women than men, with ratios of approximately 10 : 1. In contrast, differences between the sexes in rates of BED are less pronounced, with the female to male ratio estimated at 3 : 1. Available data suggest that AN and BN are equally common in white, Hispanic, and Native American women and less common in African American and Asian women. However, BED appears to occur with equal frequency in white, African American, and Hispanic women.

PATHOBIOLOGY

The etiology of eating disorders is complex, likely involving the interaction of genetic, constitutional, psychological, family, and sociocultural factors. Family history and twin studies provide strong support for the role of genetics in the pathogenesis of disordered eating. The results are particularly compelling in the case of restricting AN. However, evidence also suggests that BN and binge eating run in families and that much of the variance in observed cases is explained by genetic factors. Genetic linkage and association studies have implicated several susceptibility loci for AN and BN. Research also has suggested a relation between neonatal complications and subsequent onset of AN that may be mediated by maternal genetic variables.

Multiple psychological traits, including neuroticism and perfectionism, have been identified as putative risk factors for disordered eating. Familial overweight or obesity and parental concerns about eating, shape, and weight also have been implicated as potential contributors to the vulnerability for disordered eating. Finally, in industrialized nations, a sociocultural emphasis on shape and weight and a marked preference for a thin body type have been implicated in the complex pathogenesis of eating disorders. Thus, a given case of eating disorder likely reflects some combination of risk or vulnerability factors whose expression may be promoted by a cultural milieu in which thinness is overvalued.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Patients with eating disorders often present with depression, anxiety, and social withdrawal, as well as the specific symptoms of disordered eating. In AN, psychiatric symptoms such as irritability, obsessionality, and preoccupation with food may be secondary to semistarvation and may remit with refeeding. Physical symptoms of semistarvation or malnutrition affect virtually all systems and may include osteopenia or osteoporosis, dehydration, hypothermia, cardiovascular or renal irregularities, gastrointestinal and endocrine disturbances, and changes in neuropsychological functioning. Laboratory results may be normal, especially in restricting AN, but patients still may be at risk for cardiac events resulting from malnutrition.

Signs and symptoms of BN are most commonly associated with purging behavior and include dental enamel erosion secondary to vomiting, gastrointestinal symptoms, salivary gland hypertrophy, and electrolyte disturbances. Misuse of stimulant laxatives can cause hypomagnesia or hypophosphatemia and ultimately disrupt normal bowel functioning. Binge eating is associated with gastric distention and, in rare cases, gastric rupture.

Natural History

Age at onset of AN typically is during adolescence, but prepubertal onset does occur. New-onset AN is not common in adult women; these cases often appear to be triggered by life crisis. The onset of BN typically is during later adolescence or early adulthood, whereas onset of BED can occur well into adulthood.

Information about the natural course of eating disorders is limited. The few studies that have examined the course of AN in community samples have documented recovery rates of about 50 to 60% over 5 to 10 years of follow-up, although significant psychiatric morbidity still was present in about half of individuals. With respect to BN, spontaneous recovery rates range from 49 to 91% in community samples, but most individuals continue to report symptoms, and about 40% experience relapse. Finally, data regarding the natural course of BED and EDNOS are mixed, with some studies reporting high rates of spontaneous and sustained recovery and others suggesting that individuals with BED and EDNOS exhibit a course similar to AN and BN.

DIAGNOSIS

As is the case in all psychiatric disorders, eating disorder diagnoses are documented by review of the patient's history, symptoms, and behaviors in the course of a collaborative interview. Evaluation of comorbid psychiatric problems, particularly mood, anxiety, and substance use disorders, is critical. Assessment for the presence of suicidal ideation or behavior also is warranted. Involvement of the family is crucial for all children and adolescents who present for assessment of disordered eating. A complete physical examination is recommended for all patients, with particular attention to body mass index (weight in kilograms divided by height in meters squared), vital signs, cardiovascular function, hematologic assessment, and blood chemistries.

Patients with eating disorders frequently are examined for gastrointestinal problems or amenorrhea; however, these symptoms often remit with successful treatment of the eating disorder. Marked weight loss in young women in the absence of substance dependence, severe depression, or other documented illness suggests the need for an eating disorder evaluation.

TREATMENT Rx

Anorexia Nervosa

Research evidence to guide the treatment of AN is limited. For emaciated patients, the cornerstone of treatment is medical monitoring and supervised nutrition rehabilitation to restore body weight and normalize eating behavior. Markedly underweight individuals may require a hospital-based program to achieve weight restoration, which usually is accomplished with supervised meals and snacks provided in a supportive environment. When patients refuse to eat, nasogastric feeding may be used; continuous feeding is better tolerated than bolus feeding. "Refeeding syndrome," which is characterized by fluid and electrolyte abnormalities, most notably hypophosphatemia, as well as cardiac, neurologic, and hematologic complications, is a rare but serious adverse effect associated with behavioral management of AN (see Chapter 224 for additional information about refeeding syndrome). To prevent refeeding syndrome in AN, nutrition rehabilitation should be initiated gradually and include close medical monitoring.

With regard to psychotherapy, which is the mainstay of AN treatment when adequate nutrition is restored, several small clinical trials have documented the benefit of family therapy in the treatment of adolescent AN of short duration. The Maudsley model, in which families are helped to play a central role in the management of AN, has shown promise, but replication of the positive results in larger samples is required. The evidence base for psychotherapeutic interventions in adults with AN is meager. Preliminary reports have suggested the utility of cognitive behavior therapy (CBT), but there is no compelling evidence for the efficacy of any form of psychotherapy for adults with AN.

Similarly, there is no strong evidence favoring the use of any particular medication in treating AN. Although some research has suggested the potential utility of selective serotonin reuptake inhibitors in preventing relapse, a well-controlled clinical trial failed to show any benefit of fluoxetine for weight-restored individuals with AN. Several reports have suggested that second-generation antipsychotic agents, particularly olanzapine, may be helpful in the management of AN, but additional research is needed. Hormone treatment and vitamin supplements are not considered useful, although supplemental calcium and vitamin D often are recommended.

Bulimia Nervosa

The evidence base for treatment of BN is stronger than that for AN, but the quality of extant studies is variable. Several forms of psychotherapy have been studied; available evidence provides the best support for CBT, conducted individually or in a group format, as a means of decreasing aberrant eating and reducing the psychological symptoms of BN. Nevertheless, CBT has a significant nonresponse rate, with up to one third of patients failing to benefit. Almost all studied antidepressant agents have a moderate impact on the symptoms of BN, but as is the case with psychotherapy, there is a significant nonresponse rate. Fluoxetine at 60 mg/day is the best studied agent, and there is a U.S. Food and Drug Administration–approved indication for its use at that dose in the treatment of BN. There is no strong evidence in support of medications other than antidepressants in the treatment of BN. In clinical practice, antidepressant medication often is provided in addition to some form of psychotherapy, but there is no compelling support for the benefits of combined treatment.

BED and EDNOS

Numerous trials have examined the use of CBT, interpersonal therapy, behavioral weight management, and medications in the treatment of BED. Available evidence indicates that most overweight patients can be helped with either a behavioral weight control program or an eating disorders treatment, although the results of a recently published randomized controlled trial suggest that psychotherapy is superior to behavioral weight control in the sustained amelioration of binge eating. Pharmacotherapy with antidepressant, anticonvulsant, or anti-obesity agents also may reduce binge eating, but generally does not add to the effectiveness of psychosocial treatment. Cases of EDNOS that reflect subsyndromal variants of AN and BN usually are treated with methods appropriate for management of threshold-level eating disorders.

PREVENTION

Prevention programs for eating disorders typically focus on reducing risk factors for disordered eating and preventing the onset of broadly defined eating pathology. Meta-analytic reviews have identified several characteristics of effective eating disorder prevention programs, including a focus on at-risk individuals, the use of an interactive (versus a didactic) session format, and program content that focuses on reducing eating disorder risk factors as opposed to providing information about the development of eating problems. Numerous trials have documented that a dissonance intervention, in which young women critique the thin ideal endorsed in Western culture, is superior to various control conditions in reducing risk factors for disordered eating and the onset of symptoms. However, little is known about the utility of prevention programs for reducing the incidence of threshold-level eating disorders.

PROGNOSIS

Anorexia Nervosa

Numerous studies have described the outcome of AN in cohorts of treated patients, but the interventions have varied, and many studies have significant methodologic limitations. A meta-analysis of this literature documented that about half of individuals did not meet criteria for AN at follow-up, but most had eating disorder symptoms, and about 20% developed a chronic course of illness. Approximately 50% of patients with AN develop bulimic symptoms over time, but information relating to the temporal onset of binge eating or purging is limited. Studies consistently indicate better outcomes for adolescent patients, but time to recovery nevertheless may be protracted (5 to 6 years). Mortality rates for AN are as high as those for any psychiatric disorder; the primary causes of death are suicide and complications related to chronic starvation.

Bulimia Nervosa

The outcome of BN appears to be better than that for AN, but on average, problematic eating behaviors persist for several years in treated patients. Studies that have followed patient cohorts over time have documented that most individuals with BN achieve full recovery at some point, but rates of relapse are high (i.e., 35%), and approximately one third of patients continue to exhibit some symptoms. There are no consistent predictors of outcome in BN, although depression has been associated with a poorer response to treatment in several studies. Unlike AN, BN does not appear to be associated with an increased risk for premature death.

BED and EDNOS

Few studies have documented long-term outcomes in patients with BED. One report found that 36% of individuals who received inpatient treatment for BED continued to have an eating disorder at 12-year follow-up, which was comparable to the proportion of individuals with BN exhibiting a chronic

course of illness (28%). Virtually nothing is known about the prognosis of individuals with EDNOS.

OBESITY

MICHAEL D. JENSEN

Obesity is the most common nutritional disorder in the United States and directly or indirectly accounts for a significant portion of health-related expenses. The safest and most effective treatment approaches (lifestyle change and behavior modification) are not those commonly employed by physicians and require considerable time to implement. Recently, progress has been made in understanding the pathophysiology and treatment of obesity.

DEFINITION

The National Institutes of Health and National Heart, Lung and Blood Institute (NHLBI) report entitled "Clinical Guidelines on the Identification, Evaluation and Treatment of Overweight and Obesity" provides clear, scientifically based definitions of overweight and obesity. Body mass index (BMI) is now the recommended means to categorize weight relative to height for adults. BMI is calculated as weight (in kilograms) divided by height squared (in meters). To calculate BMI using pounds and inches, the formula is modified as follows: weight (lb)/[height (inches)]^2 × 703. The weight classifications according to BMI are summarized in Table 227-1. Individuals who are overweight (BMI of 25.0 to 29.9) may or may not be overfat. Some men may be overweight because of increased muscle mass, which is a straightforward clinical judgment. Although in general the risk of developing weight-related health problems increases with a BMI of greater than 25, the guidelines point out that intervention or discussion of weight issues with the patient may not be necessary for overweight adults who are entirely healthy or are not overfat. On the other hand, some individuals with a BMI of 27 to 29.9 develop serious metabolic complications that improve with weight loss and are candidates for more aggressive treatment, including pharmacotherapy if needed. Some populations develop the typical metabolic complications of obesity at an even lower BMI and waist circumference. The guidelines for at-risk BMI in Asian populations is 23-24, much lower than whites, Hispanics, blacks, and Polynesians.

TABLE 227-1 CLASSIFICATION OF OVERWEIGHT AND OBESITY BY BODY MASS INDEX

	OBESITY CLASS	BMI KG/M^2
Underweight		<18.5
Normal		18.5-24.9
Overweight		25.0-29.9
Obesity	I	30.0-34.9
Obesity	II	35.0-39.9
Extreme obesity	III	≥40

Data from Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults: The Evidence Report. National Institutes of Health; National Heart, Lung, and Blood Institute Publication 1998:98-4083.

The prevalence of comorbidities increases considerably at a BMI of greater than 30, the definition of obesity. Obesity is divided into three classes, also depending on BMI (see Table 227-1). Treatment approaches may differ for those who are overweight and for different classes of obesity. For example, current U.S. Food and Drug Administration guidelines indicate that pharmacotherapy can be adjunct treatment for any class of obesity, even if medical complications are not present. Familiarity with the guidelines is important. Supervisory agencies and third-party payers use them to determine who is eligible for treatment benefits. Extreme obesity (BMI > 40) is one of the key features that would prompt consideration of a patient for bariatric surgery when medical treatments have failed. Patients with class II obesity (BMI of 35.0 to 39.9) may be considered for bariatric surgery if medical treatments have failed and if severe, life-threatening complications are present.

In addition to using BMI, the NHLBI Guidelines recommend using the waist circumferences as another office assessment tool that can help with the treatment decision-making process. A waist circumference of more than 102 cm or 40 inches for men and more than 88 cm or 35 inches for women is an additional indication of risk for overweight and obesity. This measure is primarily relevant to disease risk in overweight and class I obesity categories, however. In overweight individuals, a large waist circumference changes the relative from "increased" (relative to someone with a normal BMI) to "high." In class I obesity, a large waist circumference increases the risk of disease from "high" to "very high." A large waist circumference does not affect disease risk in those with class II or class III obesity. These definitions of overweight and obesity and of high-risk waist circumference are generally applicable to those of European and African descent, but lower values are recommended for those of Asian descent. The risks of metabolic abnormalities occur at lower BMI and lower waist circumference in these populations.

EPIDEMIOLOGY

Prevalence of Obesity

The number of overweight and obese adults in the United States has increased dramatically over the past 30 years, but the rate of increase has slowed in the last 5 years. Approximately 60% of U.S. men and 51% of U.S. women are overweight or obese, although a greater percentage of women are obese than men. There are substantial differences in the prevalence of obesity by age, race, and socioeconomic status. The prevalence of obesity in adults tends to rise steadily from ages 20 to 60 years, decreasing in later years. It has been estimated that almost 75% of men aged 60 to 69 years in the United States have a BMI of more than 25. The increase in mean BMI with age is not as much of a threat to population health as a similar increase in the BMI of younger populations. The lowest mortality rates for young adults are for a BMI in the lower part of the normal range (18.5 to 24.9), whereas the BMI associated with the lowest mortality rates is somewhat above 25 kg/m^2 for those in the 60s and 70s age groups. Physicians who provide care for individual patients will want to base their weight recommendations based upon whether adverse health consequences associated with obesity are present.

The differences in overweight and obesity among African Americans, Mexican Americans, and European Americans are not subtle. African-American women and Mexican Americans of both sexes have the highest rates of overweight and obesity in the United States. When interpreting these data, however, it is important to keep in mind that there is an inverse relationship between socioeconomic status and obesity, especially among women (Chapter 5). Women in lower socioeconomic classes are much more likely to be obese than those in higher socioeconomic classes. This association reduces but does not eliminate the racial differences in the prevalence of obesity. Whether the remaining racial differences in the prevalence of obesity are due to genetic, constitutional, or social factors is not yet known.

PATHOBIOLOGY

Etiology

There are significant genetic and constitutional susceptibility aspects to obesity that are heavily affected by environmental factors. Evidence from

adoption studies and studies of twins strongly support the concept that within a given environment, a significant portion of the variation in weight is genetic. That said, however, the tremendous increase in the prevalence of obesity in the United States over the past several decades can hardly be ascribed to mass changes in the genetic makeup of Americans.

Genetic Aspects of Human Obesity

There is strong evidence for a hereditary tendency toward the regulation of body weight. The single gene defects resulting in obesity include a number of classic genetic syndromes, such as Prader-Willi and Laurence-Moon-Biedl. More recently, extremely rare monogenic forms of human obesity due to mutations in the leptin gene and leptin receptor gene have been described. The result is an actual or functional leptin deficiency, much like that seen in *ob/ob* or *db/db* mice, the animal models that stimulated the discovery of leptin. There have also been reports of inherited forms of human obesity due to mutations of genes that regulate appetite neuropeptide synthesis. Genome-wide association studies have reported a number of genes associated with higher BMI. Those that appear to predict the greatest amount of variance in BMI include the fat mass and obesity-associated *(FTO)* gene and the melanocortin-4 receptor *(MC4R)* gene. Other genes that have been reliably associated with obesity include *TMEM18, KCTD15, GNPDA2, SH2B1, MTCH2,* and *NEGR1*. Together, however, the combined effects of all the identified genetic contributions account for less than 1% of the variance in BMI. This emphasizes both the huge environmental effects and the polygenic nature of susceptibility to obesity.

Constitutional Influences on Obesity

A number of environmental influences can result in long-term, gene-like affects on body weight regulation and the tendency to be susceptible to obesity-related health problems. These modifications of gene expression without modification of the underlying DNA are termed *epigenetic effects* and are ascribed to processes such as DNA methylation and chromatin remodeling. The effect of the intrauterine environment and the perinatal period on subsequent weight and health is best studied. Undernutrition in the last trimester of pregnancy and in the early postnatal period results in a decreased risk of adult obesity, however, the low birth weight associated with undernutrition (or smoking) in late pregnancy also increases the risk of adulthood hypertension, abnormal glucose tolerance, and cardiovascular disease. In contrast, undernutrition limited to the first two trimesters of pregnancy is associated with an increased probability of adult obesity. The infants of diabetic mothers tend to be fatter than those of nondiabetic mothers, and children of diabetic mothers have a greater prevalence of obesity when they are 5 to 19 years old, independent of their mother's obesity status. Finally, intrauterine exposure to the diabetic environment results in an increased risk of diabetes mellitus and obesity in the offspring. Thus, the issue of the genes versus the environment in regard to obesity and metabolic complications of obesity is blurred in the intrauterine and perinatal time intervals. One of the striking and worrisome aspects of these metabolic effects is not only the long-term effects on the individual's weight regulation and health, but also the suggestion that these traits can be passed on to future generations.

Environmental Contributors to Human Obesity

Few would argue that there have been dramatic changes in the environment over the past 50 years. These changes allowed reduced physical activity for most Americans. In addition, alterations in the food supply have either increased or failed to allow the expected decrease in energy intake that would be needed to match the reduced energy expenditure.

Food

A number of environmental factors can influence food intake (Table 227-2). Consuming energy-dense foods results in greater energy intake because many adults respond to the volume of food taken in rather than the energy content of food. This factor likely accounts for the association between high-fat diets and excess body weight; many high-fat foods are also energy dense. When humans consume diets that are high in fat, but low in energy density, energy intake in not greater than would be expected based on the energy density of the foods. Larger food portion size has also been shown to increase food intake. Given the trend in the United States to serve larger portions of food and beverage, this could be a contributing variable toward obesity. Food variety can also affect energy intake. An increased variety of entrees, sweets, snacks, and carbohydrates in the diet is associated with an increase in body fatness and food intake. In contrast, an increase in variety of vegetables

TABLE 227-2 ENVIRONMENTAL FACTORS PROMOTING OBESITY

↓ Cost	
↑ Caloric beverages (soft drinks, juices)	

*Variety of sweets, snacks, and entrees.

available does not result in an increased energy intake and is not associated with increased body fatness. Other factors that may have broad population effects in the United States include the reduced costs of food, increased availability, and palatability. Finally, there is evidence that consumption of beverages such as soft drinks and fruit juices is not accompanied by a decrease in food intake to offset the extra energy intake. The implication is that some types of beverages will add to the energy intake during the day and promote weight gain. The evidence that is available to date suggests that dairy products do not share this property and that consumption of low-fat dairy products in the context of a weight loss program may be beneficial under some circumstances.

Several individual factors may also influence how the properties of food affect energy intake. Individuals vary with respect to their dietary restraint (the tendency to consciously limit food intake to control weight), their feelings of hunger, or their disinhibition (the tendency to overeat opportunistically). It has been proposed that interindividual differences in these factors may modify how food variety, portion size, and so forth affect the eating profile. There are also effects of the social context under which food is consumed and the emotional state of the individual.

Physical Activity

Physical activity can be divided into three categories: (1) exercise (fitness- and sports-related activities); (2) work-related physical activity; and (3) non-exercise, nonemployment (spontaneous) activity. Tables are widely available that allow one to calculate energy expenditure based on an individual's weight as well as the type and duration of exercise. Only a fraction of Americans engage in exercise at the recommended frequency, intensity, or duration that could be expected to have a protective effect on the development of obesity and other health problems. The portion of Americans who exercise regularly is about 30%, and this does not appear to be changing; therefore, it seems unlikely that a change in exercise habits over the past several decades is causing the increase in obesity. Recent data suggest that the amount of time spent in sedentary activities (e.g., watching television, computer) is an independent predictor of metabolic abnormalities associated with obesity over and above the effects of exercise per se. Thus, to the extent reduced physical activity is contributing to the epidemic of obesity, it is likely that it is reduced employment-related and spontaneous physical activity that is changing.

It is difficult to measure the energy expended in nonexercise activity. Although it seems obvious that employment physical activity has decreased with the advent of more automated systems in the workplace, there are few data in this regard. One estimate suggests that between 1982 and 1992, energy expenditure at work decreased by about 50 kcal/day. The additional changes in the workplace since that time have likely further reduced employment physical activity.

The other component of nonexercise physical activity, the activities of daily living, is equally difficult to measure. A plethora of labor-saving conveniences (e.g., drive-through food and banking, escalators, remote controls, e-mail, online shopping) have been introduced into the modern environment. Each of these further reduces the energy humans must expend to get through the day. Again, there are few hard data to assess how much of a change has actually occurred, although a reduction in daily walking trips and an increase in daily automobile trips has been documented.

Perhaps because it is easier to assess, information on how differences in sedentary activity (television watching, video games, and computer use) relate to obesity is more readily available. There is compelling evidence that more time spent in sedentary pursuits is associated with an increased risk of

overweight and obesity. The striking aspect to these studies is that the adverse effect of sedentary activities is independent of participation in traditional exercise activities.

Understanding the contributions of decreased work-related physical activity, decreases in activity of daily living, and increases in sedentary behavior can help the physician working with the patient to uncover patterns that may relate to weight gain. Physicians who are aware of these environmental factors are in a better position to help their obese patients identify which of these environmental factors are contributing to the problem and develop plans for intervention.

Regulation of Body Weight and Energy Balance

The regulation of adult body weight must be a well-balanced process. For example, the typical U.S. adult will take in and expend approximately 2000 to 3000 kcal/day. If there were a consistent error of even 1% in overconsumption of food, this would result in the gain of approximately 25 to 30 pounds of fat every 10 years if there were no change in energy expenditure. It follows that most adults regulate the average energy balance with greater than 1% precision. There appears to be regulation both of energy intake and energy expenditure through conscious and unconscious processes.

The excess energy consumed by adults is generally stored as triglycerides in adipocytes. Humans continuously recruit new adipocytes from a large preadipocyte pool, to replace dying adipocytes. Although the primary means by which adipose tissue mass expands is through increased fat cell size (adipocyte hypertrophy), this process can only store a limited amount of fat. If sufficient fat is deposited, eventually there will be a net increase in adipocyte number as more new adipocytes are created than needed to replace dying cells. Some adults recruit new adipocytes more readily than others and thus gain weight more so from adipocyte hyperplasia than from hypertrophy. Those who gain fat with large adipocytes, especially if associated with an adipose tissue inflammatory response (greater numbers of macrophages and other immune cells), are more likely to be insulin resistant and have signs of low-grade systemic inflammation (increased C-reactive protein, mildly elevated interleukin-6 and tumor necrosis factor-α).

The discovery of leptin, a protein from the cytokine family that is secreted almost exclusively by adipocytes, was the first confirmation that adipose tissue can secrete hormones that have central nervous system effects on food intake. Leptin also has other hypothalamic-pituitary functions and is proposed to have diverse peripheral physiologic actions. The leptin-deficient animal model of obesity, the *ob/ob* mouse, is severely obese, hyperphagic, hypometabolic, and sexually immature and has low levels of spontaneous activity. Administering leptin to this animal corrects all of these defects. A few humans have been found to have leptin deficiency due to mutations in the leptin gene. These children had very low plasma leptin concentrations and were hyperphagic and severely obese. They responded to exogenous leptin administration with dramatic weight loss, reduced food intake, and accelerated maturation of the pituitary-gonadal axis. With the exception of these rare mutations, however, obese humans are not leptin deficient. In fact, because plasma leptin concentrations increase logarithmically with percentage of body fat, obese humans typically have very high plasma leptin concentrations. Likewise, because women normally have more body fat than men, they also have higher plasma leptin concentrations. From what is currently known, screening for leptin deficiency is not warranted except in severe, hyperphagic obesity that begins in early childhood, is accompanied by sexual immaturity, and exists in the absence of other known causes (e.g., Prader-Willi syndrome).

Some animal models of genetic obesity (the *db/db* mouse and *fa/fa* rat) have defective leptin receptors, making them unresponsive to leptin. Although rare cases of obese humans with defective leptin receptor genes have been reported, again it appears that leptin resistance due to leptin receptor defects (or genetic post-receptor signaling abnormalities) is extremely uncommon. Clinical screening for leptin receptor mutations is not warranted given that no treatment exists.

Leptin secretion can increase 30 to 40% with brief periods of overfeeding (before changes in body composition) and is reduced by 50% in response to brief periods of underfeeding. Clinical studies indicate that low or absent leptin results in extreme hunger. Attempts to treat overweight patients with recombinant leptin have not been successful. Clinical studies suggest that falling leptin plays a role in modulating the hypothalamic-pituitary response to undernutrition, thereby serving the endocrine adaptation to starvation (reduced thyroid-stimulating hormone and gonadotrophins). In summary, the discovery of leptin has been an important advance in understanding the biology of obesity. Defects in leptin secretion or inherited defects in leptin action are very rare.

Energy Intake

Much of what has been learned about the biologic regulation of food intake has been from the study of animal models. These signals may affect different aspects of eating behavior. They can affect hunger—the compelling need or desire for food; satiation—the state of being satisfactorily full and unable to take on more; or satiety—the sense of no longer being hungry, a complex set of postprandial events that affect the interval to the next meal or the amount consumed at the next meal. Some of the signals that alter eating behavior affect one aspect, and others affect multiple aspects. For example, ghrelin, a peptide produced by the stomach, increases hunger but does not appear to affect satiation or satiety. Cholecystokinin causes satiation, but has no effect on satiety. Leptin appears to act on multiple pathways—leptin deficiency is associated with increased hunger and reduced satiation and satiety.

Peripheral satiety signals act to inhibit further food intake at some point during meal consumption. Some of the signals reach the brain through the vagus nerve and some through the systemic circulation. Examples of the proposed factors modulating appetite are listed in Table 227-3. The compounds range from gut-derived (ghrelin, cholecystokinin, glucagon-like peptide 1) and pancreas-derived (insulin) hormones to peptides such as apolipoprotein A-IV, which is secreted with chylomicrons. The signals are thought to be triggered both by mechanical stimuli (e.g., the fullness of the stomach) and the presence of nutrients in the jejunum and ileum.

The central nervous system regulation of food intake is becoming better understood. A number of neuropeptides, lipid derivatives, and monoamines have either anabolic (increased food intake with or without decreased energy expenditure) or catabolic (decreased food intake with or without increased energy expenditure) properties. A list of these molecules is provided in Table 227-4. Many of these compounds serve more than one function, such as regulation of hormone secretion (thyrotropin-releasing hormone and corticotropin-releasing hormone), wakefulness (norepinephrine), or behavior-reinforcing systems (endocannabinoids).

Energy Expenditure

There is a wide range of daily energy expenditure in adults, from less than 1400 kcal/day to more than 5000 kcal/day, with larger, more physically active individuals having the greatest energy needs. Typically, daily energy expenditure is divided into resting (or basal) metabolic rate, the thermic effect of food, and physical activity energy expenditure.

Basal Metabolic Rate

The basal metabolic rate (BMR) is the energy expenditure of laying still at rest, awake, in the overnight postabsorptive state. The resting metabolic rate (RMR) is similarly defined but is not necessarily measured before arising from bed. For most sedentary adult Americans, the RMR represents the major portion of energy expended during the day, and may range from less than 1200 to more than 3000 kcal/day. Most (~80%) of the BMR can be explained by the amount of lean tissue an individual has.

TABLE 227-3 SUGGESTED BIOLOGIC MODULATORS OF FOOD INTAKE

TABLE 227-4 CENTRAL NERVOUS SYSTEM MODULATORS OF ENERGY BALANCE

CENTRAL ANABOLIC (↑ INTAKE)	CENTRAL CATABOLIC (↓ INTAKE)
Neuropeptide Y	α-Melanocyte-stimulating hormone
Agouti-related protein	Corticotropin-releasing hormone
Melanin-concentrating hormone	Thyrotropin-releasing hormone
Hypocretins and orexins	Cocaine- and amphetamine-regulated transcript (CART)
Galanin	Interleukin-1β
Norepinephrine	Urocortin
Endogenous endocannabinoids (anandamide and 2-arachidonoylglycerol)	Oxytocin
	Neurotensin
	Serotonin

Not all components of lean tissue consume oxygen at the same relative rates. Visceral or splanchnic bed tissues account for about 25% of resting metabolic rate but a much smaller proportion of body weight. The brain, which is only a few percent of body weight, accounts for almost 15% of RMR. Likewise, the heart (~7%) and kidneys (~5 to 10%) account for greater portions of resting energy needs than their relative contribution to body mass. In contrast, resting muscle makes up 40 to 50% of lean tissue mass but accounts for only 25% of RMR. This contribution changes dramatically with exercise, however, at which time muscle can account for 80 to 90% of energy expenditure. Adipose tissue is a minor contributor to daily energy expenditure, consuming only approximately 3 kcal/kg of body fat per day. Brown fat is adipose tissue that expresses large amounts of uncoupling protein-1, a protein that allows a mitochondrial membrane proton leak, resulting in heat release as opposed to chemical work from adenosine triphosphate— "uncoupling" of substrate oxidation from chemical or mechanical work. This thermogenic tissue was thought to be present only in human infants but has recently been shown to exist in adults, albeit in amounts insufficient to have measurable thermogenic properties.

Although most of the RMR can be accounted for by the mass of lean tissue, there are also other, more subtle influences on RMR. Age, sex (women have slightly lower BMR even corrected for fat-free mass), and fat mass affect RMR. Small changes in BMR occur during the menstrual cycle (luteal phase > follicular phase). There is also evidence that heritable or family factors influence BMR, accounting for as much as 10% of the interindividual differences.

There are both obligatory and facultative components to resting metabolic rate. With an energy-restricted diet, significant reductions in BMR relative to the amount of fat-free mass occur. Reductions in the production of triiodothyronine from thyroxine and the sympathetic nervous system drive are thought to contribute to this phenomenon. Likewise, during brief periods of overfeeding, resting metabolic rate increases above that which would be expected for the amount of lean tissue present.

It has been proposed that individuals with basal metabolic rates lower than predicted are at increased risk of future weight gain. Published data suggest that the relative risk is small, and clinical effort to identify such patients is not warranted. Measurement of BMR is sometimes helpful in the evaluation of patients who insist they are unable to lose weight while following diets containing less than 1000 kcal/day. Almost without fail, their BMR is substantially greater than their reported food intake. This underscores the fact that most adults are unreliable in assessing their own food intake.

The Thermic Effect of Food

Approximately 10% of the energy content of food is expended in the process of digestion, absorption, and metabolism of nutrients. There is a significant interindividual variability in this value, however, ranging from a low of about 5% to a high of about 15% of meal calories that are "wasted" in the postprandial interval. The thermic effect of a meal is related to its carbohydrate and protein caloric content; the fat content has little stimulatory effect. Both obligatory (60 to 70%) and facultative (30 to 40%) components of the thermic effect of food have been identified. The obligatory components no doubt reflect the energy costs of digestion, absorption, and storage of nutrients. The two factors thought to play a role in the facultative component of the thermic effect of food are the postprandial insulin response and activation of the sympathetic nervous system. The thermic effect of food is somewhat lower in insulin-resistant and obese humans, but this has not been linked to future obesity.

Physical Activity Energy Expenditure

The energy expenditure of physical activity is a product of the amount of work done and the work efficiency of the individual. Although tracking the total amount of physical activity humans perform throughout the day is not easy, when it is possible to do so, it is also possible to calculate the energy expended because the published values for estimating the energy costs of work performed are generally quite accurate. Work units are expressed as metabolic equivalents (METs), a multiple of the resting metabolic rate. If an individual's resting metabolic rate is 1 kcal/minute (1440 kcal/day), a workload of 5 METs would be 5 kcal/minute. Highly trained athletes can work at extremely high METs (>16) for extended periods of time, but most sedentary individuals can only work for a limited amount of time at much lower workloads. This is because athletes have both a greater peak work capacity (or maximal amount of calories or oxygen that can be consumed) and a higher lactate threshold. The lactate threshold can be thought of as the level at which exercise begins to become so uncomfortable that it cannot be maintained much longer. The biochemical definition of lactate threshold describes the progressive rise in blood lactate concentrations observed during sufficiently high-intensity exercise. The lactate threshold may range from 50 to 90% of an individual's peak work capacity. Training raises the lactate threshold closer to the maximal workload and thus allows individuals to work at higher rates for longer periods. Thus, highly fit individuals can expend much greater amounts of energy per minute of exercise with less sense of discomfort than can obese, sedentary individuals who typically have low aerobic fitness and low lactate thresholds (sometimes on the order of 4 to 5 METs). The lactate threshold can be even lower in obese patients with type 2 diabetes, such that walking a mere 3 miles per hour can exceed their lactate threshold. Appreciating the physical limitations of patients, which can usually be overcome with a carefully designed training program, is necessary to provide realistic activity recommendations.

Exercise (fitness and sports-related activities) is commonly considered the main component of physical activity thermogenesis. Because most adults do not exercise at high levels or for a sufficient duration to expend a large amount of energy, focusing solely on "exercise" as the main component of physical activity will miss significant opportunities for improving energy balance. The benefits and energy costs of nonexercise activity can be far greater than the usual amount of exercise in which most patients can engage.

Nonexercise activity thermogenesis (NEAT) is the caloric expense of performing all activities other than exercise—employment-related and spontaneous activity. The range of observed NEAT under controlled (metabolic chamber) conditions has been from less than 100 to up to about 800 kcal/day. The energy expended from a physically demanding job or volitional exercise may or may not be offset by reductions in spontaneous (nonemployment) activity. For example, when young adult men and women take in extra exercise for more than 1 year, they respond differently: men lose weight and women do not, despite the absence of detectable change in food intake. This suggests either that woman reduce spontaneous activity in response to exercise and men do not or that subtle increases in food intake occur in women and not men. It has also been shown that unconscious increases in NEAT can serve to offset the tendency to gain weight in response to overeating. Low levels of NEAT have been reported to predict future weight gain in some populations, and there may be differences between lean and obese persons in the daily amount of NEAT, which could relate to differential tendencies to regulate weight.

Secondary Causes of Obesity

Medications

A growing number of medications cause weight gain in some or most of those patients for whom they are prescribed. Awareness of the medications that have this potential can facilitate weight loss treatment in some patients. Table 227-5 lists a number of medications that are associated with weight gain as well as alternative treatment approaches, if any, for the underlying condition.

Diseases

Less than 1% of obese patients have an underlying disease that can explain the development of their obesity. Endocrinopathies are the most common

TABLE 227-5 PHARMACOLOGIC INFLUENCES IN WEIGHT GAIN AND ALTERNATIVE THERAPIES

DRUGS THAT MAY PROMOTE WEIGHT GAIN	ALTERNATIVE TREATMENTS—WEIGHT NEUTRAL OR WEIGHT LOSS
PSYCHIATRIC AND NEUROLOGIC MEDICATIONS Antipsychotics: olanzapine, clozapine, respiridone, quetiapine, aripiprazole Antidepressants Tricyclics: imipramine, amitriptyline Triazolopyridines: trazodone Serotonin reuptake inhibitors: paroxetine, fluoxetine, citalopram Tetracyclics: mirtazapine Monamine oxidase inhibitors Antiepileptic drugs: gabapentin (higher doses), valproic acid, carbamazepine, divalproex Mood stabilizers: lithium, carbamazepine, lamotrigine, gabapentin (higher doses)	**ALTERNATIVE PSYCHIATRIC AND NEUROLOGIC MEDICATIONS** Ziprasidone Nortriptyline, bupropion, nefazodone, fluvoxamine, sertraline, duloxetine Topiramate, zonisamide (weight loss), lamotrigine (less weight gain)
STEROID HORMONES Progestational steroids Corticosteroids Hormonal contraceptives	**ALTERNATIVES TO STEROID HORMONES** Barrier methods, IUD Nonsteroidal anti-inflammatory drugs
ANTIDIABETES AGENTS Insulin (most forms) Sulfonylureas Thiazolidinediones	**ALTERNATIVE ANTIDIABETES AGENTS** Metformin Acarbose, miglitol Exenatide DPP-4 inhibitors
ANTIHISTAMINES Commonly reported with older agents; also oxatomide, loratadine and azelastine	**DECONGESTANTS, MAST CELL STABILIZERS, ANTAGONISTS OF ENDOGENOUS MEDIATORS OF INFLAMMATION**
ANTIHYPERTENSIVE AGENTS α-Adrenergic and β-adrenergic receptor blockers Calcium channel blockers: nisoldipine	**ALTERNATIVE ANTIHYPERTENSIVE AGENTS** Angiotensin-converting enzyme inhibitors, Calcium channel blockers—most other agents Angiotensin receptor blockers Diuretics
HIGHLY ACTIVE ANTIRETROVIRAL THERAPY	

secondary cause of obesity. These include Cushing's syndrome (Chapter 234), hypothalamic damage resulting in overeating (most commonly after pituitary surgery), insulinoma (Chapter 238), and hypothyroidism (Chapter 233). A Cushing's syndrome–like fat distribution is common; therefore, other physical or laboratory findings are the best clues to whether to test for this condition. These include the classic purple striae, thinning skin, easy bruising, proximal muscle weakness, and electrolyte abnormalities. Correction of Cushing's syndrome commonly results in substantial loss of excess body fat. Insulinoma is a rare tumor, and a small portion of patients with insulinoma develop obesity; only some patients consciously prevent spells by eating more often, and thus become obese. The weight gain associated with hypothyroidism is largely due to fluid retention and resolves dramatically with thyroid hormone replacement. Unfortunately, successful treatment is not available for hyperphagia due to hypothalamic damage. Occasionally, adult patients with growth hormone deficiency, most commonly following hypophysectomy, lose excess body fat with growth hormone replacement therapy.

Psychosocial Aspects of Obesity

Sexual, physical, and emotional abuse, especially in women, can result in long-term adverse consequences that include obesity. The effects of the abuse tend to be most profound if it occurs in childhood and adolescence. These women may be severely obese, suffer from chronic depression, and experience a number of psychosomatic symptoms, particularly chronic gastrointestinal distress. Identifying these issues before initiation of weight loss programs is important because successful weight loss may actually aggravate the distress experienced by these women. In addition, appropriate referral for psychiatric help may be needed before initiation of treatment for obesity.

PATHOPHYSIOLOGY

Metabolic Complications of Obesity

A central or upper body fat distribution, more so than total fat mass, is predictive of the metabolic complications of obesity. Adipose tissue release of free fatty acids (FFAs) and glycerol into the circulation through lipolysis provides 50 to 100% of daily energy needs. Adipose tissue lipolysis is regulated primarily by insulin (inhibition) and catecholamines (stimulation), although growth hormone and cortisol also stimulate lipolysis. Upper body obesity is associated with several abnormalities of adipose tissue lipolysis, most remarkably with higher FFA concentrations due to excess release postprandially. Abnormally high FFA concentrations can contribute to a number of the metabolic complications of obesity.

Insulin Resistance

The term *insulin resistance* is typically used when referring to the ability of insulin to promote glucose uptake, oxidation, and storage as well as to inhibit the release of glucose into the circulation. The primary site of insulin-stimulated glucose uptake, oxidation, and storage is skeletal muscle. The principal site of glucose production is the liver. Insulin resistance initially leads to hyperinsulinemia and may eventually lead to the development of type 2 diabetes mellitus (Chapter 237).

The ability of insulin to promote glucose uptake, oxidation, and storage in muscle and to suppress plasma FFA concentrations is reduced in upper body obesity. High plasma FFA concentrations can induce a state of insulin resistance both in the muscle (glucose uptake) and in the liver (glucose release), independent of obesity. Thus, abnormal regulation of adipose tissue FFA export is a major component of the development of insulin resistance.

Dysregulated production of a number of adipose-derived hormones, also called adipokines, is hypothesized to contribute to insulin resistance and the metabolic complications of obesity. For example, reduced secretion of adiponectin, an adipocyte-derived hormone that improves insulin action, is seen in obesity and diabetes. Increased production of resistin, interleukin-6, tumor necrosis factor-α, and retinol-binding protein-4 by adipose tissue has been linked to insulin resistance in animal models. Visfatin is another adipocyte hormone that is secreted preferentially by omental and mesenteric adipocytes and appears to function to increase insulin action, albeit through a different mechanism than adiponectin. To date, there is insufficient experimental evidence from human studies to know what role adipokines play in the metabolic complications of obesity.

Islet Cell Failure and Type 2 Diabetes Mellitus

Type 2 diabetes is generally the result of defects in both insulin secretion and insulin action (Chapter 237). Many obese individuals are insulin resistant, yet only a subset will develop diabetes mellitus. It follows that those who develop type 2 diabetes develop pancreatic β-cell decompensation with subsequent hyperglycemia. Animal (rodent) studies have suggested that a process referred to as lipotoxicity is involved in pancreatic β-cell failure. In this model, increased FFAs are proposed to contribute to the insulin secretory abnormalities seen in obesity and ultimately lead to β-cell failure. A small number of studies have suggested that FFAs have adverse effects on islet β-cell function in humans. Another explanation for the development of β-cell failure in obesity is the overproduction of islet amyloid polypeptide. This protein is co-secreted with insulin and, because of its tertiary structure, can form toxic

amyloid deposits in β cells. Amyloid deposits have been found in the pancreatic islets obtained at autopsy from patients with type 2 diabetes mellitus.

Hypertension

Blood pressure can be increased by a number of mechanisms (Chapter 67). Increased circulating blood volume, abnormal vasoconstriction, decreased vascular relaxation, and increased cardiac output may all contribute to hypertension in obesity. The effect of hyperinsulinemia to increase renal sodium absorption may contribute to hypertension through increased circulating blood volume. Abnormalities of vascular resistance also contribute to the pathophysiology of obesity-related hypertension. Under some experimental conditions, elevated FFAs have been found to cause increased vasoconstriction and reduced nitric oxide–mediated vasorelaxation, similar to that seen in the metabolic syndrome. Some obese adults have increased sympathetic nervous system activity, which could contribute to obesity-associated hypertension. Finally, angiotensinogen (also produced by adipocytes) is a precursor of the vasoconstrictor angiotensin II and is proposed to contribute to elevated blood pressure.

Dyslipidemia

Upper body obesity and type 2 diabetes mellitus are associated with increased triglycerides, decreased high-density lipoprotein (HDL) cholesterol, and a high proportion of small, dense low-density lipoprotein (LDL) particles (Chapter 213). This dyslipidemia contributes to the increased cardiovascular risk observed in the metabolic syndrome. Fasting hypertriglyceridemia is caused by increased hepatic very low density lipoprotein (VLDL) secretion, which may be driven by increased delivery of FFAs to the liver coming from both visceral fat and upper body subcutaneous fat. The reduced HDL cholesterol concentrations and the increased small, dense LDL particle concentrations associated with upper body obesity are likely an indirect consequence of elevated triglyceride-rich VLDL. Increased cholesterol ester transfer protein activity and hepatic lipase activity can theoretically account for the atherogenic shifts in triglycerides and cholesterol between lipoproteins. Genetic influences play a significant role in the expression of these lipid abnormalities. Polymorphisms in the genes for apolipoprotein E, lipoprotein lipase, apolipoprotein B-100, and apolipoprotein A-II are correlated with increased triglycerides and decreased HDL.

Endocrine Manifestations of Obesity

Obesity is associated with abnormalities of the endocrine system. One of the most common abnormalities is polycystic ovarian syndrome (PCOS). This syndrome is characterized by mild hirsutism and irregular menses or amenorrhea with anovulatory cycles. It is most commonly linked with obesity and often improves with weight loss and other treatments that improve insulin resistance. Thus, it is thought that the insulin resistance associated with obesity may trigger the development of PCOS in susceptible individuals. Whereas mild to moderate androgen overproduction is a feature of upper body obesity in women, obese men may suffer from mild to severe hypothalamic hypogonadism. This androgen deficiency improves with weight loss and does not appear to benefit substantially from testosterone replacement. There has been some concern that testosterone treatment of obese men may increase the risk of obstructive sleep apnea. Although estrogens are not elevated in obese premenopausal women, they remain somewhat above postmenopausal levels in obese postmenopausal women. Serum growth hormone concentrations are commonly low in obese adults, but insulin-like growth factor-I concentrations are often normal, and growth hormone concentrations increase with weight loss. Treatment of these patients with growth hormone has been reported to worsen insulin resistance and glucose intolerance and cannot be justified considering the costs and poor risk-to-benefit ratio.

Mechanical Complications of Obesity

The excess body weight associated with obesity is thought to be responsible for the increased prevalence of lower extremity degenerative joint disease. Extreme obesity can result in premature degenerative joint disease, and this may be especially difficult to treat surgically given the greater stress on joint replacements. Severely obese individuals may also have problems with venous stasis, which is occasionally aggravated by right heart failure (see later).

Obstructive Sleep Apnea

Sleep apnea (Chapter 100) is common in severely obese patients, tending to be more prevalent in men and in women with an upper body obese phenotype. Sleep apnea is most likely explained by enlargement of upper airways soft tissue, resulting in collapse of the upper airways with inspiration during sleep. The obstruction leads to apneas, with hypoxemia, hypercarbia, and high catecholamine and endothelin levels. The frequent arousals to restore breathing result in poor sleep quality. Sleep apnea is associated with an increased risk of hypertension, and if sleep apnea is severe, it can lead to right heart failure and sudden death. A history of daytime hypersomnolence, loud snoring, restless sleep, or morning headaches is suggestive of obstructive sleep apnea. Treatment of sleep apnea is important to improve cardiovascular risk, and the failure to recognize and treat this complication may make weight loss intervention strategies much less successful.

Cancer

The risk of breast cancer and endometrial cancer is increased in obese women (Chapter 183). It is thought that this may be due to the increased estrogen levels associated with obesity in the postmenopausal women. Obese men also have a higher mortality of cancers of the prostate and colon. The reasons for this association are unknown.

Gastrointestinal Disorders

Gastroesophageal reflux disease and gallstones are more prevalent in obese patients. Likewise, fatty liver and nonalcoholic steatohepatitis (Chapter 155) is more common in obesity. Nonalcoholic steatohepatitis can eventually progress to life-threatening hepatic cirrhosis. Weight loss and interventions that improve insulin sensitivity have been shown to improve fatty liver and nonalcoholic steatohepatitis.

DIAGNOSIS

Evaluation of Obesity

In the office practice, obtaining an accurate height and weight allows calculation of BMI, and under some circumstances, measurement of the patient's waist circumference can be useful in assessing risk (see earlier). Accurate measure of blood pressure, which may require a large blood pressure cuff, is important. The presence or absence of dyslipidemia (HDL cholesterol < 45 mg/dL for women, HDL cholesterol < 35 mg/dL for men, or triglycerides > 150 mg/dL), hypertension, glucose intolerance and diabetes, and hyperuricemia should be documented. A history suggestive of sleep apnea should prompt a referral for overnight oximetry or a sleep disorder evaluation.

A review of the patient's lifestyle, including an assessment of physical activity level and eating habits, may help provide information about why the patient is obese. A family history of obesity, or long-standing obesity, provides evidence against a secondary cause of obesity. A careful medication history and social history may help the clinician identify precipitating factors that can be modified.

Before entering a weight management program, it is important to ensure the patient is interested and ready to make lifestyle changes and has realistic goals and expectations. Often patients expect to lose large amounts of weight in short periods of time. Medical treatment programs, even if they include pharmacotherapy, seldom result in greater than 10% weight loss. This degree of weight loss is sufficient to reduce markedly the medical complications of obesity, but disappointment with "only" 10% weight loss may cause patients to quit a medically successful program. Helping the patient to realize and accept that 10% weight loss is a reasonable, initial goal can be one of the more challenging aspects for a physician.

It is sometimes necessary to delay entry into treatment programs if a patient is not ready to make lifestyle changes. In this case, a reasonable strategy is to remind the patient periodically of the potential health benefits of improved activity and eating habits. Once a willingness to make changes is apparent, treatment is more likely to succeed.

TREATMENT Rx

Obesity represents an individual's response to the environment based on genetics and learned behavior and is best viewed as a chronic disease. Therefore, treatment must be considered a long-term issue, much like diabetes, hypertension, or dyslipidemia. Substantial weight loss can be induced through severe caloric restriction, but without approaches to ensure behavioral changes, body fat is invariably regained. To the extent that environmental factors contribute to a patient's overweight status, and to the extent that the macroenvironment is unlikely to change, patients must learn how to make permanent lifestyle changes (eating and activity behavior) in order to hope for permanent weight loss. Behavior modification approaches often seek to help patients recognize and circumvent environmental cues for sedentary behavior and overeating as a means to accomplish these lifestyle changes.

Reducing energy intake is the most efficient and effective means to lose weight. For example, creating a 500 kcal/day deficit by reduced food intake can allow the loss of 1 pound of fat per week. Although possible, it is much more difficult to increase energy expenditure by 500 kcal/week through exercise. Higher levels of physical activity can prevent weight gain (or weight regain after weight loss). Some patients are able to change eating and activity habits on their own given the proper information, whereas others require formal or informal behavior modification interventions (see later) to help make these changes. In some instances, pharmacotherapy or surgery may be needed for treatment of obesity. A flow diagram on how to evaluate and manage patients with overweight and obesity is presented in Figure 227-1.

Diet

Changes in eating habits must be permanent if weight loss is to be maintained. An experienced registered dietitian can be helpful in the evaluation of a patient's eating habits and will be able to provide the needed education. The diet history may identify eating behaviors that result in excess energy intake. Although it is important to address specific adverse eating behaviors, patients need to understand some general principles regarding diet. Reducing the energy density of food (most commonly accomplished by reducing dietary fat) can allow patients to feel satiated while consuming fewer calories. A common mistake, however, is for patients to consume large quantities of easy-to-eat "nonfat" foods, thereby offsetting the expected benefits of the diet. In addition to reducing the intake of high-fat foods, patients should understand that increasing the consumption of foods high in water and fiber (fruits, vegetables, legumes, and soups) can provide satiety without excess calories. It is also important to avoid the excess intake of beverages containing substantial calories with little or no satiety. Finally, a regular pattern of eating should be encouraged.

New, fad diets are continuously being promoted with the promise of easy weight loss. A common feature of these diets is the claim that special properties of certain foods help people lose weight or are the cause of obesity. If followed, most of these diets result in weight loss because of a reduced energy intake. The reduced intake can be related to the monotony of the diet, and there have been no diets identified that cause persons to lose weight not in accordance with physiologic principles. No published data exist to support the use of fad diets in the long-term treatment of obesity. Recent studies have shown that many types of diets are able to help patients achieve long-term, medically significant weight loss. Thus, it may be less important what specific type of diet (DASH diet, Mediterranean diet, high-carbohydrate/low-fat or high-fat/low-carbohydrate diet) is recommended than for the patient to find it relatively easy to adhere to the diet.

Very low calorie diets (<800 calories per day) have been used for years to achieve accelerated weight loss. The rationale for this approach is now in question, given that the long-term results of these diets is no better and sometimes worse than the results from the standard low-calorie diet combined with behavior modification. The expensive laboratory monitoring required for very low calorie diets without an improved long-term outcome raises questions about the costs versus benefits of this approach.

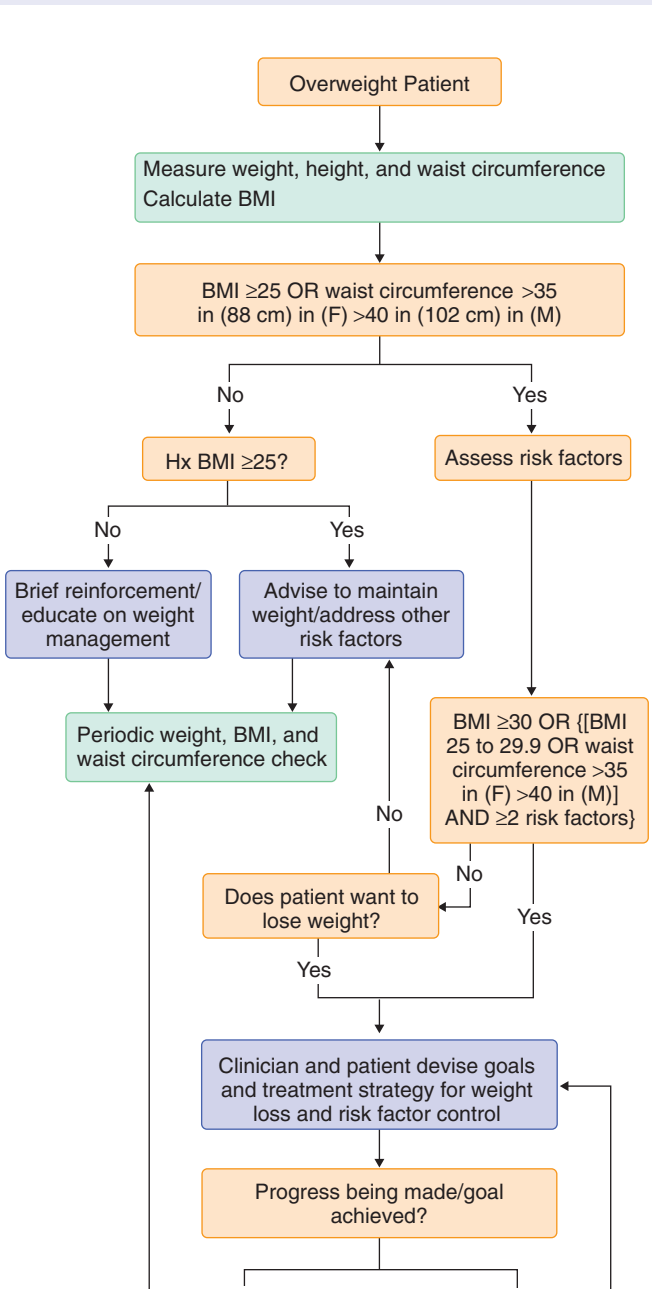

FIGURE 227-1. Flow diagram for the evaluation and management of overweight and obesity. BMI = body mass index. (Adapted from NIH/NHLBI. Clinical guidelines on the identification, evaluation and treatment of obesity in adults: the evidence report. *Obes Res.* 1998;6:51S-209S.)

Physical Activity

A long-term increase in physical activity, either through the activities of daily living or through regular exercise, is key to preventing weight regain, thereby increasing the amount of successful, long-term weight loss. Unfortunately, many overweight and obese patients are quite unfit, being unable to walk even 1 mile continuously. It is not possible for most adults to burn large numbers of calories. For example, only about 100 kcal are expended by a 70-kg adult walking 1 mile. Losing weight solely by increasing exercise is impractical for most patients. However, increasing physical activity as a means of maintaining weight loss is an attainable goal for most patients.

Successful maintenance of weight loss requires that daily energy expenditure be an average of 80 to 90% above RMR. This is a considerable increase for most patients. For example, someone with an RMR of 1500 kcal/day would need to expend about 1000 kcal/day in physical activity to meet this target. Activities other than "exercise" are important means to achieve this goal. The most commonly applicable approach is by increasing the amount of walking done throughout the day.

There are important health benefits from regular physical activity over and above the effects on weight. These include lower cardiovascular and all-cause mortality, independent of weight. The options for increasing physical activity include exercise (sports or fitness pursuits) or using lifestyle approaches. Both methods can improve fitness and allow weight stability; however, persuading obese patients to become more active is not easy. Physicians can begin by asking patients about their current and past activity habits as well as what barriers they see to increasing physical activity. This accomplishes the goal of stimulating patients to think about the issue in a tactful manner. It can help to ask the patient what personal benefits they envision as a result of increasing their level of activity. If patients agree to begin an exercise or physical activity program, they will need to monitor their activity and set realistic goals for the amount of exercise they are going to achieve. The ready availability of step counters offers a practical means for patients to track physical activity throughout the day and to assess the effects of changes in lifestyle on their activity level. There are a variety of step counters available, and the accuracy of many is questionable. Before advising a specific type, it is important to examine the literature or look for data regarding accuracy. Self-monitoring of how many steps are taken each day for 1 to 2 weeks can give the patient a good sense of their level of activity. Many Americans take as few as 4000 to 5000 steps per day, whereas it may take as many as 15,000 to 17,000 steps per day to help those who have lost significant amounts of weight to maintain that lower weight. Gradually increasing the number of steps regularly taken during the day through a series of changes in habits (e.g., parking further away, walking during work breaks) is more likely to result in long-term success for most persons than setting aside 2 hours or more for continuous walking.

Behavior Modification

Patients who are unable to make changes in eating activity habits on their own or with informal office counseling may benefit from referral to a behavior

therapist. The goals are to help patients modify their eating, activity, and thinking habits that predispose to obesity and to focus on specific pathways to achieve the goals. These pathways may include identifying and removing barriers to developing better eating or activity habits. Small, incremental, and consistent changes in behavior are encouraged. Self-monitoring of food and activity is considered a key feature to success because most obese patients underestimate food intake and overestimate exercise. Cognitive restructuring has been introduced as a way to help overcome the thought processes that can lead to failure of a weight management program. Patients are taught to identify, challenge, and correct self-defeating thoughts.

Pharmacotherapy

A limited number of drugs are currently available to help patients with weight loss. The limited amounts of weight loss that most patients experience seems to have dampened the enthusiasm of many physicians to prescribe weight loss drugs, even under circumstances that justify their use. In addition, not all overweight or obese patients are candidates for pharmacologic treatment of obesity. Table 227-6 provides criteria that should help select patients for pharmacologic treatment. Because pharmacologic treatment of obesity exposes patients to some risks and expense, it is reasonable to require an objective benefit. A rational argument can be made that prioritization should be given to those with one or more medical complications or conditions that are likely to improve with weight loss. Numerous studies have shown that medications used alone are much less effective than when they are used as a part of a comprehensive program that includes diet, exercise, and behavior modification. When prescribing antiobesity medications, it is important to set clear goals with respect to both weight loss and health benefits.

Currently Available Medications

The medications currently available for long-term use act either through appetite reduction (phentermine) or through inhibition of pancreatic lipase (orlistat), which results in fat malabsorption. Phentermine is currently approved for short-term (3 months) use. Because weight that is lost with pharmacotherapy (especially when used without a comprehensive program) is quickly regained once the medication is discontinued, agents that are approved for long-term use (orlistat) are more rational therapeutic choices.

Orlistat at the typical dose of 120 mg three times daily with meals causes about 30% of dietary fat to be malabsorbed. As expected, adverse gastrointestinal side effects, such as oily spotting, abdominal pain, excess flatus, fecal urgency, and fatty or oily stools, are not uncommon. These side effects decrease over time, and the concomitant use of bulk-forming laxatives (e.g., psyllium, methylcellulose) can reduce these symptoms. A daily multivitamin is recommended for those on long-term orlistat therapy. It is not necessary to take orlistat if a nonfat meal is being consumed.

Orlistat is now available as an over-the-counter medication. Orlistat improves the results of medical treatment programs that include diet, exercise, and behavior modification, resulting in almost twice as many patients achieving goal weight loss (10% of body weight.)

Success of Medical Therapy

It has been estimated that more than 95% of those embarking on self-diets or fad diets fail to maintain a significant weight loss for a period of time that would have meaningful health benefits. The published results of commercial programs are not impressively better, mostly because of high dropout rates. In contrast, organized, scientifically based weight management programs that employ behavior modification in addition to dietary instruction, physical activity, and medications (when indicated) can achieve impressive results. Although these programs tend to be more selective (accepting only motivated patients), the dropout rates can be acceptable (<30%), and of those remaining in the program, weight loss of more than 10% can be achieved and maintained for more than 1 to 2 years in 40 to 60% of patients. These results are more impressive than those reported with older, less comprehensive programs, wherein almost all patients regained all weight in less than 6 months.

TABLE 227-6 INDICATIONS FOR PHARMACOLOGIC TREATMENT OF OBESITY

Body mass index > 27 kg/m^2
One or more complications or conditions that are likely to improve with weight loss
Previous failure of conservative treatment with diet and exercise
Agree to 2- to 4-wk trial of making initial changes in diet and exercise before starting pharmacotherapy
Agree to continued treatment with diet, exercise, and behavioral modification while on pharmacologic treatment
Agree to periodic follow-up
Premenopausal women (able to have children) must use some form of contraception
Consider a pregnancy test when initiating treatment if any possibility of pregnancy
No contraindications to the specific drug used for pharmacologic treatment

Bariatric Surgery

Surgical treatment may be indicated for severely obese patients with severe medical complications that could be expected to improve with successful weight loss. Patients with a BMI of 35 to 40 with life-threatening complications can be considered, but more typically patients with a BMI of greater than 40 and several complications are candidates for surgery, assuming past attempts at medical treatment have failed. Because the risks and costs of surgical treatment are greater than for medical treatment, it is reasonable practice to select patients who stand to obtain more potential benefit from surgery. Contraindications to surgery include active substance abuse, defined noncompliance or inability to comply with medical care, and certain psychiatric disorders (schizophrenia, borderline personality disorder, uncontrolled depression).

A multidisciplinary team, including a physician, dietitian, psychologist or psychiatrist with expertise in this area, and surgeon experienced in bariatric procedures, is important for optimal outcome. Defining realistic expectations is an important part of the evaluation process. Patients undergoing bariatric surgery are not likely to be reduced to their ideal body weight. Successful weight loss is typically defined as losing an average of 50 to 60% of excess body weight. For example, if someone is 100 kg *overweight,* a reasonable definition of success is to lose 50 kg. Follow-up to support the necessary changes in long-term behavior is recommended to optimize weight loss outcomes.

A variety of bariatric surgical procedures have been used. The jejunoileal bypass has been abandoned for decades because of delayed, severe complications, including liver failure, renal failure, and arthropathy. If these complications are identified before end-stage organ failure, reversal of the procedure can improve or stabilize organ function. Several procedures that modify the capacity of the stomach (gastroplasty, vertical stapling, vertical banded gastroplasty, gastric sleeve and gastric banding), but do not create malabsorption of nutrients, are employed, but these are generally less effective than the Roux-en-Y gastric bypass in terms of long-term weight loss and outright surgical failure. The partial pancreaticobiliary bypass, the very long limb Roux-en-Y gastric bypass, and the duodenal switch procedures have become popular because they create a degree of malabsorption that results in greater weight loss that the standard Roux-en-Y gastric bypass. Unfortunately, the incidence of severe, even fatal vitamin and mineral deficiencies is much higher with these procedures. The laparoscopic approach has allowed the time of hospitalization to be reduced considerably and with lesser rates of incisional hernias compared with open procedures.

Following surgery, almost all of the weight loss that occurs will happen during the first 1 to 2 years. Long-term (>5 year) success rates are outstanding in good programs. Virtually all patients with successful weight loss will have a dramatic improvement in the medical complications of obesity. For these reasons, bariatric surgery has become an important tool in the treatment of severe, medically complicated obesity.

The results of the Roux-en-Y gastric bypass for treatment of morbid obesity have been very favorable. Approximately 70% of patients achieve success as defined previously with this procedure. The mortality and morbidity (e.g., infection, anastomotic leak, wound dehiscence) of this procedure are low in centers with expertise, despite the high-risk population. Laparoscopic gastric banding is becoming more popular. Following any of the malabsorptive procedures, the patients deserve permanent follow-up specifically for adverse nutritional consequences.

The long-term follow-up of patients who have undergone gastric bypass surgery is needed to ensure adequate protein, calorie, vitamin, and mineral nutrition. Supplemental vitamin B_{12}, iron, and calcium are routinely added to standard multivitamins. The most common nutritional consequences of malabsorptive procedures are disorders of calcium and vitamin D metabolism (Chapter 252). An increase in bone alkaline phosphatase may signal calcium or vitamin D deficiency. Low plasma vitamin D levels and low urinary calcium excretion should prompt aggressive replacement therapy. Iron deficiency, other fat-soluble vitamin deficiencies, and cases of copper deficiency occurring more than 5 to 10 years after surgery have been described. There have also been cases of pancreatogenous hypoglycemia that develop after bariatric surgical procedures. The symptoms are primarily postprandial and may be severe enough to warrant partial pancreatectomy. Findings at the time of surgery in these cases have ranged from islet hyperplasia and hypertrophy to multiple small insulinomas. Thus, it is important not to dismiss symptoms of postprandial cognitive dysfunction in patients who have undergone gastric bypass surgery.

PREVENTION

The dramatic increase in the prevalence of obesity over the past few decades strongly suggests that preventive strategies are needed. Public health approaches that emphasize education have been almost uniformly unsuccessful at preventing weight gain or producing weight loss. Public health strategies that virtually impose behavior change are more successful in this regard. Unless widespread efforts are made to address the problem of obesity, it is

likely that its prevalence and complications will become an ever-increasing health burden.

APPROACH TO THE PATIENT WITH ENDOCRINE DISEASE

DAVID R. CLEMMONS

Most endocrine disorders are due to either an excess or a deficiency of a hormone that is transported in the systemic circulation and therefore result in multiorgan manifestations. It is unusual for patients to present with a single isolated set of symptoms that are referable to only one organ system. Additionally, generalized nonspecific symptoms such as weakness, difficulty concentrating, lack of energy, and change in appetite occur commonly in patients with endocrine disorders. Often, a constellation of symptoms is required to point the clinician in the direction of the correct diagnosis, and single symptoms evaluated in isolation are rarely helpful even if one considers an exhaustive differential diagnosis (Table 228-1). Another important feature of the evaluation of patients presenting with endocrinologic disease is obtaining a good longitudinal history. The duration of exposure to a hormone excess or deficiency often dictates the severity of symptoms, and characterizing the symptomatic changes that occur over time can be very helpful in both selecting the tests to confirm the diagnosis and either substantiating the need for treatment or selecting the correct mode of treatment. Physical examination is helpful for confirming the likelihood of a diagnosis; for example, the presence of a symmetrically enlarged thyroid gland indicates that Graves' disease is the most likely cause of hyperthyroidism. However, because of the accuracy and precision of modern endocrinologic testing, endocrine disorders sometimes are diagnosed in the absence of symptoms or signs of overt disease (e.g., hyperparathyroidism). In such instances, a thorough history and physical examination are still important because they establish that the patient is truly in the asymptomatic phase of the disease, and this is often helpful in determining whether therapy or observation is required. A careful temporal history of a symptomatic change may also be helpful in the differential diagnosis, for example, in ascertaining whether a thyroid mass is likely due to a hemorrhagic cyst (i.e., occurring suddenly) or is a thyroid adenoma that might have evolved over an extended period. A thorough general history and physical examination may help to establish the diagnosis of diseases that are associated with endocrinologic abnormalities, such as cancers that ectopically secrete hormones, or may help to exclude the likelihood of an endocrinologic etiology of a specific disease manifestation.

Precise genetic testing to establish the etiology of endocrinologic syndromes is becoming more prevalent; therefore, an accurate family history can be useful in determining the need for genetic testing and familial screening. A thorough evaluation of medication use is also mandatory. Some medications can clearly mask the symptoms of overt endocrine disease, such as β-blockers in hyperthyroidism, and others can exacerbate the findings, such as hydrochlorothiazide use in hyperparathyroidism. Often, specific medications will confound laboratory evaluation, such as diuretics in patients with hyperaldosteronism or antihypertensive drugs in patients being screened for pheochromocytoma. Appropriate withdrawal of the medication may be required to establish a firm diagnosis. Medications may also directly alter a laboratory test, such as use of oral contraceptives in attempting to diagnose hyperthyroidism or hypothyroidism. Finally, an accurate history of the specific complaint may be challenging. For example, in evaluating male sexual dysfunction, a corroborating history from the patient's partner is often necessary for verification.

COMMON SYMPTOMS OF ENDOCRINOLOGIC DISEASE

Generalized symptoms such as weakness and fatigue are prominent features of adrenal insufficiency, hyperthyroidism and hypothyroidism, hypopituitarism, and poorly controlled diabetes mellitus. Pain is an uncommon complaint in endocrinologic disorders and is usually only seen with acute endocrinologic emergencies, such as diabetic ketoacidosis or acute adrenal insufficiency (abdominal pain). Chronic pain seen in primary or secondary hyperparathyroidism due to bone reabsorption and in osteomalacia (Chapter 252) can occur in the shafts of the long bones. Symptoms of menstrual dysfunction are common in women with adrenal insufficiency, hypopituitarism, Cushing's syndrome, hyperprolactinemia, hyperthyroidism or hypothyroidism, and polycystic ovarian disease and primary ovarian failure. Weakness and easy fatigability can be secondary to anemia, which is common in adrenal insufficiency, androgen deficiency, hypothyroidism, hyperparathyroidism, and panhypopituitarism.

The most common endocrine-related symptom of intestinal dysfunction is constipation. This occurs frequently in patients with diabetic autonomic neuropathy and in hypercalcemia, hypothyroidism, or pheochromocytoma. Diarrhea can be an early and prominent symptom in hyperthyroidism and metastatic carcinoid tumors. Fever, like abdominal pain, usually only occurs in endocrine emergencies, typically in severe adrenal insufficiency and very severe hyperthyroidism. Generalized hair loss not related to androgen excess occurs in hypothyroidism, hypopituitarism, and thyrotoxicosis. Typical male-pattern baldness can be a feature of hirsutism in women as well as Cushing's syndrome and acromegaly. Persistent recurrent headaches are a feature of expanding pituitary tumors, whereas episodic headaches occur frequently in patients with pheochromocytoma and hypoglycemia. Changes in libido are often present in patients with hyperthyroidism, hypopituitarism, hypogonadism, Cushing's syndrome, and poorly controlled diabetes mellitus. Polyuria and nocturia are features of both diabetes insipidus and diabetes mellitus and can also occur in severe hypercalcemia.

Weight gain is an early symptom of Cushing's syndrome and hypothyroidism. Weight loss accompanied by anorexia is common in adrenal insufficiency in metastatic hormone-producing tumors such as ectopic adrenocorticotropic (ACTH) hormone syndrome, type 1 diabetes mellitus, and panhypopituitarism. Weight loss with no change or an increase in appetite is common in hyperthyroidism (see Table 228-1). An important differential diagnostic issue in patients with weight loss is depression. Depression can occur concomitantly in patients with adrenal insufficiency, Cushing's syndrome, hypercalcemia, and hypothyroidism.

An important neuropsychiatric symptom is widening of mood swings, that is, an exaggeration of normal cyclothymic changes. This occurs in hyperthyroidism and Cushing's syndrome. A history of skin changes occurs with several endocrine disorders. Acanthosis nigricans occurs with severe obesity, polycystic ovarian disease, severe insulin resistance syndromes, Cushing's syndrome, and acromegaly. Acne is a symptom of androgen excess and occurs with androgen-producing tumors, polycystic ovarian disease, and Cushing's syndrome. Generalized hyperpigmentation occurs in Addison's disease and Nelson's syndrome. Dry skin is present in almost all patients with hypothyroidism. It also occurs in panhypopituitarism. In Cushing's syndrome, skin changes such as striae, plethora, and easy bruisability are common. Vitiligo occurs in association with several endocrine autoimmune diseases, most prominently with autoimmune thyroid disease and Addison's disease.

Assessment of any of these symptoms in isolation is unlikely to lead a clinician to the correct diagnosis. However, assessment of combinations of these symptoms (e.g., the combination of weight gain, constipation, cold intolerance, and dry skin in hypothyroidism) is likely to lead to the correct set of diagnostic decisions.

PHYSICAL EXAMINATION

Physical examination of a patient with a suspected endocrine disorder is extremely helpful in terms of confirming the significance of findings that were ascertained by a careful medical history (Table 228-2). Examination of the skin is important because endocrinopathies lead to skin changes that progress over time. These often occur early in the course of the illness and can be a major aid in making the correct diagnosis. Primary adrenal failure is usually accompanied by increased skin pigmentation, particularly over the creases of the palms and extensor surfaces. The oral mucosa is often hyperpigmented, which can be helpful in African Americans. Patients with Cushing's syndrome present with persistent facial plethora, acne, and characteristic striae, which are generally larger than 1 cm and exhibit a dark red to purplish hue. These are most common over the abdomen. The presence of axillary purpura is also suggestive of Cushing's syndrome and results from increased capillary fragility. Patients with acromegaly often present with excessive skin tags that increase in number over time and multiple types of benign skin tumors such as dermatofibromas and lipomas. The skin is also much thicker over the dorsum of the hand, and the amount of subcutaneous tissue in the palms is prominent. Patients with Cushing's syndrome have thinning of the skin over the forehead and around the eyes. Patients with hypothyroidism often present with evidence of hyperkeratosis, particularly over the extensor surfaces. Severe long-standing thyroid disease is also accompanied by myxedema of

TABLE 228-1 SYMPTOM CONSTELLATIONS SUGGESTING SPECIFIC ENDOCRINE DISORDERS

SYMPTOM CONSTELLATION	DIAGNOSIS
Weakness, fatigue, anorexia, loss of appetite, postural blood pressure changes	Adrenal insufficiency
Cold intolerance, dry skin, constipation, weight gain	Hypothyroidism
Fatigue, easy bruising, striae, proximal muscle weakness, central obesity, hypertension, acne	Cushing's syndrome
Weight loss, increased appetite, palpitations, tremor, emotional lability, diffuse hair thinning	Hyperthyroidism
Galactorrhea, amenorrhea, headaches	Prolactin-producing pituitary tumor
Weight loss, anorexia, loss of pubic and axillary hair	Hypopituitarism
Episodic palpitations, tremor, anxiety, headaches, sweating, weight loss	Pheochromocytoma
Episodic flushing, palpitations, abdominal cramping, and diarrhea	Carcinoid syndrome

TABLE 228-2 PHYSICAL SIGNS THAT SUGGEST SPECIFIC ENDOCRINE DISORDERS

1. Hyperpigmentation of palms, extensor surfaces, and buccal mucosa	Adrenal insufficiency
2. Facial plethora, moon facies, striae, purpura	Cushing's syndrome
3. Skin tags, acral enlargement, prognathism, orthodontia	Acromegaly
4. Proptosis, lid lag, symmetrically diffuse thyroid enlargement, hyperreflexia	Graves' disease
5. Retinal microaneurysms, macular edema	Diabetic retinopathy
6. Short stature, web neck, loss of tears	Turner's syndrome
7. Shield-like chest, short fourth vertebra	Primary ovarian failure

the extremities, a specific skin finding of thickening of both the dermis and epidermis due to mucopolysaccharide accumulation. In contrast, patients with Graves' disease present with thinning of the skin, but more prominently with skin that is moist and warm. Both adrenal insufficiency and hyperthyroidism or hypothyroidism can be associated with vitiligo. The nails in hyperthyroidism reveal onycholysis in cases of longer duration. Hair changes occur commonly with several endocrinopathies. In hypothyroidism, the hair becomes coarse, whereas in hyperthyroidism, diffuse thinning occurs. Longstanding hypothyroidism can be accompanied by loss of the lateral third of the eyebrow hair. Hirsutism with hair growth over the areolae and along the linea alba is present in patients with gonadal dysfunction or with hyperandrogenism due to polycystic ovarian disease or androgen-producing tumors. In contrast, patients with hypopituitarism or hypogonadism often present with loss of pubic and axillary hair.

The eye examination can be helpful in establishing the diagnosis of hyperthyroidism. Graves' ophthalmopathy occurs in 40% of patients and presents with exophthalmos that can be unilateral. Extraocular movement assessment is important in patients with pituitary tumors because local expansion of these tumors can lead to third, fourth, or sixth nerve palsies, whereas compression of the optic tracts can cause the distinctive visual field defect of bitemporal hemianopsia. On neck examination, ascertainment of whether a goiter is smooth, symmetrical, and multinodular or a single nodule can be helpful in guiding further work-up in the evaluation of hyperthyroidism.

Cardiovascular evaluation is helpful for evaluating the severity and duration of endocrine illness. Patients with hyperthyroidism have evidence of increased sympathomimetic activity, including tachycardia, a widened pulse pressure, and prominent precordial activity. Flow murmurs may be heard as a result of increased cardiac output, and occasionally a bruit is easily heard on auscultation of the thyroid. In patients with hypothyroidism and Addison's disease, these findings are reversed. Specific cardiac abnormalities, such as coarctation of the aorta, may be present in patients with primary ovarian failure due to Turner's syndrome. Patients with pheochromocytoma often have a postural blood pressure change of greater than 20 mm Hg. Cardiomyopathy can be a feature of acromegaly. Hypertension is common in many endocrine disorders, including hypercalcemia, hyperparathyroidism, acromegaly, diabetes mellitus, obesity, Cushing's syndrome, primary aldosteronism, and pheochromocytoma.

Nearly all patients with acromegaly demonstrate evidence of hand and foot enlargement, a very unusual occurrence in adulthood. This often manifests as a history of changing ring size or shoe size and is easily demonstrable on physical examination. Patients with hyperthyroidism often have a significant hand tremor and evidence of peripheral bruits on auscultation. Evaluation of the extremities is also helpful in the differential diagnosis of metabolic bone disease. The presence of bowing of the legs can be found in either dietary or X-linked hypophosphatemic rickets. The presence of edema is usually an early sign of disorders of hormone-producing tumors that result in salt retention, including Cushing's syndrome and hyperaldosteronism. Measurement of upper to lower segment ratios and span is helpful in establishing the timing and onset of puberty in primary gonadal disorders.

Pelvic examination is a major aid to the differential diagnosis of ovarian disorders. The presence of polycystic ovaries can sometimes be determined by palpation as well as the absence of ovarian tissue. The absence of a uterus is important in the differential diagnosis of pseudohermaphroditism, and the evaluation of external genitalia can be important in establishing the presence of congenital adrenal hyperplasia. Vaginal dryness is a sign of severe estrogen deficiency, as is breast atrophy. Hyperprolactinemia often first manifests as the presence of expressible galactorrhea.

Neurologic changes can occur in a variety of diseases. Evaluation of the ability to detect monofilament or vibratory sensation is an important tool for evaluating the presence of diabetic neuropathy. The presence of peripheral motor nerve defects in diabetes is also an important presenting sign, as is the presence of a cranial nerve palsy, such as third nerve palsy. Funduscopic examination can reveal microaneurysms, even in patients with undiagnosed type 2 diabetes, and this can be helpful for estimating antecedent duration of illness. Hyporeflexia with a delayed relaxation phase is one of the earliest physical changes in hypothyroidism and is prominent in most patients with clinically significant disease; hyperreflexia occurs in hyperthyroidism. Patients with Cushing's syndrome often have extreme proximal muscle weakness, and this occurs in severe long-standing hyperthyroidism. Midgut carcinoids frequently present with severe flushing and diarrhea. The skin characteristically has an unusual purplish hue, and this change typically lasts for the duration of the episode, about 20 to 30 minutes. Mental status changes occur frequently in patients with Cushing's syndrome, hyperthyroidism, and extreme hypercalcemia.

LABORATORY EVALUATION

Patients with endocrinologic diseases are frequently diagnosed in an asymptomatic state as a result of abnormal radiologic evaluation or hormonal testing abnormalities.

The most common radiologic conundrums occur in patients who are noted incidentally to have small pituitary, thyroid, or adrenal masses. Although most of these patients generally do not have a hormonal dysfunction syndrome, proper evaluation to exclude the presence of a functionally active tumor is usually necessary. For pituitary tumors, the minimal evaluation would include measurements of a baseline serum prolactin level and, in cases with suggestive symptoms, of 24-hour urine free cortisol and of growth hormone after glucose suppression. In patients with incidentally found adrenal masses ("incidentalomas"), important findings are a large tumor mass (i.e., >4 cm), the hypertension or hypokalemia, and symptoms and signs of Cushing's syndrome. If any of these are present, appropriate evaluation to exclude hyperaldosteronism, Cushing's syndrome, and pheochromocytoma should be undertaken.

The sensitivity and specificity of hormonal testing have reached levels that have significantly changed the initial evaluation of patients for endocrine disorders. For example, screening of asymptomatic patients for thyroid disease, disorders of lipoprotein metabolism, and disorders of gonadal dysfunction are common and widespread.

Hormones are often measured using immunologic detection methods. Most measurements use blood or urine samples to detect the active hormone. Occasionally, measurement of a metabolite of the active hormone, such as 25-hydroxycholecalciferol (a vitamin D metabolite), is more reliable than that of the parent hormone. Some hormones (e.g., thyroxine) have a very long half-life in plasma, and therefore a measurement at any time of day reflects the ability of the gland to produce that hormone. However, other hormones (e.g., growth hormone) are secreted episodically, and therefore a static measurement may or may not be indicative of hormone excess or

deficiency. In these cases, suppression or stimulation testing is used to confirm the diagnosis. Usually, an exogenous substance (e.g., ACTH) is administered either orally or intravenously, and the production of the hormone (e.g., cortisol) by the gland is either stimulated or suppressed.

Many hormones are present in the circulation bound to binding proteins. With the exception of peptide hormones that circulate in the free (unbound) form, this can cause problems in interpretation: medications or concomitant illnesses can result in a major change in the concentration of the binding protein, which, in turn, alters the total hormone concentration. This problem can be obviated either by measuring the binding protein itself or by direct measurement of the free hormone, such as measurement of free thyroxine. Free hormone measurements, however, can be less reliable than total hormone measurements; therefore, a decision sometimes needs to be made wherein the reliability of the assay is compared with the quality of the information that will be provided.

Often, static hormone measurements are used for screening, for example, morning cortisol in screening for the presence of hypoadrenalism. Subsequently, stimulation or suppression testing is used for confirmation of the diagnosis. In some cases, plasma measurements are much less reliable than urinary testing (e.g., in ruling in or out the presence of pheochromocytoma). In these cases, 24-hour urinary measurement of hormone is often required to document overproduction or deficiency. Urinary assays have the advantage of providing integrative assessment over 24 hours and thus are less likely to be susceptible to errors due to episodic hormonal secretion over time. Occasionally, measurements of other substances, such as electrolytes or metabolites, are also informative for confirming the diagnosis. For example measurement of 24-hour urinary calcium can be important in the differential diagnosis of hypercalcemia. Metabolites in the urine may be extremely important in the evaluation of adrenal disorders and in documentation of pheochromocytoma and carcinoid syndrome. Simultaneous measurements of two substances is extremely helpful in the diagnosis of some disorders. Measurement of simultaneous serum calcium and parathyroid hormone (PTH) is important for confirming the presence of hyperparathyroidism. Likewise, simultaneous measurement of blood glucose and insulin can be important in screening for the presence of an insulin-producing tumor. Indirect measurement of hormonal status can also be important; for example, measurement of insulin-like growth factor-I, which is inducible by growth hormone (GH), provides an integrative measure of GH secretion. Similarly, measurement of hemoglobin A_{1c} provides an integrative measurement of long-term blood sugar control in diabetes.

Imaging studies are commonly used in endocrine diagnosis. Magnetic resonance imaging and computed tomography are helpful in evaluating pituitary and adrenal masses. Scanning of the thyroid gland using radioactive iodine is useful for evaluation of the functional status of thyroid nodules and the functional activity of the thyroid gland as a whole. Bone mineral density testing is now commonplace in screening of patients for osteoporosis and in the evaluation of patients with established fracture syndromes. Imaging can also be combined with hormonal measurements. Specifically, cannulation of the adrenal veins can be helpful in confirming the presence of functioning adrenal tumors such as aldosteronomas and pheochromocytomas. Likewise, determining the location of ectopically located tumors such as those producing ACTH can often be confirmed by venous sampling procedures. Similarly, intraoperative measurements of hormones that change rapidly, such as intraoperative PTH, can help determine whether surgical removal of the hormone-secreting tumor has been adequate. The primary use of biopsy in endocrinologic diagnosis is fine-needle aspiration of the thyroid gland. This procedure can be done safely in the outpatient setting, often aided by ultrasound guidance. It is a highly accurate method for determining whether further diagnostic evaluation or therapeutic intervention is necessary.

GENETIC EVALUATION

Use of genetic testing in endocrinologic diagnosis has become much more commonplace. Polymerase chain reaction amplification of DNA obtained from peripheral blood cells is often used to determine the presence of a specific disorder. This has been extremely useful in differential diagnosis, for determining prognosis, and for deciding whether family screening is required (e.g., in the presence of multiple endocrine neoplasia). Whether genetic testing is required is often dictated by whether this information is necessary to solve a differential diagnostic problem (e.g., disorders of vitamin D metabolism) or to decide whether more extensive surgery should be required (e.g., in pheochromocytoma) or whether family screening is necessary (e.g., in multiple endocrine neoplasia 2 syndrome).

EVALUATION OF THE RESPONSE OF AN ENDOCRINE DISEASE TO TREATMENT

Most hormone excess syndromes are treated surgically by removal of the particular endocrine gland that is oversecreting the hormone. However, follow-up of these patients mandates that (1) it be established that the disease has truly been cured by gland resection or (2) if residual disease is present, and (3) determining whether repeat operation is likely to be of benefit to the patient or some other means of treating the patient should be undertaken. These decisions generally need to be made in consultation with surgeons and radiotherapists. If an endocrine deficiency is present, hormone replacement therapy is most often used to correct the disorder. In some cases, the efficacy of substitution therapy can be measured directly by laboratory testing, such as measurement of thyroid-stimulating hormone during thyroxine replacement. In other cases (e.g., measurement of ACTH suppression during substitution therapy for adrenal insufficiency), testing could lead to misleading information and overtreatment of patients; therefore, a combination of return of symptoms and signs to normal, laboratory testing, and indirect tests (e.g., potassium, blood urea nitrogen, and creatinine in the case of adrenal insufficiency) is required to determine the adequacy of replacement therapy. Understanding the pharmacology of the particular synthetic hormone used is important for proper replacement therapy. For example, synthetic glucocorticoids vary greatly in their half-life, and therefore dosage and timing of administration are important issues for patients receiving these hormones. Some patients, such as those with hypopituitarism, require substitution with multiple hormones, and often these need to be coordinated (e.g., glucocorticoid dosage in a patient with panhypopituitarism is dependent on the dosage of thyroid hormone that is administered). Because monitoring thyroid-stimulating hormone is not useful in such patients, empirical substitution with both hormones is required to establish that the therapeutic regimen results in return of functional activity to normal. At times, hormone excesses may have to be treated with ancillary medications; for example, β-blockade may be useful in patients with hyperthyroidism, and both α- and β-blockade are often necessary in patients with pheochromocytoma. The etiology of osteoporosis is often unknown. In most cases, this disease is generally treated by administration of agents that inhibit bone reabsorption by a variety of mechanisms, including the bisphosphonates, estrogen replacement therapy, and calcitonin.

Hormones are also used throughout medicine for treatment of other disorders, and sometimes these treatments result in a hormone excess syndrome. The most common example is administration of high-dose glucocorticoid therapy for immune suppression resulting in Cushing's syndrome. Similarly, growth hormone may be administered to children with short stature who do not have GH deficiency. PTH is the only agent available for stimulation of an anabolic effect in bone; therefore, it is administered to patients with osteoporosis even though they do not have hypoparathyroidism. Octreotide acetate, a long-acting derivative of somatostatin, can be useful for controlling gastrointestinal symptoms in patients with neuroendocrine tumors. Supraphysiologic doses of progesterone are commonly used as contraceptives. Hormone antagonists are also used in both endocrine and nonendocrine disorders. Estrogen receptor antagonists are commonly used in breast cancer therapy, as are androgen receptor antagonists in prostate cancer therapy. Similarly, gonadotropin-releasing hormone agonists have been found to be useful in patients with prostate cancer that is metastatic to bone. Prostaglandin antagonists are commonly used in acute and chronic inflammatory disorders, and angiotensin receptor antagonists as well as renin antagonists are used in the treatment of hypertension, whether it is due to an endocrine or nonendocrine etiology. A comprehensive knowledge of the actions of these hormones can intelligently guide the proper use of these agents in treating nonendocrine disorders.

229 PRINCIPLES OF ENDOCRINOLOGY

DAVID R. CLEMMONS

REGULATION OF THE ENDOCRINE SYSTEM

Following their synthesis and secretion, hormones either act locally on neighboring cells (termed *paracrine actions*) or, after secretion into the general circulation, are transported to a distant site and function to stimulate target tissues. They also act on a cell of origin (termed an *autocrine action*). The endocrine system is under finely tuned control, most importantly through the process of negative feedback regulation, which functions to maintain homeostasis. Negative feedback regulation occurs when the hormone or metabolite level in blood reaches a concentration to which the system is set to respond in terms of altering hormone biosynthesis or secretion. For example, the pituitary gland, which secretes thyroid-stimulating hormone (TSH) to stimulate the thyroid gland to produce triiodothyronine (T_3) and thyroxine (T_4), is highly sensitive to feedback regulation (Fig. 229-1). The T_3 and T_4 from the circulation are transported to the pituitary, where they bind to the thyroid hormone receptor. When T_3 or T_4 reaches a threshold concentration, the receptor transmits a signal to stop the synthesis of TSH. In some cases, such as parathyroid hormone feedback, regulation occurs through the concentration of the primary metabolite (e.g., calcium), which feeds back directly onto the calcium-sensing receptor in the parathyroid glands. This receptor then transmits a signal to the nucleus to shut down parathyroid hormone (PTH) synthesis. In this way, each hormonal feedback loop maintains homeostasis. Sometimes, this can occur through a physical stimulus rather than a biochemical action. In the case of blood pressure regulation, when the renin and aldosterone concentrations have reached a certain level, changes in arterial blood pressure and renal blood flow feed back through the juxtaglomerular apparatus in the kidney to suppress renin production. This results in less conversion of angiotensinogen to angiotensin I and maintenance of blood pressure regulation. The result of hormone excess syndromes is disruption of this equilibrium, leading to an unrestrained excess of the hormone, which disrupts negative feedback regulation. Although under these conditions negative feedback regulation may still exist, either the set point is changed, or the tumor produces the hormone in such an episodic fashion that negative feedback regulation becomes irrelevant. The latter example would apply to Cushing's syndrome caused by an adrenal adenoma, whereas if the primary problem is an adrenocorticotropic hormone (ACTH)-producing pituitary tumor, the set point of the tumor is altered, resulting in production of ACTH that is subject to altered feedback regulation. Under certain circumstances, loss of negative feedback regulation results in significant hormonal abnormalities but no pathophysiologic changes. For example, in patients with ACTH-producing pituitary tumors, after removal of the adrenal glands, there is excess secretion of ACTH, but no effect will ensue other than hyperpigmentation.

A hormone may be produced by an endocrine gland (e.g., cortisol by the adrenal gland), or it may be produced by several cell types scattered throughout the body (e.g., prostaglandins). A hormone may be produced by a single cell type that occurs in multiple locations, such as adiponectin production by adipose tissue. The chemical structures of many hormones are similar. Steroid hormones are derived from cholesterol, as is vitamin D. Retinoids are derived from carotenoids in the diet and the eicosanoids from fatty acids. Some peptide hormones require not only synthesis and secretion by their gland of origin but also proteolytic processing following their release into the circulation. For example, angiotensinogen is secreted by the liver as an inactive prohormone that is proteolytically cleaved twice. The first cleavage occurs in the kidney by renin and results in angiotensin I, which is still inactive, and the second is in the lung by converting enzyme to form angiotensin II, a potent vasoconstrictor. Thyroid hormone contains the amino acid tyrosine, which is modified by iodination. Thus, ambient iodine intake and factors that control iodine uptake by the thyroid gland are important determinants of thyroid hormone production. Neurotransmitters can also function as hormones. Catecholamines are secreted not only by nerve endings but also by the adrenal medulla into the general circulation and are necessary for maintenance of normal blood pressure and cardiac function.

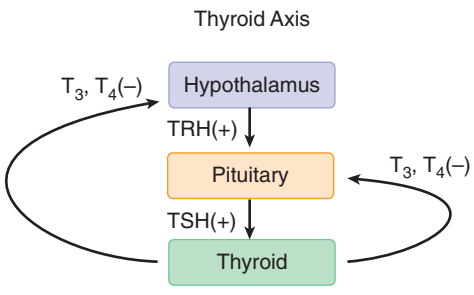

FIGURE 229-1. Hypothalamic-pituitary-thyroid axis illustrating negative feedback regulation. Following thyroid-stimulating hormone (TSH) secretion by the pituitary, the thyroid gland secretes T_3 and T_4, which feed back on the hypothalamus and pituitary to suppress further increases in thyrotropin-releasing hormone (TRH) and TSH secretion.

Several processes are involved in the synthesis of hormones. Peptide hormone synthesis is initiated with transcription of the encoding gene under the direct regulation of transcription factors. The nascent RNA is processed and translated into the peptide hormone. The peptide hormone is then modified by glycosylation or proteolytic cleavage and stored in storage granules until it is released. Some hormones are stored for extended periods and then released abruptly in response to stimuli. For example, insulin is stored in granules in the islet cells of the pancreas and released in response to fluctuations in blood glucose. This allows for rapid minute-to-minute regulation of plasma glucose concentrations based on carbohydrate intake or demands by tissues. Chronic exposure to the appropriate stimulus can also lead to increased cell number within the target endocrine gland. Thus, chronic exposure to hypoglycemia will increase islet cell size and number, leading to increased insulin secretion. Long-term exposure to hypocalcemia will result in the same change within the parathyroid glands. Excess TSH or ACTH will result in hypertrophy and hyperplasia of thyroid or adrenal cortical tissue, respectively.

Steroid hormones are derived from cholesterol by actions of several enzymes on the cytochrome P-450 class of oxidases. The first step in steroid hormone synthesis is rate limiting and involves cleavage of the cholesterol side-chain residues to pregnenolone. Trophic hormones such as ATCH stimulate the transcription of an enzyme termed *steroidogenic acute regulator,* or *STAR*, which acts within the mitochondria to activate the transport of cholesterol and its cleavage to pregnenolone. Steroid synthesis is then regulated by the specific enzymes that are induced by the specific trophic hormone; for example, if glucocorticoid production is required, 17- and 21-hydroxylases are activated, whereas if mineralocorticoid synthesis is required, 18-hydroxylase, a distinct enzyme, is activated.

HORMONE TRANSPORT IN THE GENERAL CIRCULATION

Because so many important hormones have to be transported through the circulation to their distal sites of action to achieve target cell effects, the capacity to bind and transport hormones can be an important determinant not only of the ambient plasma concentration but also of the amount that is bioavailable to cells and tissues. Steroid hormones and thyroxine are transported almost solely in protein-bound form. The globulins that bind these hormones are synthesized in the liver, and their synthesis is influenced by a variety of factors, including estrogens and androgens, genetic defects, and a variety of medications. These binding globulins can be measured directly, and sometimes this is necessary to determine whether a suspected deficiency or excess is in fact really due to a major change in the binding protein. Occasionally, peptides such as vasopressin or insulin-like growth factor-I also bind to binding proteins, and therefore binding proteins can be determinants of their plasma concentrations. At times, measurement of free hormone is required to ascertain whether a hormone excess or deficiency is present because of the severity of the binding protein abnormality (Chapter 228).

Hormone Action

Both peptide and steroid hormones bind specifically to receptors, which are complex, multifunctional proteins located on the surface of the cells (peptide hormone receptors) or in the cytoplasm (steroid hormone receptors). The

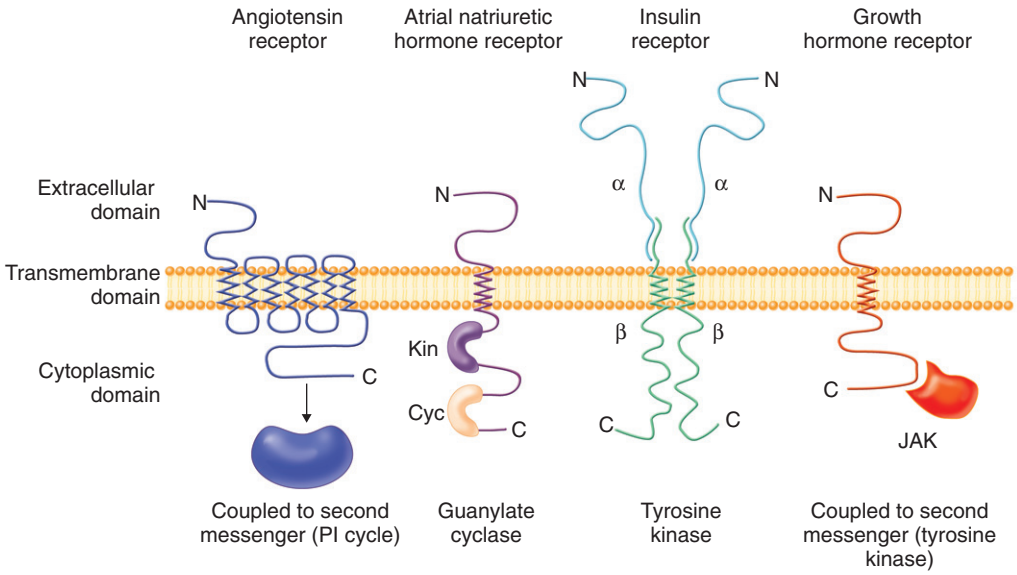

FIGURE 229-2. Structures of different types of peptide hormone receptors.

peptide hormone receptors have a ligand recognition domain, a domain that spans the plasma membrane, and a cytoplasmic domain. The extracellular domain contains the hormone recognition sequence, and the cytoplasmic domain contains the signal transduction apparatus.

Based on this general structure, peptide hormone receptors have been classified into four types (Fig. 229-2). The most common form is the 7-transmembrane domain receptor. These receptors contain the amino-terminal domain, which contains the hormone-binding unit, seven regions that cross the plasma membrane, and a cytoplasmic domain that is coupled to guanylate nucleotide–binding proteins or G proteins. Binding of the ligand to the receptor activates the G protein by a series of conformational changes resulting in a change in the shape of the cytoplasmic domain that allows it to interact directly with the G protein. The G proteins then function through a subunit signaling mechanism resulting in coordinate activation of enzymes such as adenylate cyclase or phospholipase C. These enzymes initiate a series of intracellular signaling events that trigger specific enzymatic reactions or downstream signaling events that initiate the biochemical changes that mediate the hormone's actions. Examples include calcium mobilization in cells by PTH, thyroxine biosynthesis in response to TSH, or steroidogenesis in response to ACTH or luteinizing hormone (LH).

A second group of receptors, the tyrosine kinase receptors, also contain an extracellular domain that is involved in ligand recognition. Ligand-binding sites within this group are highly specific, and this is a major determinant of activation of this class of receptors. Following hormone binding, these receptors undergo a conformational change that causes autocatalytic activation of intrinsic enzymatic activity contained within the sequence of the cytoplasmic domain (see Fig. 229-2). The prototype of this group is the insulin receptor, wherein the cytoplasmic domain contains an enzyme with protein kinase enzymatic activity. Once the enzyme is autocatalytically activated, it autophosphorylates intrinsically located tyrosines, which then form docking sites for signal transduction proteins that contain specific sequences that can bind to phosphorylated tyrosines, called SH2 or PTB domains. These sequences recognize a particular amino acid sequence surrounding the phosphotyrosine, which provides another level of specificity of activation. Activation of the insulin receptor then triggers binding of a transducer protein, termed *insulin receptor substrate-1* (IRS-1), that binds to these SH2 or PTB domains. IRS-1 undergoes further tyrosine phosphorylation by the intrinsic kinase activity of the insulin receptor. The phosphotyrosines act as docking sites for other important catalytic enzymes. The most important for glucose transport is the PI-3 kinase enzyme. This enzyme binds to specific phosphorylated tyrosines that are surrounded by specific flanking amino acids within the IRS-1 sequence. Its binding results in PI-3 kinase activation, which further activates a series of downstream signal transduction events leading to stimulation of glucose transport. Tyrosine kinase receptors can also activate a series of signaling events that lead to an increase in the transcription of specific genes. For example, activation of the IGF-I receptor leads to stimulation of an enzyme called MAP kinase. Its activation leads to its translocation to the nucleus, wherein it specifically activates gene transcription. Thus, tyrosine kinases represent an extremely diverse and functionally significant class of enzymes that are able to regulate multiple pleiotropic events within cells and greatly influence hormone action.

A third class of receptors is the cytokine receptors. The peptide hormones, growth hormone and leptin, both activate cytokine receptors to initiate signaling (see Fig. 229-2). Unlike receptors with intrinsic tyrosine kinase activity, once these receptors undergo a conformational change, they recruit tyrosine kinases to their cytoplasmic domain. These kinases then phosphorylate the receptor directly. The phosphorylated tyrosines on the receptor mediate the binding of a specific class of transcription factors termed *signal transducers of activators of transcription* (STATS). The STATS are then further phosphorylated by the same tyrosine kinase that phosphorylates the receptor, resulting in their activation and transport to the nucleus where they initiate gene transcription. A fourth class of membrane proteins that interact with hormones is termed *ligand regulated transporters*. These bind to a diverse set of ligands such as low-density lipoprotein, transferrin, and atrial natriuretic peptide. The cytoplasmic domain is not involved in signaling; instead, after transport of the active substance such as low-density lipoprotein across the cell membrane, the substance is endocytosed and further processed. This is also the model for the receptors for atrial natriuretic hormone and transferrin, with the latter being internalized together with its bound iron molecule.

Nuclear Receptors

Nuclear receptors, present in the cytoplasm of target cells, are important for mediating the actions of steroid hormones, thyroid, retinoids, vitamin D, fatty acids, and prostaglandins (Fig. 229-3). After ligand binding, the receptor-hormone complex is translocated to the nucleus. Each receptor contains a DNA-binding domain that contains zinc fingers or regions of a protein that are linked to a zinc atom that allows the receptor to assume a conformation that fits in a groove in the DNA. The complex binds to specific regions of DNA (called promoters) that control the gene transcription. In general, these receptors dimerize before binding. At times, heterodimers form instead of homodimers. An example of this is steroid hormone receptors that bind with the retinoid X receptor to form a heterodimer. Specific DNA sequence domains that are arranged in repetitive sequences form the nuclear receptor–binding site. Small variations in these sequences provide specificity. Although specificity for binding to this sequence is relatively high, there is some overlap. For example, high concentrations of ligand-activated progesterone receptor can bind to glucocorticoid receptor–regulated genes. In some cases, the activated hormone receptor, such as the thyroid hormone receptor, interacts with a specific protein in the nucleus, in this case CREB-binding protein, to activate transcription. These binding proteins are capable of interacting with more than one transcription factor. In many cases, the ligand-hormone complex interacts with the DNA in a *cis* manner and enhances transcription of target genes. Hormone-activated receptors can also repress transcription. Several major negative feedback loops operate through this process. For example, the activated cortisol receptor will suppress ACTH secretion, and activated thyroid hormone receptors will suppress TSH α- and β-subunit transcription. Other cytoplasmic signaling molecules can modify these responses through DNA-binding proteins. An example is cyclic adenosine

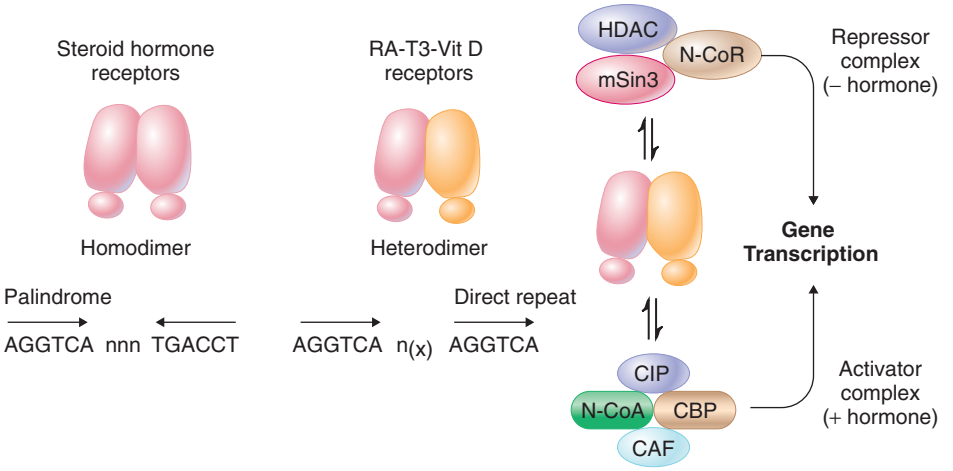

FIGURE 229-3. How steroid hormone receptors function. *Left,* Glucocorticoid receptor family members bind as homodimers to palindromic DNA sites. Thyroid hormone receptor family members bind primarily as heterodimers with retinoid X receptor to direct repeat DNA sites separated by varying numbers of base pairs. *Right,* As a result of hormone binding, repressor complexes dissociate and activator complexes bind to nuclear receptors. Repressor complexes contain histone deacetylase (HDAC), and activator complexes contain histone acetylase (CAF).

monophosphate binding, which regulates CREB activation. CREB then binds to DNA to control gene transcription by peptide hormones.

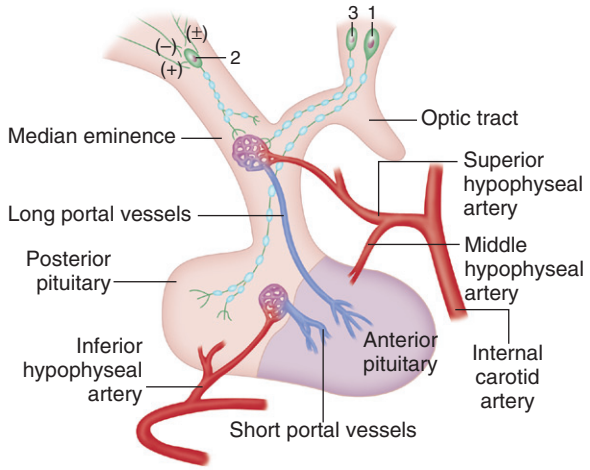

FIGURE 230-1. Neuroendocrine organization of the hypothalamus and pituitary gland. The posterior pituitary is fed by the inferior hypophyseal artery and the hypothalamus by the superior hypophyseal artery, both branches of the internal carotid artery. Most of the blood supply to the anterior pituitary is venous by way of the long portal vessels, which connect the portal capillary beds in the median eminence to the venous sinusoids in the anterior pituitary. Hypophysiotropic neuron 3 in the parvocellular division of the paraventricular nucleus and neuron 2 in the arcuate nucleus are shown to terminate in the median eminence on portal capillaries. These neurons of the tuberoinfundibular system secrete hypothalamic releasing and inhibiting hormones into the portal veins for conveyance to the anterior pituitary gland. Neuron 2 is innervated by monoaminergic neurons. Note that the multiple inputs to such neurons, using neuron 2 as an example, can be stimulatory, inhibitory, or neuromodulatory, in which another neuron may affect neurotransmitter release. Neuron 1 represents a peptidergic neuron originating in the magnocellular division of the paraventricular nucleus or supraoptic nucleus and projecting directly to the posterior pituitary by way of the hypothalamic-neurohypophyseal tract. NEUROENDOCRINOLOGY AND THE NEUROENDOCRINE SYSTEM

MARK E. MOLITCH

NEUROENDOCRINE REGULATION

Neuroendocrinology refers to the area of endocrinology in which the nervous system interacts with the endocrine system to link neural activity with metabolic and hormonal homeostatic activity. The *neurohypophysial* neurons originate from the paraventricular and supraoptic nuclei, traverse the hypothalamic-pituitary stalk, and release vasopressin and oxytocin from nerve endings in the posterior pituitary. The *hypophysiotropic* neurons, localized in specific hypothalamic nuclei, project their axons to the median eminence to secrete their peptide and bioamine releasing and inhibiting hormones into the proximal end of the hypothalamic-pituitary portal vessels (Fig. 230-1). The median eminence receives its blood supply from the superior hypophysial artery, which arborizes into a rich capillary bed. The capillary loops extend into the median eminence and coalesce to form the long portal veins that traverse the pituitary stalk and end in the pituitary. The neuroendocrine system operates through a series of feedback loops that regulate pituitary and target organ hormone levels. Target organ hormones can feed back at both the hypothalamic and the pituitary levels to complete the loop. The feedback loops can be perturbed, resulting in alterations of set points by such factors as length of day (circadian periodicity), stress, nutritional status, and systemic illness.

Hypophysiotropic Hormones

Regulation of pituitary hormones by the hypophysiotropic hormones is quite complex, in part because of the multiplicity of substances present in the hypothalamus that can affect pituitary hormone secretion and in part because of the redundancy and overlapping nature of the feedback loops alluded to earlier. In addition, some hypophysiotropic hormones exert effects on more than one pituitary hormone.

Thyrotropin-Releasing Hormone

The primary neuroendocrine functions of thyrotropin-releasing hormone (TRH) are to stimulate the synthesis and release of thyroid-stimulating hormone (TSH) and prolactin. In cases of hypothyroidism, the increased TRH synthesis and binding to the pituitary results in increased TSH and prolactin levels. Correction of the hypothyroidism with thyroid hormones decreases the elevated TSH and prolactin levels. Conversely, in cases of hyperthyroidism, TSH levels are markedly suppressed. Although TRH is the major regulator of TSH synthesis and secretion, the role of TRH as a physiologic prolactin-releasing factor (PRF) is undefined.

Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone (GnRH) is a 10–amino acid peptide; its neurons originate in the epithelium of the medial part of the olfactory placode. This origin of GnRH-producing neurons from olfactory epithelium is of clinical interest with respect to the entity of Kallmann's syndrome, in which GnRH deficiency is associated with agenesis of the olfactory bulbs.

One form of Kallmann's syndrome is caused by loss of function of a protein (anosmin) that facilitates the embryologic migration of these GnRH-producing neurons. The primary function of GnRH is to stimulate the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Only one GnRH has been identified, and the differential secretion of LH and FSH is due to variations in sensitivity of the feedback effects of steroid and peptide hormones and variations in sensitivity to GnRH. GnRH pulsatile secretion directly increases its own receptor number whereas continuous administration of GnRH is associated with a decrease. In women, positive and negative steroid hormone feedback regulation of the hypothalamic-pituitary-gonadal axis occurs at both the pituitary and the hypothalamic levels, the hypothalamic effects being alteration of GnRH pulse amplitude and frequency and the pituitary effects being modulation of the gonadotropin response to GnRH. In males, testosterone decreases GnRH pulsatile secretion, with a resultant decrease in gonadotropin pulse amplitude and frequency as well as a decreased gonadotropin response to exogenous GnRH.

The negative feedback effects of inhibin, a peptide produced by testicular Sertoli cells and ovarian granulosa cells, are predominantly on FSH at the pituitary, where inhibin causes a decrease in the sensitivity of gonadotrophs to GnRH. The related ovarian protein activin stimulates basal and GnRH-stimulated FSH synthesis and release from the pituitary, but its primary action is to facilitate the response of ovarian granulosa cells to FSH. Another gonadal peptide, follistatin, also inhibits the oophorectomy- and GnRH-induced rise in FSH selectively, primarily by binding to activin. These ovarian peptides are also found in the pituitary and may therefore have additional local effects on gonadotropin secretion.

GnRH has been administered in pulsatile fashion to individuals with hypogonadotropic hypogonadism secondary to GnRH deficiency with great success, that is, restoration of normal sexual function and fertility. Long-acting GnRH agonists have been used to downregulate GnRH receptors and gonadotropin secretion in a variety of conditions, including precocious puberty, prostate cancer, breast cancer, uterine fibroids, and endometriosis. Direct GnRH antagonists that compete for the GnRH receptor are used for similar conditions.

Somatostatin

Somatostatin (also known as *somatotropin release-inhibiting factor*) inhibits GH secretion. The interaction of somatostatin and growth hormone–releasing hormone (GHRH) on GH secretion is complex. GH secretory episodes are associated with increased GHRH secretion, often accompanied by low somatostatin levels; the basal or trough GH levels are associated with low GHRH levels and more elevated somatostatin levels. Somatostatin also inhibits basal and stimulated TSH secretion. However, GH is about 10-fold more sensitive to inhibition by somatostatin than is TSH, thus suggesting that the physiologic role of somatostatin in inhibiting TSH secretion is limited.

Somatostatin is also present in D cells of the pancreatic islets, the gut mucosa, and the myenteric neural plexus. Through paracrine and endocrine actions, it suppresses the secretion of insulin, glucagon, cholecystokinin, gastrin, secretin, vasoactive intestinal polypeptide (VIP), and other gastrointestinal hormones, as well as such functions as gastric acid secretion, gastric emptying, gallbladder contraction, and splanchnic blood flow. Analogues of somatostatin have been developed for the treatment of acromegaly, carcinoid tumors, VIP-secreting tumors, TSH-secreting pituitary tumors, and islet cell tumors.

Corticotropin-Releasing Hormone

Corticotropin-releasing hormone (CRH) releases adrenocorticotropic hormone (ACTH), β-endorphin, β-lipotropin, melanocyte-stimulating hormone (MSH), and other peptides generated from pro-opiomelanocortin (POMC) in equimolar amounts. CRH mediates 75% of the ACTH response to stress. The remaining 25% is due to vasopressin. CRH and vasopressin have synergistic effects on ACTH release. CRH and vasopressin are not always released coordinately, however, and stress selectively activates the vasopressin-containing subset of CRH neurons. Cortisol feeds back to decrease ACTH secretion at both the hypothalamic and the pituitary levels. ACTH and β-endorphin also feed back negatively to decrease CRH release by the hypothalamus. Central bioamines, opioids, and peptides influence CRH secretion. Monokines released by inflammatory tissue, such as interleukin-1, interleukin-6, and tumor necrosis factor-α, stimulate the synthesis and release of CRH and vasopressin from the hypothalamus. The consequent increase in cortisol then reduces the intensity of the inflammatory response and release of these monokines, thus completing the feedback loop. CRH receptors are widely distributed in the brain, and increases in CRH are associated with activation of the sympathetic nervous system, suppression of the parasympathetic nervous system, stimulation of arousal, and increased learning performance. CRH may also be involved in the regulation of body weight; with overfeeding, increased leptin stimulates CRH, which causes decreased food intake and increased energy expenditure.

Biosynthetic human CRH has become available for clinical use. Its major utility is in the differential diagnosis of Cushing's disease versus ectopic ACTH syndrome, with the finding that patients with Cushing's disease respond with a greater than 35% increment, whereas those with ectopic ACTH secretion have a lesser response. If the results are equivocal, CRH testing during bilateral inferior petrosal sinus sampling for ACTH often provides additional discriminatory information.

Growth Hormone–Releasing Hormone

GHRH dose-dependently stimulates GH secretion. With repetitive administration, GHRH can cause the release of sufficient GH in children with GHRH deficiency to result in an increase in IGF-I levels and an acceleration of growth. Both IGF-I and GH feed back negatively on GH secretion. This negative feedback results in both a decrease in GHRH and an increase in somatostatin. The feedback effect of IGF-I is clinically relevant, as documented by the high circulating GH levels that occur in IGF-I-deficient states, such as renal insufficiency and cirrhosis. In children with mutations of the GH receptor resulting in their not being responsive to GH (GH insensitivity syndrome, also known as Laron-type dwarfism), IGF-I levels are very low, and GH levels are correspondingly elevated. A separate GH-stimulating system for GH secretion involves a distinct receptor, termed the *GH secretagogue* (GHS) receptor, that interacts with a 28–amino acid peptide called Ghrelin that was initially isolated from the stomach. GHS receptor and Ghrelin messenger RNA are both present in the pituitary and hypothalamus of humans. The interaction of Ghrelin physiologically with GHRH and somatostatin is complex but appears to be of minor importance. However, Ghrelin may play a more important role in the regulation of appetite and food intake.

Prolactin Inhibitory Factor

The inhibitory component of hypothalamic regulation of prolactin secretion predominates over the stimulatory component. Dopamine is the major physiologic prolactin inhibitory factor. It is likely that in most physiologic circumstances that cause a rise in prolactin, such as lactation, a simultaneous fall in dopamine occurs along with a rise in a PRF such as VIP. Blockade of endogenous dopamine receptors by a variety of drugs, such as the neuroleptics, causes a rise in prolactin. Lesions that interrupt the basal hypothalamic neuronal pathways carrying dopamine to the median eminence or that interrupt portal blood flow, such as craniopharyngiomas or other large mass lesion, result in decreased dopamine reaching the pituitary and hyperprolactinemia.

Prolactin-Releasing Factor

A number of hypothalamic peptides other than TRH have also been shown to have PRF activity. VIP stimulates prolactin synthesis and release at concentrations found in hypothalamic-pituitary portal blood. Within the VIP precursor is another similarly sized peptide known as peptide histidine methionine, which also has PRF activity. The precise roles of VIP versus peptide histidine methionine are not clear. It appears to be of negligible physiologic importance in humans.

Endogenous Opioid Peptides

Most data now suggest a modest role for endogenous opioid peptides in neuroendocrine regulation. The endogenous opioid peptides have a common 5–amino acid sequence at their amino termini (Tyr-Gly-Gly-Phe-Met [or Leu]) that is important for their binding to endogenous opioid receptors and bioactivity. Three major opioid peptide receptors and three major groups of opioid peptides are recognized. The μ-receptor mediates most of the endocrine effects and analgesia. The primary peptide ligand for the μ-receptor is β-endorphin, which is derived from POMC. The δ-receptor mediates behavioral, analgesic, and some endocrine effects and has as its primary peptide ligands met- and leu-enkephalins, which are derived from proenkephalin A. It is much less well blocked by naloxone than is the μ-receptor. The κ-receptor mediates sedation and ataxia and binds primarily dynorphin and the neoendorphins. A fourth receptor has recently been described that has considerable sequence homology with the δ-receptor and binds to an endogenous 17–amino acid peptide called nociceptin (also known as orphanin FQ).

POMC is a 31-kD precursor peptide that harbors within it ACTH, β-lipotropin, and β-endorphin. POMC undergoes tissue-specific post-translational processing. In the anterior pituitary, its major cleavage products are β-lipotropin and ACTH, with a significant proportion of β-lipotropin being further processed to β-endorphin. In the pituitary intermediate lobe, the major products are α-MSH, corticotropin-like intermediate peptide, β-endorphin, and γ-lipotropin. Brain POMC, however, is processed primarily to β-endorphin, γ-lipotropin, and ACTH, with most of the ACTH being further processed to corticotropin-like intermediate peptide and α-MSH. The pentapeptide enkephalins are derived from the 28-kD precursor proenkephalin A. Neuronal perikarya containing the enkephalins are widely distributed throughout the brain. Dynorphin is a 17–amino acid peptide derived from a 28-kD precursor called proenkephalin B or prodynorphin. Shorter peptides called α- and β-neoendorphin, which have 10 and 9 amino acids, respectively, have also been isolated. These peptides react almost exclusively with the κ-receptor. Nociceptin is a 17–amino acid peptide derived from a κ precursor called pronociceptin. High concentrations of nociceptin and its receptor are present in the hypothalamus as well as in other areas of the brain that serve as the sources of monoamine neurotransmitters. In general, nociceptin appears to have an anti-opioid or antinociceptive effect. The hypothalamus contains abundant opioid receptors. The effects of opioid peptides on anterior pituitary hormone secretion are produced through modulation of hypothalamic bioamines and hypophysiotropic factors.

The specific functions of the various opioid peptides and the opioid receptors are still not completely understood, although evidence links them to a number of body functions, including stress, mental illness, narcotic tolerance and dependence, eating, drinking, gastrointestinal function, learning, memory, reward, cardiovascular responses, respiration, thermoregulation, seizures, brain electrical activity, locomotor activity, pregnancy, and neuroimmune activity. Endogenous opioids have an inhibitory influence on gonadotropin secretion through action on GnRH secretion. Exogenous β-endorphin and enkephalin analogues increase serum GH and prolactin levels, but blockade of endogenous opioid pathways with naloxone does not alter basal or stimulated GH or prolactin levels. Opioids feed back negatively on ACTH and β-endorphin secretion, and naloxone can increase basal and stimulated ACTH levels. Overall, the effects of the endogenous opioids on normal physiologic regulation of the various pituitary hormones in humans is minimal.

Central Nervous System Rhythms and Neuroendocrine Function

Pituitary hormones are secreted in a pulsatile fashion with a number of rhythms superimposed. The pulse amplitude of a pituitary hormone reflects the amount of releasing hormone and factors that alter sensitivity to that releasing hormone. Thus, the amplitude can be altered by the presence of inhibitory factors (e.g., GHRH versus somatostatin), nutritional factors, feedback effects of target organ hormones, and prior stimulation that depletes the releasable hormone pool. Pulse frequency is governed by the frequency of release of the hypophysiotropic factor, which is regulated by the hypothalamic pulse generator system.

The pituitary has an intrinsic rhythm of small amplitude with a frequency of every 2 to 10 minutes. Superimposed on this intrinsic rhythm is a rhythm caused by the pulsatile release of hypophysiotropic releasing factors, with or without the withdrawal of a corresponding inhibitory factor. Rhythms that are shorter than 1 day are referred to as *ultradian* rhythms. The next layer of rhythmicity is the *circadian* rhythm, that is, a rhythm with approximately 24-hour periodicity. These rhythms are usually synchronized with the 24-hour period by a periodic environmental cue such as the dark-light cycle. The suprachiasmatic nucleus functions as a circadian pacemaker and receives light-induced electrical impulses from the retina transmitting those impulses to the pineal gland, where they are converted to hormonal signals. Signals for a rhythm with a periodicity longer than 24 hours, an *infradian* rhythm, include the gravitational influence of the moon, which gives rise to the menstrual cycle.

A number of factors may influence circadian and infradian rhythms. One of the most important is the sleep-wake cycle. GH, TSH, prolactin, ACTH, and pubertal LH secretion are all entrained more to the sleep-wake cycle than to the dark-light cycle. Each has an increase and maximal level that occur following sleep onset. The profound diurnal variation in cortisol and ACTH is often used as an index of "normality" of the system. Loss of this diurnal rhythm occurs with disordered regulation by CRH, which may be due to endogenous depression or excessive alcohol intake, or autonomous secretion of ACTH in Cushing's disease. Loss of the diurnal rhythm of cortisol has been used as a diagnostic test for Cushing's syndrome.

Interesting changes occur in gonadotropin secretion as a child passes through puberty into adulthood. Early in puberty, the amplitude of the pulses increases during sleep at night, especially for LH, but in adulthood, this nocturnal rise is lost. In patients with anorexia nervosa, the pattern of gonadotropin secretion often reverts to this pubertal pattern. This phenomenon suggests that body composition may in some way affect regulation of the pulsatile secretion of gonadotropins. The percentage of body fat has been proposed as being important in the timing of the onset of puberty. Recent studies implicate leptin as the signal indicating this change in body composition.

NEUROENDOCRINE DISEASE

Diseases of the Hypothalamus

Diseases may affect the hypothalamus by discrete localization in the hypothalamus, being part of a generalized central nervous system (CNS) disease such as neurosarcoidosis, or indirectly by a process such as hydrocephalus (Table 230-1). Furthermore, hormonal changes mediated by functional alterations in hypothalamic regulation may occur in systemic illnesses.

The axons projecting to the median eminence that contain the various hypophysiotropic factors are concentrated in the basal portion of the

TABLE 230-1 ETIOLOGY OF HYPOTHALAMIC DISEASE

NEONATES
Congenital embryopathic disorders: agenesis of the corpus callosum, cleft palate *(HESX1)*
Congenital disorders: isolated hormone and receptor mutations, combined pituitary hormone deficiency *(PIT1, PROP1)*, Laurence-Moon-Bardet-Biedl syndrome, Prader-Labhart-Willi syndrome
Tumors: glioma, hemangioma
Trauma
Hydrocephalus, hydranencephaly, kernicterus
1 MONTH TO 2 YEARS
Tumors: glioma, especially optic glioma, hemangiomas
Infiltrative disease: Langerhans cell histiocytosis, meningitis
Hydrocephalus
2-10 YEARS
Tumors: craniopharyngioma, glioma, dysgerminoma, hamartoma, leukemia, ganglioneuroma, ependymoma, medulloblastoma
Infiltrative disease: Langerhans cell histiocytosis, meningitis, tuberculosis, encephalitis
Irradiation: for nasopharyngeal tumors, intracranial tumors, leukemia
Functional: psychosocial deprivation
10-25 YEARS
Congenital disorders: Kallmann's syndrome, gonadotropin-releasing hormone receptor defects
Tumors: craniopharyngioma, pituitary tumors, glioma, hamartoma, dysgerminoma, dermoid, lipoma, neuroblastoma
Trauma: subarachnoid hemorrhage, vascular aneurysm, arteriovenous malformation
Infiltrative diseases: Langerhans cell histiocytosis, sarcoidosis, tuberculosis, meningitis, encephalitis, leukemia
Chronic hydrocephalus or increased intracranial pressure
Functional: hypogonadotropic hypogonadism associated with weight loss, exercise
25-50 YEARS
Tumors: pituitary tumors, meningioma, craniopharyngioma, Rathke's cleft cyst, glioma, lymphoma, angioma, colloid cysts, ependymoma
Infiltrative diseases: sarcoidosis, Langerhans cell histiocytosis, tuberculosis, viral encephalitis
Subarachnoid hemorrhage, vascular aneurysms, arteriovenous malformation
Irradiation: for pituitary adenoma, nasopharyngeal tumors, intracranial tumors
Nutritional: Wernicke's disease
Functional: hypogonadotropic hypogonadism associated with weight loss, exercise
50 YEARS AND OLDER
Tumors: pituitary tumors, meningioma, craniopharyngioma, sarcoma, glioblastoma, lymphoma, colloid cysts, ependymoma
Vascular: infarct, subarachnoid hemorrhage, pituitary apoplexy, aneurysm
Irradiation: for pituitary adenoma, nasopharyngeal tumors, intracranial tumors
Infiltrative diseases: encephalitis, sarcoidosis, meningitis
Nutritional: Wernicke's disease

Modified from Plum F, Van Uitert R. Non-endocrine diseases of the hypothalamus. In: Reichlin S, Baldessarini RJ, Martin JB, eds. *The Hypothalamus*. New York: Raven Press; 1978:415.

hypothalamus. Thus, lesions located within this final common pathway might be expected to cause significant decreases in secretion of some or all of the pituitary hormones except prolactin, which may increase because of the elimination of tonic inhibition by dopamine. Diabetes insipidus (Chapter 232) may also occur. Symptoms resulting from hypothalamic dysfunction are related to the size of the lesion and consequently to the area of the hypothalamus involved, as well as to the rapidity of the increase in lesion size. Slowly growing lesions tend to cause problems of hormone dysregulation rather than dramatic symptoms. Large, slowly growing lesions may cause more acute problems, such as when a slight increment in growth eliminates the remaining vestiges of vasopressin or ACTH secretion. The best way of discerning lesions affecting the hypothalamus is by magnetic resonance imaging (MRI) with gadolinium enhancement, although computed tomographic scanning with intravenous contrast is also effective. Formal visual field testing may discern impingement of the optic nerves and chiasm by hypothalamic lesions. Detailed testing of hypothalamic-pituitary function may reveal evidence of functional hypothalamic disruption with great sensitivity.

CONGENITAL EMBRYOPATHIC DISORDERS

The most common embryopathic disorders to affect the hypothalamus are the midline cleft syndromes, which cause varying degrees of defects of midline structures, especially the optic and olfactory tracts, the septum pellucidum, the corpus callosum, the anterior commissure, the hypothalamus, and the pituitary. The clinical features of patients with midline cleft defects varies in severity from cyclopia to cleft lip and from isolated hypothalamic hormone defects to panhypopituitarism. The combination of absent septum pellucidum associated with optic nerve hypoplasia is referred to as septo-optic dysplasia and is associated with abnormalities of hypothalamic and other diencephalic structures. Some patients with septo-optic dysplasia and hypothalamic hypopituitarism have sexual precocity, presumably caused by a lack of inhibitory influences from other parts of the hypothalamus and intact GnRH-producing structures. Children with very mild midline cleft defects consisting of cleft lip, cleft palate, or both have an increased risk of GH and other pituitary hormone deficiencies. MRI studies of patients with "idiopathic" GH deficiency show absence of the infundibulum in nearly 50%.

Mutations responsible for these developmental defects are the subject of active investigation. Mutations in the human *HESX1* gene cause agenesis of the corpus callosum and panhypopituitarism. Case reports of mutations in other transcription factors, such as *Pitx2* (Rieger's syndrome) and *GLI2,* describe patients with varying brain and skull developmental abnormalities along with varying degrees of hypopituitarism. Kallmann's syndrome is a condition characterized by anosmia or hyposmia and hypogonadotropic hypogonadism. The diagnosis is made by finding anosmia and low gonadotropin levels, and MRI will show absence or hypoplasia of the olfactory bulbs. The X-linked form of Kallmann's syndrome, representing about 85% of cases, is due to a gene defect (*KAL1*) resulting in loss of function of a protein called anosmin that facilitates the embryologic migration of GnRH-producing neurons from the olfactory placode to the hypothalamus and the olfactory nerves to the olfactory bulbs. The pituitary is usually intact in this condition, and treatment with pulsatile GnRH therapy or gonadotropins results in spermatogenesis and normal gonadal function. In some patients, other neurologic abnormalities may be present, including cerebellar ataxia, nerve deafness, color blindness, cleft lip and palate, mental retardation, and disordered thirst.

TUMORS

The most common tumors affecting the hypothalamus are *pituitary adenomas* that have significant suprasellar extension. These tumors can cause varying degrees of hypopituitarism and hyperprolactinemia, either by compressing the normal pituitary or, more commonly, by affecting the pituitary stalk and mediobasal hypothalamus. Surprisingly, diabetes insipidus (Chapter 232) is a rare finding in patients with pituitary adenomas. In patients with normal or elevated prolactin levels, pituitary function often returns following therapy.

Craniopharyngiomas are the next most common tumors affecting the hypothalamus. Microscopically, craniopharyngiomas consist of cysts alternating with stratified squamous epithelium. The cyst fluid is usually thick and dark, and the material is often calcified. They arise from remnants of Rathke's pouch. A closely related lesion is *Rathke's cleft cyst,* which develops from the space between the anterior and rudimentary intermediate lobes. Rathke's cleft cysts are lined with cuboidal as opposed to squamous epithelium, and the cyst fluid is usually a white, mucoid fluid. Craniopharyngiomas may be difficult to remove in their entirety, and postoperative radiation reduces recurrences. Rathke's cleft cysts less commonly recur. Craniopharyngiomas most commonly arise during childhood, but they may also occur in adults and even elderly people. These tumors come to attention because of mass effects, including headache, vomiting, visual disturbance, seizures, hypopituitarism, and polyuria. Some patients have galactorrhea, amenorrhea, and hyperprolactinemia, features suggestive of a prolactinoma. Careful endocrine testing reveals varying degrees of hypopituitarism in 50 to 75%, modest hyperprolactinemia in 25 to 50%, and often diabetes insipidus. Surgical extirpation of craniopharyngiomas commonly causes a worsening of pituitary function, often resulting in complete panhypopituitarism and diabetes insipidus because of stalk section, and may cause damage to the hypothalamic centers that regulate thirst, body temperature, and food intake. Irradiation may also be helpful, especially in children.

Suprasellar dysgerminomas arise from primitive germ cells that have migrated to the CNS during fetal life and are structurally identical to germ cell tumors of the gonads. They most commonly occur in children, in whom they cause decreased growth because of hypopituitarism, as well as diabetes insipidus and visual problems. Hyperprolactinemia occurs in more than 50% of affected children, and 10% have precocious puberty from the production of human chorionic gonadotropin by the tumor. The finding of an elevated human chorionic gonadotropin level in the spinal fluid may be diagnostic. As opposed to craniopharyngiomas, these tumors are very radiosensitive, and radiation therapy combined with chemotherapy is the preferred treatment.

A hypothalamic *hamartoma* is a nodule of growth of hypothalamic neurons attached by a pedicle to the hypothalamus between the tuber cinereum and the mammillary bodies and extending into the basal cistern. Asymptomatic hamartomas may be present in up to 20% of random autopsies; rarely, these lesions may enlarge and disrupt hypothalamic function because of compression of adjacent tissue. A variant of hamartoma consisting of similar tissue present within the anterior pituitary but without a neural attachment to the hypothalamus is called a choristoma or gangliocytoma. These neuronal tumors are of particular endocrine interest because they can produce hypophysiotropic hormones. A number of cases associated with precocious puberty have been reported in which the hamartomas produced GnRH. Successful treatment has been reported with surgery and with the administration of a long-acting GnRH analogue, which suppresses gonadotropin secretion but does not affect the tumor itself. If the hamartoma does not cause other problems from mass effects, medical therapy with the GnRH analogue may be the best choice because surgery can be noncurative or even fatal. Some gangliocytomas have been reported that produce GHRH and acromegaly or CRH and Cushing's syndrome.

Other tumors and space-occupying lesions occurring in the suprasellar area include arachnoid cysts, meningiomas, gliomas, astrocytomas, chordomas, infundibulomas, cholesteatomas, neurofibromas, lipomas, and metastatic cancer (particularly from the breast and lung). Any such lesion may manifest as varying degrees of hypopituitarism, diabetes insipidus, and hyperprolactinemia, and surgical therapy often worsens the hormonal deficit and may cause other hypothalamic damage.

INFLAMMATORY AND INFILTRATIVE DISORDERS

CNS involvement in cases of *sarcoidosis* occurs (Chapter 95) in 1 to 5% of patients, as determined on clinical grounds, and in up to 16% of cases at autopsy. Isolated CNS sarcoidosis is uncommon. When sarcoidosis does involve the CNS, the hypothalamus is involved in 10 to 20% of cases. Sarcoid granulomas can involve the hypothalamus, stalk, or pituitary and may be infiltrative or occur as a mass lesion. The most common endocrine findings are varying degrees of hypopituitarism, diabetes insipidus, and hyperprolactinemia. Obesity secondary to hypothalamic involvement by sarcoidosis has also been reported. In patients with isolated CNS sarcoidosis, the diagnosis may be extremely difficult. Examination of cerebrospinal fluid usually shows elevated protein levels, low glucose levels, pleocytosis, and variable elevations of angiotensin-converting enzyme. However, biopsy is often necessary. Although corticosteroid therapy has been reported to at least partially reverse the thirst disorders, anterior pituitary hormone deficits usually do not respond.

Langerhans cell histiocytosis infiltration of the hypothalamus may cause diabetes insipidus, varying degrees of hypopituitarism, and hyperprolactinemia. It is the most common cause of diabetes insipidus in children. Usually, this infiltration appears as a thickening of the pituitary stalk, but it may also appear as a mass lesion of the hypothalamus or the pituitary. Osteolytic

lesions may be present in the jaw or mastoid, so radiographs of the jaw are a worthwhile part of the diagnostic evaluation of an unknown suprasellar mass or diabetes insipidus. Therapy consists of local surgery, focal irradiation, or chemotherapy with alkylating agents and high-dose corticosteroids.

VASCULAR DISEASE

An enlarging aneurysm may manifest as a mass lesion of the hypothalamic-pituitary area and may cause hypopituitarism and visual field defects. Obviously, the distinction must be made before surgery. Tumors and aneurysms may also coexist, and careful radiologic evaluation with MRI is necessary to discern such association. Hypothalamic disease caused by vascular infarction is extremely rare. In the past several years, it has been found that subarachnoid hemorrhage may be associated with varying degrees of hypopituitarism in almost half of cases. On the other hand, diabetes insipidus is uncommon.

TRAUMA

Traumatic brain injury (TBI) can cause defects ranging from isolated ACTH deficiency to panhypopituitarism with diabetes insipidus. Within the first 72 hours of trauma, GH, LH, ACTH, TSH, and prolactin levels may actually be elevated in blood, perhaps because of acute release. These levels subsequently fall, and either pituitary function returns to normal or hypopituitarism develops. Overall, the frequency of hypopituitarism in TBI is less than in subarachnoid hemorrhage, occurring in about one fourth of surviving patients. In patients dying of head injury, anterior pituitary infarction has been found in 16% of cases, posterior pituitary hemorrhage in 34%, and hypothalamic hemorrhage or infarction in 42% of cases. The paraventricular and supraoptic nuclei and median eminence are particularly involved with microhemorrhages, hence the high frequency of panhypopituitarism with diabetes insipidus. With frontal injuries, the brain travels backward, but the pituitary cannot move; consequently, the pituitary stalk becomes avulsed, with interruption of the portal vessels. Most patients with head injury are hyperprolactinemic, which clinically confirms that the hypothalamus or stalk is the primary site of injury. In the past, pituitary function in patients with TBI and subarachnoid hemorrhage has not been assessed, and the role of untreated hypopituitarism in the long-term disability of such patients is unknown.

Irradiation

Whole-brain irradiation for intracranial neoplasms frequently results in hypothalamic dysfunction, as evidenced by endocrine abnormalities and behavioral changes. The most common endocrine abnormality is hyperprolactinemia, but hypopituitarism also occurs. When the radiotherapy is targeted to the hypothalamic area, hypopituitarism occurs even more frequently. The frequency of loss of pituitary function is so high that all patients who have had their pituitary and hypothalamic areas irradiated must be monitored periodically for the purpose of detecting these deficits. However, the development of such deficiencies may take many years, so that yearly testing is warranted for up to 20 years. It appears that stereotactic irradiation using the gamma knife apparatus or a linear accelerator for pituitary and other parasellar tumors causes a risk of hypopituitarism similar to that of conventional irradiation.

Effects of Hypothalamic Disease on Pituitary Function

Hypothalamic disease can cause both pituitary hyperfunction and hypofunction in varying degrees of severity. Although severe disease can cause absolute deficiencies of the various hormones, milder disease may cause a subtle alteration in feedback loops and timing such that, for example, the integration of signals necessary for menstrual cycling is lost, with subsequent "hypothalamic" amenorrhea. Furthermore, the hypothalamic defects may be interrelated. The rather common finding of hyperprolactinemia occurring with hypothalamic dysfunction causes a hypogonadotropic hypogonadism that is reversible when the elevated prolactin levels are brought down to normal. In many cases, no structural lesion can be found on MRI, and a functional defect caused by altered neurotransmitter regulation is invoked.

Growth Hormone

Loss of normal GH secretion is the most common hormonal defect occurring with structural hypothalamic disease. About three fourths of cases with congenital, idiopathic GH deficiency have a normal GH response to exogenous GHRH, which implies that the defect is probably disordered hypothalamic regulation. Defects in the gene for GHRH have not been found, but a rare form of GH deficiency has been found to be caused by a mutation in the GHRH receptor. A reversible form of idiopathic GH deficiency caused by inadequate parental care and affection is referred to as the emotional deprivation syndrome or psychosocial dwarfism. Restoration of a proper social environment for such a child results in prompt normalization of GH secretion and growth. It has been hypothesized that the disordered GH regulation is due to psychogenic alteration of the neurotransmitter balance necessary for normal GHRH and somatostatin secretion. Other systemic illnesses such as inflammatory bowel disease, often occult, may also cause decreased GH secretion and growth; treatment of the systemic illness will correct the growth abnormality. Treatment of children and adults with GH deficiency is discussed in Chapter 231.

Gonadotropins

Hypothalamic Hypogonadism

The primary defect in this group of disorders is thought to involve the secretion of GnRH, with resultant impairment in pituitary gonadotropin secretion and gonadal function. The disorders causing these conditions may be primary, that is, congenital defects, or acquired. Depending on the time of onset, they are manifested as either delayed puberty, interruption of pubertal progression, or loss of adult gonadal function. The lesions causing these disorders may cause loss of other hormones or may be isolated to GnRH. Loss of gonadotropin secretion as the result of hypothalamic structural damage is the second most common defect after GH deficiency. However, a substantial portion of these defects are due to hyperprolactinemia and are reversible with correction of the hyperprolactinemia. In some cases, the defect is idiopathic. Defects in the gene for GnRH have not been found, but mutations in the GnRH receptor do occur.

In children, if the disorder is limited to GnRH and the gonadotropins, prior growth and development are normal, but the growth spurt occurring at puberty is lost. Undescended testes are present in 50% of patients with GnRH deficiency, probably secondary to the absence of gonadotropins during fetal development. The most common congenital lesion causing prepubertal GnRH deficiency is Kallmann's syndrome, which affects 50% of males and 37% of females seen with isolated gonadotropin deficiency (see earlier). In patients with GnRH deficiency, replacement of GnRH through subcutaneous administration every 2 hours with a portable pump causes a rapid rise in LH and FSH, a rise in testosterone to normal, and the development of normal spermatogenesis. Similar approaches in women result in ovulatory cycles in 80%. The success of such therapy confirms the original hypothesis of a primary defect of GnRH secretion. In men, comparable results can be obtained with exogenous gonadotropins given three times per week and is much more practical. GnRH therapy is not successful in those with GnRH receptor mutations. Replacement with testosterone alone causes adequate androgenization but does not result in an increase in testicular size or in spermatogenesis.

Loss of formerly normal GnRH secretion in adults may be due to structural hypothalamic damage such as a tumor, a functional change unassociated with a detectable lesion, or hyperprolactinemia. Structural disease must be excluded in such patients by computed tomography or MRI. Most cases of functional hypogonadotropic hypogonadism occur in women, the most common causes being weight loss, excessive exercise, psychogenic stress, or systemic illness, but idiopathic forms occur as well. In some patients, the exercise results in a loss of body fat not detected with total body weight measures, and it is unclear whether the hypogonadism is directly due to the loss of body fat or to the exercise per se. Studies of pulsatile gonadotropin secretion in such patients reveal absent pulses. Usually, the gonadotropin response to injected GnRH is normal. Regain of weight and stopping of the exercise result in resumption of normal gonadal function. Furthermore, the administration of leptin to such women results in a resumption of normal gonadotropin pulsatile secretion and ovulation, confirming the key role that leptin has in mediating the influence of body energy stores on reproductive function. Hyperprolactinemia occurring postpubertally can also decrease GnRH and the pulsatile secretion of LH and FSH and thereby result in anovulation with oligomenorrhea and amenorrhea in women and impotence and infertility in men.

Two goals in the treatment of idiopathic, functional hypogonadotropic amenorrhea are (1) restoration of a normal estrogen status to promote well-being and to prevent osteoporosis and (2) facilitation of ovulation for fertility. The former can generally be achieved with cyclic estrogen and progesterone, whereas the latter may require clomiphene or GnRH or gonadotropin therapy. In men, similar goals may be achieved with testosterone or GnRH or gonadotropins.

Hypothalamic Hypergonadism (Precocious Puberty)

Precocious puberty is defined as the onset of puberty before the age of 8 years in girls or 9 years in boys. Pseudoprecocious puberty is that resulting from peripheral (gonadal or adrenal) causes. Central, "true," or GnRH-dependent precocious puberty is characterized by hormonal changes similar to those that occur at the time of normal puberty, that is, an increase in the pulsatile release of LH, an increase in the gonadotropin response to GnRH, and an increase in gonadal steroid secretion. GnRH-dependent precocious puberty therefore represents premature activation of the GnRH pulse generator by a variety of lesions, or it may also be idiopathic. Fewer than one fourth of cases of central precocious puberty occur in boys, but they tend to have more serious underlying disease. In boys with central, GnRH-dependent precocious puberty, hypothalamic hamartomas account for 38% of cases, other CNS lesions represent 31%, familial disease accounts for 23%, and idiopathic disease accounts for only 8%. The picture is quite different in girls, however: hypothalamic hamartomas account for only 15% of cases, other CNS lesions represent 14%, the McCune-Albright syndrome (polyostotic fibrous dysplasia) accounts for 6%, and fully 65% are idiopathic. Dysgerminomas in the suprasellar or pineal region can produce chorionic gonadotropin, which acts like LH in its stimulation of gonadal function. Usually, such tumors cause increased sex steroid formation but fail to cause ovulation.

Therapy for central GnRH-dependent precocious puberty consists of surgical removal of the tumor or medical therapy with a long-acting GnRH analogue. The latter can suppress gonadotropin and sex steroid hormone levels and cause a stabilization or even regression of secondary sex characteristics and a slowing of growth and bone maturation in most cases. When therapy is discontinued at the normal time of puberty, sex steroid levels increase, secondary sexual characteristics again develop, growth increases, and regular menses develop spontaneously.

Prolactin

Hypothalamic Hyperprolactinemia

Structural or infiltrative lesions of the hypothalamus, such as those discussed earlier, can decrease the amount of dopamine reaching the lactotrophs and thus cause modest hyperprolactinemia (usually <100 ng/mL). Because their therapy is quite different, it is very important to differentiate nonsecreting pituitary adenomas with extensive suprasellar extension causing prolactin elevations in this range from prolactin-secreting adenomas, which usually cause prolactin elevations 5 to 50 times higher. A peculiarity of some two-site immunoassays, referred to as the "hook effect," can sometimes cause a very high prolactin level to read falsely normal or just mildly elevated; a 1:100 dilution of the serum sample with saline will show the true level when the specimen is rerun. If there is any question about an assay being susceptible to the hook affect, in patients with very large tumors, prolactin should be measured undiluted and at 1:100 dilution to avoid this important spurious finding. A number of medications, antipsychotics in particular, can cause hyperprolactinemia, primarily by interfering with central catecholamines (Table 230-2).

Therapy is generally directed at the underlying cause. The hyperprolactinemia itself may impair gonadal function, so efforts may also be made to lower prolactin levels with dopamine agonists. Prolactin levels usually fall quite readily in such patients. Restoration of gonadal function is not automatic, however, because the primary hypothalamic lesion may also directly impair release of GnRH. In that circumstance, both dopamine agonists and sex steroid replacement may be necessary. When administration of psychotropic medications that cause the hyperprolactinemia cannot be stopped, dopamine agonists may be used but very rarely have been reported to exacerbate the psychosis. In such cases and in others in which fertility is not an issue, treatment with cyclic estrogen and progesterone replacement can be carried out safely.

Idiopathic Hyperprolactinemia

Idiopathic hyperprolactinemia is a diagnosis of exclusion. Prolactin levels in this condition are usually less than 100 ng/mL. In such cases, small pituitary or hypothalamic tumors could exist that are beyond the resolution of current imaging techniques, but when such patients are monitored for many years, it is very uncommon for tumors to later be visualized. Idiopathic hyperprolactinemia can cause amenorrhea, galactorrhea, impotence, infertility, and loss of libido, just as occurs with hyperprolactinemia of other causes, so the idiopathic hyperprolactinemia may need to be treated. Premature osteoporosis related to the estrogen deficiency may also occur. The only possible treatment is dopamine agonists, and these agents are successful in more than 90% of cases. Alternatively, cyclic estrogen and progesterone replacement may be given, but fertility will not be restored.

Thyroid-Stimulating Hormone

Hypothalamic hypothyroidism is due to a central lesion that impairs the secretion of TRH, usually along with the loss of other hormones. It occurs considerably less commonly than hypothalamic GH and gonadotropin deficiency. Defects in the gene for TRH have not been detected, but a case has been reported of a TRH receptor mutation causing hypothyroidism. TSH levels in this syndrome are generally normal or even slightly elevated. TSH in these patients is biologically less active than normal and binds to the TSH receptor less well because of altered glycosylation as a result of the TRH deficiency. Treatment is with L-thyroxine, and monitoring of therapy is done solely by measurement of free thyroxine (T_4) levels and not TSH levels.

Adrenocorticotropic Hormone

ACTH deficiency caused by hypothalamic lesions is uncommon. It may occur with the loss of other hormones but may also appear as an isolated deficiency. In the absence of CNS lesions or a history of trauma, most cases of isolated ACTH deficiency appear to be a pituitary autoimmune disorder. However, in patients with hypothalamic disease as the cause, basal ACTH levels are low, and the ACTH response to injected CRH may be prolonged and exaggerated, much as is the TSH response to TRH. Treatment is with glucocorticoids; mineralocorticoids are not needed.

Vasopressin

Diabetes insipidus can develop as a result of destructive lesions in the supraoptic and paraventricular nuclei or in the mediobasal hypothalamus in the path of the neural fibers containing vasopressin (Chapter 232) that are passing on to the posterior pituitary. Irritative lesions can trigger the release of vasopressin in an unregulated fashion and thereby result in the syndrome of inappropriate antidiuretic hormone (vasopressin) secretion.

Effects of Hypothalamic Disease on Other Neurometabolic Functions

A number of functions that affect the internal milieu, in addition to anterior and posterior pituitary function, are regulated, at least in part, by the hypothalamus and include temperature control, behavior, consciousness, memory, sleep, food intake, and carbohydrate metabolism.

Alterations in Food Intake

Hypothalamic Obesity

Destruction of the mediobasal hypothalamus will sometimes inhibit satiety and may result in hyperphagia and hypothalamic obesity. The hyperphagia is due to destruction of noradrenergic fibers originating in the paraventricular nucleus and passing through the mediobasal hypothalamus. Because of their location, such lesions also usually produce hypopituitarism and diabetes insipidus. In a number of rare syndromes (Prader-Willi, Laurence-Moon-Biedl-Bardet) with obesity as a major characteristic, hypothalamic causes have been postulated but not proved. Prader-Willi is the most common of these syndromes and occurs in 1 in 25,000 births. It is characterized by hypotonia, obesity, short stature, mental deficiency, hypogonadism, and small hands and feet. About 70% of patients with Prader-Willi syndrome have a chromosome 15 deletion (15q11-q13) on the paternally derived chromosome. In the few cases studied at autopsy, no discernible hypothalamic lesions were detected.

Hypothalamic Anorexia

Lesions of the lateral hypothalamus, which destroy nigrostriatal dopaminergic fibers that pass through this area, produce hypophagia along with an increase in peripheral norepinephrine turnover and metabolic rate. This syndrome is very rare, probably owing to the requirement for bilateral lesions. The hormonal changes that occur in anorexia nervosa appear to all be secondary to the weight loss, and no evidence has been found for a primary hypothalamic disorder in this syndrome.

Hyperglycemia

Hypothalamic activation as part of the generalized response to stress can cause release of GH, prolactin, and ACTH, which serve as counter-regulatory hormones with respect to insulin. These hormones promote lipolysis, gluconeogenesis, and insulin resistance, resulting in glucose elevation. Of more importance in the acute response to stress, this hypothalamic response results in sympathetic activation with release of catecholamines that inhibit insulin secretion and stimulate glycogenolysis.

Temperature Regulation

The anterior hypothalamus and preoptic area contain temperature-sensitive neurons that respond to internal temperature changes by initiating certain thermoregulatory responses necessary to restore a constant temperature. Measures that dissipate heat include cutaneous vasodilation, sweating, and panting, and measures that increase body heat include increasing metabolic heat production, shivering, and cutaneous vasoconstriction.

Rare patients have been reported with anterior hypothalamic lesions that cause paroxysmal or sustained hypothermia or hyperthermia from failure of these thermoregulatory activities. Some cases of paroxysmal hypothermia and hyperthermia respond to anticonvulsant medications, which suggests that the neuronal discharge effecting the temperature changes is seizure-like.

Poikilothermy results from an inability to dissipate or generate heat to keep the body temperature constant in the face of varying ambient temperatures. This condition results from bilateral lesions in the posterior hypothalamus and rostral mesencephalon, which are the areas responsible for the final integration of thermoregulatory neural efferents. Patients with this condition do not feel discomfort with temperature changes and are unaware of having a problem. Depending on the ambient temperature, they may experience life-threatening hypothermia or hyperthermia.

ANTERIOR PITUITARY

MARK E. MOLITCH

ANATOMY AND EMBRYOLOGY

The pituitary is divided into anterior (adenohypophysis) and posterior (neurohypophysis) lobes. The optic chiasm, formed by the decussation of the optic nerves, is positioned directly above the pituitary gland. Specialized vascular structures located in the median eminence of the hypothalamus drain into portal veins that course down the pituitary stalk to join the sinusoidal capillaries of the anterior lobe. Hypothalamic hormones enter these capillaries and flow to the anterior pituitary. Venous drainage from the anterior lobe is into the cavernous sinuses, which drain into the petrosal sinuses. The six major pituitary cell types include somatotrophs (growth hormone [GH] producing), lactotrophs (prolactin [PRL] producing), corticotrophs (ACTH producing), thyrotrophs (thyroid-stimulating hormone [TSH] producing), and gonadotrophs (follicle-stimulating hormone [FSH] and luteinizing hormone [LH] producing).

The pituitary is formed from the fusion of Rathke's pouch (which gives rise to the anterior pituitary) and a portion of the ventral diencephalon (which gives rise to the posterior pituitary). Several transcription factors are important in the development of the various types of pituitary cells. Lhx3 is present in somatotrophs, lactotrophs, and thyrotrophs, and mutations in this gene result in complete deficits of GH, PRL, TSH, and the gonadotropins. Mutations in *HESX1* usually are associated with dysplasia of the septum pellucidum and optic tracts in addition to multiple pituitary hormone deficits. The transcription factor Pit-1 is produced in somatotrophs, lactotrophs, and thyrotrophs. Mutations in the *PIT1* gene prevent the development of these cells and cause deficiencies of GH, PRL, and TSH. This lineage relationship explains why some GH-producing tumors also secrete PRL and some TSH-producing tumors co-secrete GH. Prop-1, another transcription factor, is critical for the development of somatotrophs, lactotrophs, and thyrotrophs. Mutations in the *PROP1* gene result in deficiencies of GH, PRL, and TSH and in some affected individuals there is delayed puberty. Combined pituitary hormone deficiency (GH, PRL, TSH) has an incidence of about 1 in 8000 births, and 10% have an affected relative. More than half of these cases are due to *PIT1* or *PROP1* mutations. Pitx1 and Pitx2 activate the expression of genes coding for the development of all five types of pituitary cells, and mutations of the *PITX2* gene have been found to cause combined GH-TSH and GH-ACTH deficiencies. Tpit is specific to corticotroph cells, and *TPIT* gene mutations cause isolated ACTH deficiency.

Somatotrophs constitute 40 to 50% of anterior pituitary cells; lactotrophs, 15 to 25%; corticotrophs, 10 to 20%; and gonadotrophs 10%. Only 5% of pituitary cells are thyrotrophs.

RADIOLOGY OF THE PITUITARY

Magnetic resonance imaging (MRI) provides excellent resolution of the pituitary and surrounding cerebrospinal fluid (CSF) and vascular and central

nervous system structures. There is less radiation exposure with MRI than with computed tomography (CT), allowing repeated imaging. However, bone structures are not as well defined by MRI compared with CT. On MRI, the normal anterior pituitary appears isointense with brain white matter, whereas the posterior pituitary exhibits high signal intensity ("bright spot"). The optic chiasm is readily identified because it is surrounded by hypodense areas. Pituitary adenomas typically appear hypointense on T1-weighted images and show less enhancement with gadolinium than surrounding normal tissue. Focal hypodense areas are also seen in about one fourth of normal individuals, which may correspond to cysts or nonfunctioning small adenomas, emphasizing the importance of endocrine evaluation.

REGULATION OF THE PITUITARY AXIS

The pituitary gland integrates the influences of an array of positive and negative signals to modulate hormone secretion. PRL is the only major pituitary hormone that is not subject to feedback inhibition by hormones produced in target tissues. It is controlled by positive and negative input from the hypothalamus, the latter being dominant.

The principles of feedback regulation are illustrated by the hypothalamic-pituitary-thyroid axis. Hypothalamic thyrotropin-releasing hormone (TRH) stimulates TSH secretion from the pituitary. TSH increases thyroid hormone secretion, which in turn suppresses hypothalamic TRH as well as pituitary TSH. A typical regulatory loop therefore has both positive (TRH, TSH) and negative (thyroxine [T_4], triiodothyronine [T_3]) components, allowing a high degree of control of hormone levels. The pituitary gland integrates positive TRH signals and the negative effects of thyroid hormone. The concept of feedback regulation is important not only for understanding pituitary physiology but also because it provides the basis for analyzing pituitary gland function using stimulation and suppression tests.

The feedback regulatory systems just described are superimposed on hormonal rhythms that are used for adaptation to the environment. Seasonal changes, the daily occurrence of the light-dark cycles, and stress have major impacts on the secretion of pituitary hormones (Chapter 230). Because many hormones are released in a pulsatile manner and in a rhythmic fashion, these characteristics of secretion should be considered when attempting to relate serum measurements to normal values. Although it is possible to characterize pulsatile patterns of hormone secretion using frequent blood sampling (every 10 minutes), this is not practical in a clinical setting. Alternative approaches include stimulation and suppression tests or the use of "integrated" measurements of hormone production, such as 24-hour urine free cortisol as an index of ACTH secretion or insulin-like growth factor-I (IGF-I) as a biologic marker of GH action.

HYPOPITUITARISM

Pituitary hormone deficiencies can be caused by loss of hypothalamic stimulation or by direct loss of pituitary function. When hypopituitarism is accompanied by diabetes insipidus or hyperprolactinemia, one should consider hypothalamic etiologies.

PATHOBIOLOGY

A variety of congenital and acquired causes of hypopituitarism have been described (Table 231-1). Congenital deficiencies of multiple pituitary hormones are often caused by mutations in the genes for the transcription factors mentioned previously (*HESX1, LHX3, PIT1, PROP1*). Gene mutations have been found at several steps leading to pituitary hormone secretion, including those for the hypophysiotropic releasing factor receptors for gonadotropin-releasing hormone (GnRH), growth hormone–releasing hormone (GHRH), and TRH; those for the pituitary hormone structures for GH, ACTH, and the β-subunits of FSH, TSH, and LH; and those for the target organ receptors for GH, ACTH, TSH, and LH. Mutations of the GH gene have been shown to be heterogeneous. Some are large deletions that are inherited in an autosomal recessive manner and involve genetic recombination between related DNA sequences in the duplicated GH gene cluster. Point mutations have also been described, and some of these can be inherited in an autosomal dominant manner. Mutations of the other types described earlier generally cause autosomal recessive forms of selective hormone deficiencies. The congenital embryopathic disorders causing hypopituitarism are discussed in Chapter 230.

Neoplastic lesions, particularly pituitary macroadenomas, are the most common cause of acquired hypopituitarism. Pituitary adenomas cause hypopituitarism in several different ways. In some cases, there is direct destruction or compression of the normal pituitary. Compression of the pituitary stalk can impair blood supply to the pituitary as well as decrease input from hypothalamic hormones. Hemorrhage into tumors can lead to pituitary infarction. A mild degree of hyperprolactinemia (usually <200 ng/mL) is characteristic of disorders that cause stalk compression, and hyperprolactinemia further impairs gonadotropin secretion. A variety of other neoplasms that occur near the sella, such as craniopharyngiomas, can also cause hypopituitarism (see Table 231-1).

Radiation causes hypopituitarism primarily because of its effects on hypothalamic function, although high-dose radiation (e.g., proton beam) can also cause direct pituitary damage. The sellar region is subjected to radiation in the treatment of pituitary adenomas, craniopharyngiomas, optic gliomas, meningiomas, dysgerminomas, and neoplasms of the oropharynx. The effects of radiation can be delayed several years, and patients at high risk should be evaluated yearly. Although GH and gonadotropin deficiencies develop first in most patients, ACTH or TSH deficiencies occasionally occur first, emphasizing the need to evaluate each of the major axes.

TABLE 231-1 CAUSES OF HYPOPITUITARISM

GENETIC DEFECTS
Hypophysiotropic hormone gene defects
Hypophysiotropic hormone receptor gene defects
GHRH receptor defect
GnRH receptor defect
TRH receptor defect
Pituitary hormone gene defects
Gonadotropins: LH β- and FSH β-subunit gene defects
Growth hormone: defects in GH gene
Thyrotropin: defects in TSH β-subunit gene
Multiple hormone (GH, PRL, TSH) defects: due to mutation in *PIT1* gene and *PROP1* gene
Pituitary hormone receptor genetic defects
Growth hormone receptor defects: GH insensitivity syndrome (Laron-type dwarfism)
ACTH receptor defects: congenital insensitivity to ACTH
LH receptor defects
FSH receptor defects
TSH receptor defects
CONGENITAL EMBRYOPATHIC DEFECTS
Anencephaly
Midline cleft defects: septo-optic dysplasia, basal encephalocele, cleft lip and palate
Pituitary aplasia
Kallmann's syndrome (GnRH defect with anosmia)
ACQUIRED DEFECTS
Tumors: pituitary adenomas, craniopharyngiomas, dysgerminomas, meningiomas, gliomas, metastatic tumors, hamartomas, Rathke's cleft cysts
Irradiation
Trauma: surgery, external blunt trauma
Empty sella syndrome
Vascular
Pituitary apoplexy
Sheehan's syndrome
Internal carotid aneurysm
Vasculitis
Subarachnoid hemorrhage
Inflammatory and infiltrative diseases
Sarcoidosis
Langerhans' cell histiocytosis (histiocytosis X, eosinophilic granuloma)
Tuberculosis, syphilis
Meningitis
Lymphocytic hypophysitis, infundibulohypophysitis
Metabolic
Hemochromatosis
Amyloidosis
Critical illness
Malnutrition
Anorexia nervosa
Psychosocial deprivation
Idiopathic

ACTH = adrenocorticotropic hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone releasing hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; PRL = prolactin; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

Empty sella syndrome can occur as a primary or as an acquired condition. It is caused by defects in the diaphragma sella that allow herniation of the arachnoid membrane into the hypophyseal fossa. In long-standing cases, sellar enlargement occurs, probably because of persistent transmission of intracranial pressure. Imaging studies reveal the pituitary gland as a flattened rim of tissue along the floor of the sella. Primary empty sella occurs most commonly in women and may be associated with features of benign intracranial hypertension. Pituitary function is usually normal, but 10% have mild hyperprolactinemia, probably because of stretching of the pituitary stalk. Acquired forms may occur as a result of surgery, radiation, or pituitary infarction (usually of an adenoma).

Pituitary apoplexy is a syndrome caused by hemorrhage into a tumor with associated infarction and leakage of the blood into the arachnoid space, with resultant fever and stiff neck. When the hemorrhage is large, there can be mass effects with headache and cranial nerve compression within the cavernous sinus. Asymptomatic infarctions are found in about 10 to 15% of pituitary adenomas. In the absence of a tumor, predispositions to apoplexy include trauma, pregnancy, anticoagulation, sickle cell anemia, and diabetes mellitus. Pituitary infarction in the peripartum period (*Sheehan's syndrome*) is usually associated with significant obstetric hemorrhage and hypovolemia. Although Sheehan's syndrome can manifest acutely with vascular collapse, it more commonly has a subacute manifestation consisting of postpartum inability to lactate, amenorrhea, and symptoms of adrenal insufficiency.

Infiltrative diseases such as sarcoidosis, histiocytosis, and tuberculosis cause hypopituitarism by infiltrating the hypothalamus and stalk rather than the pituitary. In lymphocytic hypophysitis, there is massive infiltration of the pituitary by lymphocytes and plasma cells with destruction of the parenchyma; it is believed to have an autoimmune basis. The lesion is usually large, and patients present with either symptoms or signs of hypopituitarism or those of a mass lesion (i.e., visual field defects and headaches). Some patients may have mild hyperprolactinemia and diabetes insipidus. Almost all cases have been reported in women, and most present during or after pregnancy. Because of the presentation as a mass lesion during pregnancy, such lesions may be confused with prolactinomas. Mild PRL elevation points to a nonsecretory lesion rather than a prolactinoma. MRI cannot reliably differentiate pituitary adenoma from hypophysitis, although hypophysitis usually manifests with a diffuse enlargement of the pituitary that enhances, rather than as a focal lesion. Diagnosis is usually made by biopsy, but the lesion may be suspected clinically if it manifests during or just after pregnancy. Careful pituitary function testing is mandatory because many patients have died of adrenocortical insufficiency. Although the prognosis is not clear, a number of cases have resolved spontaneously. An entity with similar histologic findings involving the stalk and posterior pituitary, referred to as *infundibuloneurohypophysitis*, can cause diabetes insipidus. A third variant, *panhypophysitis*, involves both lobes of the pituitary. These last two forms occur in both sexes and are generally not associated with pregnancy. The causes and interrelationships between these entities remain unknown.

The pituitary may undergo damage because of iron deposition in patients with hemochromatosis (Chapter 219) and amyloid fibrils in patients with systemic amyloidosis (Chapter 194). Functional, reversible hypopituitarism of varying degrees occurs in patients with severe systemic illness, severe psychosocial and emotional deprivation, and severe weight loss—particularly in those with anorexia nervosa.

DIAGNOSIS AND TREATMENT

Rx

The diagnosis of hypopituitarism rests on the stimulation tests that are summarized in Table 231-2. Therapy depends on the nature and severity of the hormone deficiencies as well as on the desired clinical end points. The goals are to replace hormones in a physiologic manner and to avoid the consequences of over-replacement. Examples of hormonal replacement paradigms are provided in Table 231-3. Adjustment of hormone doses is done primarily based on clinical findings; TSH levels are not helpful for adjusting thyroxine doses in patients with central hypothyroidism. Even when conventional hormone replacement (adrenal, thyroid, gonadal) is carried out appropriately, there is a twofold excess risk for death. Although untreated GH deficiency has been hypothesized to be the cause of this excess risk, this has not been proved. The benefits of GH therapy are less clear than those of the other pituitary hormones and include improvements in body composition, bone, lipids, and quality of life; although there are few adverse effects, treatment involves daily injections.

PITUITARY TUMORS

PATHOBIOLOGY

Pituitary tumors are classified according to the hormones that they produce and their size: microadenomas, less than 10 mm in diameter; macroadenomas, more than 10 mm in diameter; and macroadenomas with extrasellar extension. In general, the levels of hormones produced by the tumors parallel the size of the tumors. The prevalence of the different types of pituitary adenomas, based on surgical data, is summarized in Table 231-4. Immunohistochemical studies, using antibodies specific for each of the major pituitary hormones, have been used to define tumor phenotype. Pituitary adenomas are rarely malignant but can be locally invasive.

Most pituitary tumors are monoclonal. This finding does not exclude a role for hormonal stimulation as a predisposing factor for somatic mutations, and the hormonal environment may also affect the rate of tumor growth (e.g., Nelson's syndrome). Supporting the concept that somatic mutations lead to pituitary tumorigenesis, a subset (35 to 40%) of somatotroph adenomas have activating mutations in the gene for the Gsα-subunit, resulting in two different amino acid (Arg201 and Glu227) substitutions. Either mutation causes the Gsα-subunit to stimulate adenylyl cyclase in a constitutive manner. The elevated intracellular cyclic adenosine monophosphate levels lead to increased cell growth as well as GH production. Mutations in other oncogenes, such as *ras, Rb,* and *p53* are uncommon in pituitary tumors. Thus, the nature of the somatic mutations causing most pituitary tumors remains unknown.

Three types of inherited predispositions to pituitary tumors are recognized. Patients with McCune-Albright syndrome (Chapter 239) occasionally develop pituitary adenomas as well as characteristic abnormalities in other tissues, particularly the ovary, bone, and thyroid. Interestingly, the McCune-Albright syndrome is also caused by mutations in the gene for the Gsα-subunit. However, the somatic mutations in McCune-Albright occur early during development, so that multiple tissues are affected. In multiple endocrine neoplasia type 1 (MEN 1) (Chapter 239), the predisposition to pituitary tumors is inherited in an autosomal dominant manner and occurs in conjunction with tumors of the parathyroid and pancreas. Familial isolated pituitary adenoma (FIPA) syndrome is autosomal dominant and has low or variable penetrance. Germline mutations have been found in the gene for the aryl hydrocarbon receptor–interacting protein (*AIP*), which functions as a tumor suppressor. Such mutations have been found in about one third of FIPA families, most commonly in those with GH- and PRL-producing tumors.

CLINICAL MANIFESTATIONS

Mass Effects of Pituitary Adenomas

Many of the clinical manifestations of pituitary adenomas are related to the hypersecretion of hormones. However, the mass effects of the enlarging tumor can also lead to specific signs and symptoms (Chapter 195). Particularly in the case of nonfunctioning tumors or in those that produce gonadotropins, the primary clinical manifestations are related to effects of the tumor on surrounding structures.

Headaches are common in patients with macroadenomas and appear to be caused by expansion of the diaphragma sellae or by invasion of bone. The sudden onset of severe headache associated with nausea, vomiting, and altered consciousness can also be caused by hemorrhagic infarction with sudden enlargement of a pituitary adenoma. Severe cases require glucocorticoid treatment and possible surgical decompression.

Pituitary tumors that extend superiorly can affect visual fields. Expansion into the suprasellar region exerts pressure on the optic chiasm, usually in the central region where nerves emanating from the inferior and medial part of the retina (superior and temporal visual fields) cross, leading to bitemporal hemianopsia. Visual field loss is variable, however, and is affected by the location and flexibility of the chiasm as well as by the direction and extent of tumor growth. Large tumors may invade the cavernous sinus or surround an optic nerve, leading to other patterns of visual field changes or loss of visual acuity. The tumor size and the direction and degree of extrasellar extension are best evaluated with MRI with gadolinium. If the tumor abuts the chiasm on MRI, formal visual field testing should be performed. Even long-standing visual loss may be reversible.

The normal pituitary is often compressed into a thin rim of tissue by large pituitary adenomas. Hypopituitarism probably results more from compression of the hypothalamic-pituitary stalk than from direct pressure on the normal pituitary. GH deficiency and hypogonadotropic hypogonadism are

TABLE 231-2 TESTS OF PITUITARY INSUFFICIENCY

HORMONE	TEST	INTERPRETATION
Growth hormone (GH)	*Insulin tolerance test:* Regular insulin (0.05-0.15 U/kg) is given IV and blood is drawn at −30, 0, 30, 45, 60, and 90 min for measurement of glucose and GH.	If hypoglycemia occurs (glucose < 40 mg/dL), GH should increase to >5 μg/L.*
	Arginine-GHRH test: GHRH 1 μg/kg IV bolus followed by 30 min infusion of L-arginine (30 g)	Normal response is GH > 4.1 μg/L.
	Glucagon test: 1 mg IM with GH measurements at 0, 60, 90,120, 150 and 180 min	Normal response is GH >3 μg/L.
Adrenocorticotropic hormone (ACTH)	*Insulin tolerance test:* Regular insulin (0.05-0.15 U/kg) is given IV and blood is drawn at −30, 0, 30, 45, 60, and 90 min for measurement of glucose and cortisol.	If hypoglycemia occurs (glucose < 40 mg/dL), cortisol should increase by >7 μg/dL or to >20 μg/dL.
	CRH test: 1 μg/kg ovine CRH IV at 8 AM with blood samples drawn at 0, 15, 30, 60, 90, 120 min for measurement of ACTH and cortisol	In most normal individuals, the basal ACTH increases twofold to fourfold and reaches a peak (20-100 pg/mL). ACTH responses may be delayed in cases of hypothalamic dysfunction. Cortisol levels usually reach 20-25 μg/dL.
	Metyrapone test: Metyrapone (30 mg/kg to max. 2 g) at midnight with measurements of plasma 11-deoxycortisol and cortisol at 8 AM. ACTH can also be measured. A 3-day test is also available. Basal cortisol should be >5-6 μg/dL before test.	A normal response is 11-deoxycortisol > 7.5 μg/dL or ACTH > 75 pg/mL. Plasma cortisol should fall below 4 μg/dL to ensure an adequate response.
	ACTH stimulation test: ACTH 1-24 (Cosyntropin), 0.25 mg IM or IV. Cortisol is measured at 0, 30, and 60 min.	A normal response is cortisol >18 μg/dL. In suspected hypothalamic-pituitary deficiency, a low-dose (1-μg) test may be more sensitive.
Thyroid-stimulating hormone (TSH)	*Basal thyroid function tests:* free T_4, free T_3, TSH	Low free thyroid hormone levels in the setting of TSH levels that are not appropriately increased.
Luteinizing hormone (LH), follicle-stimulating hormone (FSH)	*Basal levels of LH, FSH, testosterone, estrogen*	Basal LH and FSH should be increased in postmenopausal women. Low testosterone levels in conjunction with low or low-normal LH and FSH are consistent with gonadotropin deficiency.
	GnRH test: GnRH (100 μg) IV with measurements of serum LH and FSH at 0, 30, and 60 min	In most normal persons, LH should increase by 10 IU/L and FSH by 2 IU/L. Normal responses are variable, and repeated stimulation may be required.
	Clomiphene test: clomiphene citrate (100 mg) is given orally for 5 days. Serum LH and FSH are measured on days 0, 5, 7, 10, and 13.	A 50% increase should occur in LH and FSH, usually by day 5.
Multiple hormones	*Combined anterior pituitary test:* GHRH (1 μg/kg), CRH (1 μg/kg), GnRH (100 μg) are given sequentially IV. Blood samples are drawn at −30, 15, 30, 60, 90, and 120 min for measurements of GH, ACTH, LH, and FSH.	Combined or individual releasing hormone responses must be evaluated in the context of basal hormone values and may not be diagnostic (see text).

*Values are with polyclonal assays.
CRH = corticotrophin-releasing hormone; GHRH = growth hormone-releasing hormone; GnRH = gonadotropin-releasing hormone; IM = intramuscularly; IV = intravenously; T_3 = triiodothyronine; T_4 = thyroxine; TRH = thyrotropin-releasing hormone.

TABLE 231-3 HORMONAL REPLACEMENT THERAPY IN HYPOPITUITARISM*

PITUITARY AXIS	HORMONAL REPLACEMENTS
Growth hormone (GH)	In children, GH (0.25 mg/kg) SC daily. In adults, GH (0.3-1.2 mg) SC daily. Titrate dose to achieve IGF-1 levels in middle to upper part of normal range. Women receiving oral estrogens require higher doses.
Prolactin	None
Adrenocorticotropic hormone–cortisol	Hydrocortisone (10-15 mg PO q AM; 5-10 mg PO q PM)or prednisone (2.5 mg PO q AM; 2.5 mg PO q PM). Dose adjusted on clinical basis. Stress dosing: 50-75 mg hydrocortisone IV q8hr
Thyroid-stimulating hormone–thyroid	L-Thyroxine (0.075-0.15 mg) PO qd
Gonadotropins-gonads	FSH and LH (or hCG) can be used to induce ovulation in women. hCG alone or with FSH can be used to induce spermatogenesis in men. Pulsatile GnRH (via pump) is less commonly used for GnRH-deficient subjects. In men, testosterone enanthate (100-300 mg) IM q1-3wk or testosterone cyclopentylpropionate (100-300 mg) IM q1-3wk. Testosterone transdermal patches can also be used (5 mg qd). Testosterone gel (1%) 1-2 packets (5-10 g) daily In women, conjugated estrogens (0.625-1.25 mg) or mestranol (35 mg) PO days 1-25 each month cycled with medroxyprogesterone acetate (5-10 mg) PO days 15-25 each month. Low-dose contraceptive pills may also be used. Estrogen-containing transdermal patches are also available.
Posterior pituitary	Desmopressin, 0.05-0.2 mL (5-20 μg) intranasally once or twice daily, or tablets (0.1-0.4 mg q8-12hr) or 0.5 mL (2 μg) SC.

*Replacement therapy is dictated by the types of hormone deficiencies and by the clinical circumstances. In each case, the recommended preparations and doses are representative but need to be adjusted for individual patients. Other hormonal preparations are also available.
FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; hCG = human chorionic gonadotropin; IGF-I = insulin-like growth factor-I; IM = intramuscularly; LH = luteinizing hormone; PO, orally; SC = subcutaneously.

particularly common. Slightly elevated PRL levels (generally <200 ng/mL) occur in cases of stalk compression because of diminished inhibition by dopamine. It is important not to mistake such tumors for prolactinomas because they will not decrease in size in response to medical therapy with dopamine agonists. A peculiarity of some two-site immunoassays, referred to as the "hook effect," can sometimes cause a very high prolactin level to read falsely normal or just mildly elevated; a 1:100 dilution of the serum sample with saline will show the true prolactin level. Preoperative hypopituitarism caused by a large pituitary mass is reversible in up to half of patients after surgical decompression. Diabetes insipidus (vasopressin deficiency) is rarely caused by pituitary tumors and should raise the suspicion of a craniopharyngioma or other hypothalamic disorders.

TABLE 231-4 PREVALENCE OF DIFFERENT TYPES OF PITUITARY ADENOMAS

TYPE OF PITUITARY ADENOMA	DISORDER	HORMONE PRODUCED	PREVALENCE (%)*
Somatotroph	Acromegaly and gigantism	Growth hormone	10-15
Lactotroph (prolactinoma)	Hypogonadism, galactorrhea	Prolactin	25-40
Corticotroph	Cushing's disease	Adrenocorticotropic hormone	10-15
Gonadotroph	Mass effects, hypopituitarism	Follicle-stimulating hormone and luteinizing hormone	15-20
Thyrotroph	Hyperthyroidism	Thyroid-stimulating hormone	<3
Nonfunctioning/ null cell	Mass effects, hypopituitarism	None	10-25

*The prevalence rates represent ranges described in several different large surgical series. Mixed tumors (e.g., growth hormone and prolactin) and plurihormonal adenomas are not shown. Rates vary depending on methods used to establish the diagnosis. Prolactinomas were underestimated in most recent pathologic series because they are largely managed medically. Most glycoprotein hormone–producing pituitary tumors were classified as nonfunctioning adenomas until the application of immunohistochemical studies.

TREATMENT

Surgery

Except for prolactinomas, surgery is the primary mode of therapy for pituitary tumors that warrant intervention. Indications for surgery include reduction in hormone levels and decompression to relieve mass effects or to prevent further tumor expansion. Currently, the transsphenoidal route, usually with an endoscopic, endonasal approach, is used almost exclusively for decompression or extirpation of pituitary tumors. Because of substantially greater morbidity, subfrontal craniotomy is reserved for patients with tumors that require extensive exploration of the suprasellar region and surrounding structures. In experienced hands, transsphenoidal surgery is effective, and complications are uncommon (<5% complication rate) but include CSF leak, hemorrhage, optic nerve injury, hypopituitarism, and sinusitis. Transient diabetes insipidus occurs in about 5% of patients after surgery but rarely persists long term. Mortality rates are less than 1%. Complication rates increase with increasing size of the tumor and when a craniotomy is performed.

Surgical cure rates are largely a function of the size and location of the pituitary mass. When stringent hormonal criteria are used to assess surgical success rates, less than 30% of macroadenomas are cured by transsphenoidal surgery, although considerable improvements in hormone levels or mass effects can be achieved. On the other hand, hormone hypersecretion by microadenomas can be corrected completely in 80 to 90% of patients, although the cure rates vary considerably at different institutions. Even with apparent surgical cure, 10 to 20% of tumors may recur over several years, resulting in a redevelopment of the hormone oversecretion syndrome.

Radiation Therapy

Irradiation is usually used as adjunctive therapy after surgery or in combination with medical therapy. Radiation has typically been administered over 5 weeks at a dose of 45 Gy using cobalt-60 or a linear accelerator. Proton beam therapy delivers very high doses of radiation within a localized region, but it is limited to intrasellar lesions and is not widely available. More recently, a radiation therapy technique referred to as stereotactic radiotherapy has been employed for many patients with pituitary tumors. With this technique, approximately the same dosage of radiation is administered as a single dose through multiple ports using a computerized matching of irradiation to tumor geometry. Response rates are slow (several years, but somewhat more rapid with stereotactic therapy). Complete remission is rarely achieved with any of these types of irradiation. Stereotactic radiotherapy appears to be particularly useful for residual tumor in the cavernous sinus because the normal structures that course through that area (carotid artery, cranial nerves III, IV, V_1, V_2, VI) are relatively radioresistant. Because the time to recurrence for most nonfunctioning macroadenomas is 5 to 10 years, and not all tumors recur, it is often reasonable to follow patients with imaging techniques, reserving irradiation for those with evidence of residual tumor or recurrence if no tumor was visible postoperatively.

Complications of irradiation are dose related but can also be idiosyncratic. Partial or complete hypopituitarism occurs in 50 to 70% of patients and is primarily due to hypothalamic injury. Conventional irradiation is associated with an increased risk for stroke. Second tumors occur in the radiation field in about 2% of patients over a 20-year period. Less common complications include optic nerve damage, brain necrosis, and cognitive dysfunction. Whether stereotactic radiotherapy will have similar rates of complications is at present unknown. Early studies show that hypopituitarism is developing at a rate similar to that seen with conventional therapy.

Medical Therapy

The emergence of medical therapies for pituitary tumors has dramatically affected patient management. Dopamine agonists, bromocriptine and cabergoline, have a primary role in the management of prolactinomas. They induce a rapid fall in PRL levels and, importantly, decrease tumor size. Dopamine agonists are also used in the management of acromegaly, although the GH responses and effects on tumor size are much less pronounced than in prolactinomas. Somatostatin analogues, such as octreotide and lanreotide, act to suppress the secretion of a number of hormones, including GH and TSH, and have been used to treat acromegaly and TSH-producing tumors. Medical therapy for Cushing's disease is primarily directed toward inhibition of steroid biosynthesis. These drugs include ketoconazole, metyrapone, etomidate, and mitotane. Because of substantial side effects and because patients with Cushing's disease tend to escape from the cortisol-suppressing effects of these drugs, medical therapy is used primarily as an adjunctive treatment or to reduce cortisol levels preoperatively. Another new category of drugs to treat pituitary tumors includes the receptor blockers. Pegvisomant is a GH analogue with altered binding to the GH receptor that competitively inhibits GH binding to its receptor and is used in the treatment of acromegaly. Mifepristone can block the action of cortisol at its receptor and is being evaluated for the treatment of Cushing's syndrome.

GROWTH HORMONE

The most important regulators of GH are the hypothalamic hormones: GHRH, which is stimulatory, and somatostatin, which is inhibitory. GH increases the production of IGF-I (formerly known as somatomedin C). The Gsα-subunit, which is coupled to the GHRH receptor, is one of the targets for activating mutations that lead to somatotroph adenomas.

IGF-I inhibits GH secretion, and it acts at both the pituitary and hypothalamic levels. In addition to reflecting GH action (primarily at the liver), serum IGF-I is also sensitive to nutritional and metabolic changes. In cases of starvation, anorexia nervosa, and poorly controlled diabetes, IGF-I levels are low, resulting in increased levels of GH. In cases of obesity, GH levels are low, and GHRH responses are blunted, but IGF-I levels are generally normal and actually increase with increasing body mass index. Stress, exercise, and a variety of neurogenic stimuli also increase GH secretion. Estrogens stimulate GH secretion, but their effects are less pronounced than for PRL, and they inhibit the stimulatory effect of GH on IGF-I production.

Large bursts of GH secretion characteristically occur at night in association with slow-wave sleep. GH levels increase during puberty and decline gradually in adulthood. The amplitude of GH pulses is greater in women than in men, likely reflecting the effects of estrogens. Spontaneous GH pulses can reach 50 ng/mL; consequently, random GH levels can be quite variable. GH responses to GHRH are also variable even within an individual, owing to changes in endogenous somatostatin tone.

GH acts through a single transmembrane receptor that is structurally related to PRL and cytokine receptors. The GH molecule has two distinguishable receptor binding domains that allow it to contact two separate receptor molecules to induce receptor dimerization. Mutations in the gene for the GH receptor cause GH resistance and severe growth retardation, a condition referred to as the GH insensitivity syndrome (Laron-type dwarfism). GH levels are elevated and IGF-I levels are low, reflecting the inability of the mutant receptor to transduce the GH signal. Mutations have also been found in signaling intermediates (such as the signal transducers of activators of transcription *STAT5b* gene) that mediate GH actions.

Many of the growth and metabolic effects of GH are transmitted indirectly through the actions of IGF-I. GH stimulates IGF-I production in most tissues, where it then exerts autocrine or paracrine effects. Circulating IGF-I is derived predominantly from the liver and is a useful marker of GH action because it has a longer half-life and integrates the effects of GH pulses. Although IGF-I levels are used in the diagnosis of acromegaly and to assess the integrity of the GH axis, factors other than GH (e.g., malnutrition) can alter IGF-I levels. IGF-I acts through widely distributed receptors that are structurally related to insulin receptors. In addition to its growth-promoting and anabolic effects, IGF-I also stimulates mitogenesis in many tissues. The bioactivity of IGF-I is itself modulated by six IGF-binding proteins (IGFBPs). These IGFBPs can inhibit or enhance IGF actions. IGFBP-3 is the major IGFBP in plasma; it is regulated by GH, and its levels generally parallel those of IGF-I.

GH has its major effects on linear growth but also influences a variety of metabolic pathways. Some of these effects are mediated by GH directly, whereas others are conferred by IGF-I. Although the relative roles of GH and IGF-I are debated, their actions are cooperative in many cases. The effects of GH on linear growth appear to be mediated largely by IGF-I, which has been used to stimulate growth in patients with the GH insensitivity syndrome. Linear growth in the fetus and neonate is not GH dependent, as illustrated by the fact that GH-deficient infants have normal birth lengths, although intrauterine IGF-I and IGF-II may be important for fetal growth independent of GH. In contrast, normal postnatal linear growth requires GH, as illustrated by the clinical manifestations of GH deficiency. GH and IGF-I act together to accelerate linear growth markedly, particularly at the time of puberty when sex steroids enhance GH and IGF-I levels.

Growth hormone also induces lipolysis and stimulates anabolic activity, including amino acid uptake and protein synthesis. As a result, it reduces body fat, increases lean body mass, and leads to positive nitrogen balance. These properties of GH are most strikingly seen in GH-deficient children who have undergone replacement. GH opposes many of the actions of insulin and can be considered diabetogenic. In diabetic individuals, nocturnal GH secretion accounts in large part for the dawn phenomenon, in which there is a decrease in glucose utilization, causing a tendency toward hyperglycemia.

GROWTH HORMONE DEFICIENCY

Causes of GH deficiency include hypothalamic-pituitary disorders, GHRH receptor mutations, GH gene mutations, combined pituitary hormone deficiencies, GH receptor mutations, IGF-I receptor mutations, radiation, and psychosocial deprivation (Chapter 230). The clinical manifestations of GH deficiency depend on the time of onset and the severity of hormone deficiency. Children with complete GH deficiency have slow linear growth rates (approximately 3 cm/year), and they rapidly fall below normal on standardized growth charts. GH-deficient children have normal skeletal proportions, and many have a pudgy, youthful appearance because of decreased lipolysis. Particularly in the setting of cortisol deficiency, there is a predisposition to hypoglycemia.

Basal GH does not provide a reliable measure of GH reserve, whereas low IGF-I is consistent with GH deficiency. However, not all patients documented to have GH deficiency by stimulation testing have IGF-I levels that are below the normal range. GH deficiency is assessed using insulin-induced hypoglycemia, which activates central nervous system pathways, leading to stimulation of both GH and ACTH secretion (see Table 231-2). The insulin tolerance test requires careful monitoring for symptoms of severe hypoglycemia, such as confusion or depressed consciousness. This test should be avoided in patients with seizure disorders or coronary artery disease. Insulin doses (0.1 to 0.15 U/kg) may need to be decreased if glucocorticoid deficiency is suspected or increased in conditions of insulin resistance (e.g., obesity). Alternatives to the insulin tolerance test for evaluation of GH are a combination of arginine and GHRH given intravenously or glucagon given intramuscularly.

TREATMENT

Rx

In children with well-documented GH deficiency, GH replacement is effective and is essential to increase final adult height. In a typical regimen, recombinant GH (0.025 mg/kg) is given daily as subcutaneous injections. The efficacy of GH treatment depends on when it is initiated as well as replacement of other hormone deficiencies, if they coexist. In the setting of multiple hormone deficiencies, replacement of thyroid hormone and cortisol is necessary for effective GH action. On the other hand, sex steroids lead to epiphyseal closure and limit linear growth. Consequently, GH is more effective before puberty; if exogenous sex steroids are given, low doses should be used. GH has also been shown to increase the final height of girls with Turner's syndrome (chromosomal XO state) and children with end-stage renal disease.

Only about one third of children with isolated, idiopathic GH deficiency are found to be GH deficient when retested as adults. Thus, all such patients should be retested before GH therapy is continued or restarted unless they have proven molecular defects as the cause of their GH deficiency. Studies show that GH treatment can increase lean body mass, decrease fat mass, and improve the sense of well-being in adults with documented GH deficiency. In most studies, safety data for long-term GH administration show negligible adverse effects. Whether GH treatment in adults will affect the increased mortality rate associated with hypopituitarism remains to be seen. Adverse effects occur at lower doses in adults compared with children; a starting dose of 0.2 to 0.3 mg/day has been recommended, with gradual titration guided by clinical benefits, adverse effects, and IGF-I levels.

GROWTH HORMONE EXCESS: ACROMEGALY AND GIGANTISM

PATHOBIOLOGY

GH-producing pituitary tumors account for 10 to 15% of pituitary tumors (see Table 231-4). GH-producing tumors are frequently mixed tumors that secrete more than one hormone. PRL is produced in about 40% of somatotroph adenomas, and some patients may present because of symptoms due to the hyperprolactinemia (i.e., amenorrhea, galactorrhea, or both). Ectopic production of GHRH (usually carcinoid or pancreatic islets) is a well-documented but rare (<1%) cause of acromegaly that can result in somatotroph hyperplasia. Activating Gsα-subunit mutations occur in 35 to 40% of somatotroph adenomas. Molecular defects in the remaining 60 to 65% of somatotroph adenomas remain unidentified.

CLINICAL MANIFESTATIONS

Tumors that secrete GH cause acromegaly in adults and gigantism in children in whom GH excess occurs before epiphyseal closure. Acromegaly affects men and women with equal frequency and is most often recognized when patients are in their 30s or 40s, usually after a decade of GH excess. The most striking features of acromegaly usually involve the face, hands, and feet. The diagnosis is often suspected because of changes in facial appearance that include enlargement of the lower jaw (prognathism), the nose and lips, and the sinuses (causing frontal bossing) (Fig. 231-1). Oral cavity changes include malocclusion, increased spacing between the teeth, and enlargement of the tongue. A hollow, resonant voice is caused by changes in the vocal cords and the soft tissues of the hypopharynx. Sleep apnea may occur in patients with soft tissue obstruction of the pharynx but may also occur because of a central disorder. In addition to bony enlargement, there is a marked increase in the soft tissue of the hands and feet, leading to progressive increases in ring, glove, and shoe size. A moist, doughy, enveloping handshake is characteristic

FIGURE 231-1. Clinical features of acromegaly. Serial photographs of a 64-year-old woman with acromegaly. Over an 11-year period, there is a progressive coarsening of facial features, including enlargement of the nose and lips and development of prognathism. She also experienced hypertension, arthropathy, and enlargement of the hands (not shown). (From Molitch ME. Clinical manifestations of acromegaly. *Endocrinol Metab Clin North Am.* 1992;21:597-614.)

of acromegaly. Arthritis (hands, feet, hips, knees) is common (75%) and is caused by cartilage and synovial overgrowth. Some degree of carpal tunnel syndrome is seen in about half of patients. Skin changes include increased skinfolds, particularly over the brow and forehead. The skin is usually oily, owing to increased sebaceous activity and sweating. Skin tags are common, and their presence correlates with the presence of colonic polyps. Galactorrhea may be seen in women, and reproductive dysfunction occurs in both women and men when PRL levels are elevated. Headaches, visual field defects, and other neurologic symptoms depend on the location and extent of tumor growth.

Acromegaly causes a two- to three-fold increase in mortality rate. Most of the increased mortality can be attributed to cardiovascular and cerebrovascular diseases and may be related to the increased prevalence of hypertension (25 to 35%) and diabetes mellitus (10 to 25%) in patients with acromegaly. There is evidence for cardiac hypertrophy in most patients, and symptomatic heart disease, consisting of coronary ischemia or congestive heart failure or both, occurs in 15 to 20% of patients. Sleep apnea may predispose patients to cardiac dysrhythmias. Some analyses have found an increased risk of premalignant polyps and colon cancer, and screening with colonoscopy is generally recommended. The disfigurement, metabolic complications, and increased mortality associated with acromegaly emphasize the importance of early diagnosis and implementation of appropriate therapy to lower the GH levels into the normal range.

DIAGNOSIS

Because GH is secreted in a pulsatile manner, and because the amplitude of normal GH pulses can be large (>50 ng/mL), random GH level measurements are not very useful in making the diagnosis of acromegaly. IGF-I levels provide an integrated index of GH production and provide a better screening test for acromegaly. IGF-I levels decrease with age, so normal ranges must be age adjusted. IGF-I levels correlate well with 24-hour GH production rates and with disease activity. The most standardized test for acromegaly is the glucose tolerance test (Table 231-5). In acromegaly, increased glucose levels fail to suppress GH levels to below 1 ng/mL with polyclonal antibody immunoassays and to levels below 0.4 ng/mL using newer monoclonal antibody two-site assays. Co-secretion of PRL should be evaluated. After the diagnosis of acromegaly is made, radiologic studies, preferably using MRI, should be used to evaluate the extent of tumor growth. Unlike in Cushing's disease and prolactinomas, most patients with acromegaly have macroadenomas.

TABLE 231-5 SELECTED TESTS OF EXCESS PITUITARY FUNCTION

HORMONE	TEST	INTERPRETATION
Growth hormone (GH)	*Basal IGF-1*	Elevated IGF-1 levels are consistent with acromegaly when interpreted in the context of age and nutritional status.
	Oral glucose suppression test: after 75-g glucose load, GH is measured at −30, 0, 30, 60, 90, 120 min	GH should be suppressed to <1 μg/L in normal persons with polyclonal radioimmunoassays; <0.4 μg/L with two-site monoclonal assays. GH may paradoxically increase in acromegaly.
Prolactin	*Basal prolactin levels*	Elevated prolactin (>200 μg/L) is consistent with a prolactinoma. When prolactin levels are between 20 and 200 μg/L, other causes of hyperprolactinemia should be considered.
Adrenocorticotropic hormone (ACTH)	*Measurement of 24-hr urine free cortisol*	Elevated level is suggestive of Cushing's syndrome, but it has several other causes as well.
	Midnight salivary cortisol: special tubes with cotton pledgets available to collect saliva at 11 PM to midnight	In normal persons, the midnight salivary cortisol is very low because of the normal diurnal variation. In patients with Cushing's syndrome, the salivary cortisol is elevated.
	Overnight dexamethasone suppression test: dexamethasone (1 mg) PO at midnight followed by 8 AM plasma cortisol	In normal persons, AM cortisol should be suppressed to <5 μg/dL. Normal test excludes Cushing's syndrome. Other disorders can cause failure to suppress normally.
	Low-dose dexamethasone suppression test: dexamethasone (0.5 mg) q6hr for eight doses with basal and end of treatment measurements that may include 24-hr urine collections for free cortisol or 17-hydroxysteroids and AM plasma cortisol and ACTH.	Urine free cortisol should be <20 μg/24 hr; serum cortisol should be suppressed to <6 μg/dL. Failure to suppress cortisol production is consistent with the diagnosis of Cushing's syndrome.
	High-dose dexamethasone suppression test: dexamethasone (2 mg) q6hr for eight doses with basal and end-of-treatment measurements that may include 24-hr urine collections for free cortisol or 17-hydroxysteroids and AM plasma cortisol and ACTH.	The high-dose test is intended to distinguish Cushing's disease (pituitary adenoma), ectopic ACTH production, and adrenal adenoma. The 90% suppression of urine free cortisol production is suggestive of Cushing's disease. Less than 50% suppression suggests ectopic ACTH or adrenal adenoma. Low ACTH levels are consistent with adrenal adenoma.
	CRH test: ovine CRH (1 μg/kg) is administered IV, and ACTH and cortisol are drawn at −15, 0, 15, 30, 60, 90, and 120 min	In Cushing's disease, there is usually a 50% increase in ACTH and a 20% increase in cortisol. Adrenal adenoma is associated with suppressed ACTH. Ectopic ACTH is associated with high basal ACTH and cortisol levels that are not affected by CRH.
	Petrosal sinus ACTH sampling: the inferior petrosal sinus is catheterized, ideally bilaterally, and plasma ACTH is compared with simultaneous peripheral samples. The sampling can be done in conjunction with CRH stimulation.	In Cushing's disease, the ratio of ACTH in the petrosal sinus to the periphery is at least 2 basally and at least 3 after CRH. In ectopic ACTH, the ratio of petrosal sinus to peripheral level is <1.5.
Thyroid-stimulating hormone (TSH)	*Basal thyroid function tests*	An inappropriate normal or elevated TSH in the setting of increased free thyroid hormone levels is consistent with a TSH-producing tumor or other causes of inappropriate TSH secretion.
	Free α-subunit level	Elevated levels associated with inappropriately elevated TSH are suggestive of a TSH-producing tumor.
Follicle-stimulating hormone (FSH), luteinizing hormone (LH)	*Basal FSH, LH, testosterone*	Increased LH and testosterone levels in males are consistent with LH-secreting tumors. Elevated FSH and low-normal testosterone are suggestive of an FSH-producing tumor if primary gonadal failure is not present. In females, assessment of excess hormone secretion is difficult because of changes during the menstrual cycle and at menopause.
	TRH test: TRH (200 μg) is given IV with measurements of serum FSH, LH, FSH β-, and LH β-subunits at 0, 20, 60 min.	Stimulation of LH, FSH, or their free β-subunits is suggestive of a gonadotropin-producing adenoma. TRH is not available in the United States.

CRH = corticotropin-releasing hormone; IGF = insulin-like growth factor; TRH = thyrotropin-releasing hormone.

TREATMENT

Rx

The goals of therapy are to reverse or prevent tumor mass effects and to reduce the long-term morbidity and mortality that result from excess GH production. Correction of the disorder prevents further physical disfigurement and can result in substantial resolution of soft tissue changes and improvements in metabolic derangements. Although reductions in GH levels are associated with improvements in symptoms, the ultimate goal is to achieve normal GH and IGF-I levels and to prevent tumor recurrence without incurring hypopituitarism.

Transsphenoidal surgery results in GH levels below 2.5 ng/mL in 80% of patients with microadenomas when performed by experienced neurosurgeons. This level, along with GH suppression below 1 ng/mL during an oral glucose tolerance test, and a normal IGF-I level have been associated with a normalization of the increased mortality of acromegaly. Patients with macroadenomas are less often cured by surgery (<30%) but usually have reductions in GH levels.

Medical therapies for acromegaly include dopamine agonists, such as cabergoline; somatostatin analogues, such as octreotide and lanreotide; and a GH receptor antagonist, pegvisomant. Although cabergoline can reduce GH and IGF-I levels in many patients, normal levels are achieved in only about 10 to 20%. Long-acting preparations of octreotide and lanreotide that can be given by intramuscular injection every 4 weeks reduce GH and IGF-I levels in almost all patients, with normal levels of IGF-I being achieved in about 50 to 60% of cases. Tumor size is reduced modestly in about one half of cases. Of those achieving normal levels of GH and IGF-I, about 10 to 20% can eventually be successfully withdrawn from treatment after several years. Somatostatin analogues are useful as adjunctive therapy in patients who are not cured by surgery or radiation and in some cases are used primarily when a surgical cure is not possible, such as in those with cavernous sinus invasion. Side effects of somatostatin analogues include diarrhea and increased risk of cholelithiasis, although cholecystitis and need for cholecystectomy are rare. Some patients experience additive beneficial effects from combining these two classes of medications while keeping the dose of each drug low enough to avoid adverse effects. Pegvisomant is a biosynthetic GH analogue that prevents binding of GH to its receptor. It is capable of normalizing IGF-I levels in more than 90% of patients with corresponding clinical benefits, but it has no effects on the tumor itself. Pegvisomant is given by daily subcutaneous injection; although it generally has been held in reserve for patients not responding optimally to other treatment modalities, there is increasing use now as initial medical therapy when tumors are not large because of its high biochemical and clinical efficacy.

Radiation is not recommended as primary therapy for acromegaly because of the long time (5 to 10 years) required for reductions in GH levels and the high incidence of hypopituitarism and other complications. Adjunctive radiation therapy may be required for patients with macroadenomas when GH levels or mass effects persist after transsphenoidal surgery and medical therapy. Recent data suggest that stereotactic radiotherapy may be the most efficacious form of radiotherapy for acromegaly.

PROLACTIN

Prolactin and GH appear to be derived from a common ancestral gene, which accounts for the similarities in their structures and some overlap in their functional properties. Although large molecular weight forms of PRL due to binding to immunoglobulin G (IgG), termed *macroprolactin*, react in radioimmunoassays, they have diminished biologic potency. Estrogen stimulates lactotroph proliferation, and their number is consequently greater in females than in males and during pregnancy (~70% of pituitary cells).

Secretion of PRL is controlled by tonic inhibition by dopamine, which acts through D_2-type receptors on lactotrophs. PRL biosynthesis and secretion are stimulated by the hypothalamic peptides TRH and vasoactive intestinal peptide (VIP). Hypothyroidism causes increased TRH output and increased sensitivity of the lactotrophs to TRH and can result in hyperprolactinemia. Dopamine inhibition is the dominant influence for PRL secretion; therefore, PRL is the one pituitary hormone that increases after pituitary stalk section. Secretion of PRL is pulsatile and increases with sleep, stress, chest wall stimulation, and pregnancy. PRL levels are usually less than 15 to 20 ng/mL in women and 10 to 15 ng/mL in men. The primary function of PRL is to induce and sustain lactation. During pregnancy, PRL levels increase, and, in conjunction with other hormones (estrogens, progesterone, thyroid hormone, cortisol, and insulin), breast epithelium is stimulated to proliferate, and milk synthesis is induced. High levels of estrogen and progesterone inhibit lactation during pregnancy, and their decline post partum permits lactation to occur. Neural pathways leading to the secretion of oxytocin provide the "let-down" reflex that induces lactation in response to suckling. Early in the postpartum period, PRL secretion is stimulated by suckling, but this response becomes damped with time as the frequency of suckling episodes decreases. PRL also suppresses gonadotropins, probably by a direct action on GnRH-secreting neurons. As a result, breast-feeding can suppress ovulation.

PROLACTIN DEFICIENCY

Prolactin deficiency is rare and occurs primarily in the setting of combined hormone deficiencies. The only recognized consequence of PRL deficiency is the absence of postpartum lactation, and this scenario may be found with pituitary infarction occurring as a result of obstetric hemorrhage (Sheehan's syndrome). No effects on breast development or other tissues have been described in PRL deficiency.

HYPERPROLACTINEMIA

PATHOBIOLOGY

Hyperprolactinemia can occur as a consequence of pharmacologic alterations in the pathways that control PRL secretion or of physiologic or metabolic effects on PRL production and clearance or as a neoplastic condition. Prolactinomas are neoplastic growths of lactotroph cells and are the most common type of pituitary adenoma (25 to 40%). Estrogen is a potent stimulus for lactotroph proliferation; however, there is no clear association between estrogens (e.g., oral contraceptive use) and the incidence of prolactinomas. However, the very high estrogen levels present during pregnancy may cause about 30% of large prolactinomas to increase in size. Diminished dopamine tone, such as may occur with prolonged treatment with antipsychotic agents, results in increased PRL but has not been shown to cause prolactinomas.

Microprolactinomas constitute the great majority of tumors in premenopausal women. In contrast, macroadenomas are more commonly seen in men and postmenopausal women. The predominance of smaller tumors in premenopausal women may be accounted for by an ascertainment bias because elevated PRL levels in this group lead to clinical manifestations (amenorrhea, galactorrhea, or infertility). Subclinical prolactinomas exist in men and many older women, and about 5% of apparently normal individuals have PRL-positive microadenomas in autopsy series.

CLINICAL MANIFESTATIONS

Hyperprolactinemia causes galactorrhea and oligomenorrhea or amenorrhea in premenopausal women. Estrogen facilitates PRL-induced galactorrhea, which explains why it is less common in postmenopausal women and in women with prolonged hypogonadism. Amenorrhea is primarily a consequence of PRL suppression of GnRH, although PRL may also have inhibitory effects at the level of the pituitary and the gonad. Amenorrhea is associated with infertility, and PRL levels should be a routine part of the hormonal evaluation of infertility. Estrogen deficiency can cause decreased libido, vaginal dryness, and dyspareunia. Long-standing estrogen deficiency also leads to osteopenia in many women. Oral contraceptives may mask PRL-induced oligomenorrhea or amenorrhea that becomes apparent on their discontinuation. In postmenopausal women, prolactinomas are often identified because of mass effects rather than because of their hormonal effects.

In men, hyperprolactinemia causes hypogonadism with suppressed LH and FSH levels and low testosterone levels. Hypogonadism causes diminished libido, impotence, infertility, and, rarely, gynecomastia or galactorrhea. Diminished libido may also reflect suppression of GnRH because testosterone replacement is not as effective as suppression of hyperprolactinemia. Hyperprolactinemia is found in 1 to 2% of men being evaluated for sexual dysfunction.

DIAGNOSIS

There are four primary categories of causes of hyperprolactinemia that must be distinguished if the correct therapy is to be instituted: (1) physiologic or metabolic hyperprolactinemia; (2) pharmacologic hyperprolactinemia; (3) hypothalamic or pituitary stalk compression; and (4) prolactinoma (see Table 231-4). With the exception of pregnancy and renal failure, physiologic causes of increased PRL result in minor elevations in PRL, usually less than 50 ng/mL. Primary hypothyroidism should be excluded as a cause of mild hyperprolactinemia. A careful drug history should be obtained in all patients with hyperprolactinemia because of the large number of agents that can stimulate PRL secretion. Psychotropic medications, in particular, can increase PRL either by reducing dopamine production or by blocking its action. In

most cases, the degree of hyperprolactinemia caused by drugs is less than 150 ng/mL. A variety of suprasellar and parasellar mass lesions cause hyperprolactinemia (generally between 20 and 100 ng/mL) because of compression of the hypothalamus or pituitary stalk. Unless there is very good evidence for physiologic or drug-induced hyperprolactinemia, even patients with mild hyperprolactinemia should be evaluated with CT or MRI to distinguish among idiopathic hyperprolactinemia, microprolactinomas, and other large mass lesions that cause stalk compression, resulting in decreased dopamine reaching the lactotrophs. However, a specific caution is needed when some two-site assays are used because patients with very high PRL levels may appear to have PRL levels that are normal or only modestly elevated, owing to the "hook effect," in which the very high PRL levels saturate the antibodies in the assay. To avoid this problem, PRL levels should be remeasured at 1:100 dilution in patients with macroadenomas and normal to modestly elevated PRL levels because PRL levels in samples with the hook effect will then increase dramatically. When no pituitary lesions are seen by radiographic studies and physiologic and pharmacologic causes of hyperprolactinemia cannot be identified, the diagnosis of idiopathic hyperprolactinemia is made. Idiopathic hyperprolactinemia may represent microprolactinomas too small to be detected accurately by imaging or altered hypothalamic regulation of PRL secretion. Whether such patients should be treated depends on the clinical effects of hyperprolactinemia. When followed for several years, few of these patients develop large tumors, only 10 to 15% show MRI evidence of microadenomas, and in one third of cases, the hyperprolactinemia resolves.

TREATMENT Rx

The natural history of prolactinomas has been evaluated in several series. Although large prolactinomas evolve from smaller lesions, it is uncommon (~7%) for microprolactinomas to progress to macroadenomas. Because of the slow rate of growth, it is reasonable to monitor patients with microprolactinomas without treatment by periodic measurement of PRL levels unless the hyperprolactinemia is causing symptoms that warrant therapy.

When hyperprolactinemia causes hypogonadism, osteopenia, or infertility, a dopamine agonist such as cabergoline or bromocriptine is the therapy of choice. Dopamine agonists normalize PRL levels and correct amenorrhea-galactorrhea in 80 to 90% of patients. Cabergoline is more effective, has fewer adverse side effects than bromocriptine, and has the additional advantage in only having to be taken once or twice weekly. Bromocriptine must be started in low doses with gradual increases to avoid side effects (nausea, dizziness, somnolence, and nasal stuffiness).

Cabergoline may cause a considerable reduction in tumor size in patients with macroprolactinomas, about 80 to 90% having a greater than 50% reduction in tumor size, but such size reduction is seen in only about two thirds of patients treated with bromocriptine. Visual field defects are a very sensitive index of tumor size, and improvements can be seen in about 90% of patients with defects. Thus, it is reasonable to use cabergoline as first-line therapy even in patients with visual field defects as long as visual acuity is not threatened by rapid progression or recent tumor hemorrhage. Many patients treated with cabergoline whose tumors shrink to the point of nonvisualization on MRI and whose PRL levels are normal can maintain normal PRL levels and not experience tumor re-expansion after therapy has been discontinued. In some cases, prolactinomas appear to be resistant to a dopamine agonist, but it is important to ensure compliance and to be certain that the underlying lesion is a prolactinoma and not some other cause of hyperprolactinemia. In these cases, switching from bromocriptine to cabergoline may be successful. Larger than standard doses (>2 mg/week) of cabergoline may be effective in normalizing PRL levels. The very high doses of cabergoline used in patients with Parkinson's disease have been associated with cardiac valvular abnormalities; such abnormalities have not been found with conventional doses of cabergoline used in patients with prolactinomas, but monitoring with echocardiography may be prudent in patients taking larger than standard doses. Alternatively, transsphenoidal surgery may be used. Although initial remission rates (80 to 90%) for transsphenoidal surgery of microprolactinomas are good, there is long-term recurrence in about 20% of patients. For macroprolactinomas, the initial remission rates with surgery are closer to 30%, with a similar recurrence rate. Radiation therapy, usually stereotactic, is reserved for patients with macroadenomas not responding to either medical or surgical treatment.

Dopamine agonist therapy for infertility, or when there is a possibility of pregnancy, deserves special consideration. These medications can induce ovulation in 80 to 90% of patients with hyperprolactinemia. Although neither bromocriptine nor cabergoline has been associated with congenital malformations, most physicians and patients prefer to avoid their use once pregnancy has been achieved. A form of barrier contraception is usually recommended until two to three regular menstrual cycles have occurred. Subsequently, pregnancy can be confirmed if a menstrual period is missed, allowing discontinuation of medication with exposure of the fetus to the drug for only 3 to 5 weeks. At present, the safety data for pregnancy outcome are much more limited for cabergoline; therefore, some clinicians prefer bromocriptine when fertility is desired. Less than 2% of patients with microadenomas, but 31% of patients with macroadenomas, develop symptoms of tumor enlargement (headaches, visual field defects) during pregnancy. If symptoms develop, MRI and formal visual field testing should be performed. If there is evidence of visual field compromise or tumor growth, dopamine agonist therapy should be restarted to shrink the tumor. PRL levels are not very useful because they are normally increased in pregnancy and an enlarging tumor may not cause PRL production to increase substantially. Because problems of tumor growth occur most often in patients with macroadenomas, consideration can also be given to the option of transsphenoidal decompression before pregnancy in women with large tumors, as long as fertility can be preserved. If the patient is far advanced in her gestation at the time tumor growth occurs, consideration could also be given to delivering the baby.

ADRENOCORTICOTROPIC HORMONE

Adrenocorticotropic hormone is a 39–amino acid peptide that is derived from a precursor polypeptide pro-opiomelanocortin (POMC; 241 amino acids), which encodes several peptides, including ACTH and β-lipotropin (Chapter 230). The biologically active portion of ACTH resides within the first 18 of its 39 amino acids. However, because a synthetic peptide (cosyntropin) that includes the first 24 amino acids has a longer half-life, it is used clinically to assess adrenocortical function. In cases with neoplastic ectopic production of ACTH, the levels of precursor peptides or their processed products may be elevated.

The primary effect of ACTH is to stimulate the adrenal gland to produce cortisol. It also stimulates secretion of adrenal androgens and mineralocorticoids, although production of mineralocorticoids is controlled primarily through non–ACTH-dependent mechanisms (i.e., the renin-angiotensin system) (Chapter 234). Consequently, mineralocorticoid function is preserved in ACTH deficiency, in contrast to primary adrenal insufficiency, which is characterized by loss of glucocorticoid and mineralocorticoid function. Long-term stimulation by ACTH causes adrenal hyperplasia and enlargement. On the other hand, ACTH deficiency leads to adrenal atrophy.

Hypothalamic CRH is the most important stimulator of ACTH secretion. Chronic stimulation by CRH causes corticotroph cell hyperplasia, which can be seen in cases of ectopic CRH production. Cortisol inhibits ACTH secretion, blunts the ACTH response to CRH, and inhibits CRH production. After prolonged glucocorticoid suppression of the hypothalamic-pituitary-adrenal axis, the amount of endogenous CRH secretion appears to be rate limiting and can require several months to recover.

Plasma ACTH is secreted in discrete pulses (10 to 80 pg/mL), so random measurements are of little value. Most clinical tests are therefore based on levels of cortisol or its metabolites, which tend to integrate the effects of ACTH. ACTH and cortisol secretion exhibit marked diurnal rhythms, being greatest at night several hours after the initiation of sleep. Cortisol levels are greatest in the early morning and reach a nadir in the late afternoon and evening. Patients with Cushing's disease lose or exhibit a blunted diurnal rhythm of ACTH and cortisol secretion. ACTH secretion can be stimulated by a variety of different forms of stress, including psychological stimuli such as fright, anticipation of athletic competition, or surgery. Depression is associated with activation of the hypothalamic-pituitary-adrenal axis and impaired dexamethasone suppressibility. Hypoglycemia induces ACTH secretion through a central mechanism. The resulting increase in cortisol secretion represents one of several counter-regulatory mechanisms that increase glucose production. Insulin-induced hypoglycemia provides a mechanism for testing the integrity of the hypothalamic-pituitary-adrenal axis (see Table 231-2). Serious trauma and infection activate an array of cytokines that stimulate CRH and ACTH secretion. Because cortisol levels are often increased up to 10-fold in these circumstances, similar adjustments in cortisol replacement doses may be required in seriously ill patients with adrenal insufficiency.

ADRENOCORTICOTROPIC HORMONE DEFICIENCY: SECONDARY HYPOCORTISOLISM

Secondary hypocortisolism causes symptoms of glucocorticoid deficiency, including nausea, vomiting, weakness, fatigue, fever, and hypotension. In addition to reduced levels of cortisol, abnormal laboratory test findings can include hyponatremia, hypoglycemia, and eosinophilia. Depending on its cause, the severity of cortisol deficiency in cases of secondary adrenal insufficiency is often not as marked as in primary adrenal insufficiency

(Chapter 234). In addition, mineralocorticoid function is preserved in secondary adrenal deficiency. Consequently, the clinical manifestations of volume depletion are less pronounced, and hyperkalemia is not a feature of ACTH deficiency. Because ACTH levels are low, hyperpigmentation is not seen as in primary adrenal insufficiency. In women, reduced adrenal androgens can decrease libido and cause loss of axillary and pubic hair.

The most common cause of ACTH deficiency is treatment with exogenous glucocorticoids, which causes suppression of the hypothalamic-pituitary-adrenal axis. Sudden withdrawal of glucocorticoids or an increased requirement induced by the superimposition of severe illness can elicit symptoms of glucocorticoid deficiency. Congenital forms of ACTH deficiency are rare. When present, ACTH deficiency usually occurs in combination with the loss of other pituitary hormones, although acquired, isolated ACTH deficiency does occur, particularly in women with lymphocytic hypophysitis.

ACTH reserve is most often evaluated using the insulin tolerance test. Caution should be exercised before inducing hypoglycemia in patients with suspected adrenal insufficiency. Insulin-induced hypoglycemia stimulates central responses to neuroglycopenia and mimics some stresses that activate ACTH secretion. The metyrapone test provides an alternative to the insulin tolerance test. By blocking the 11-hydroxylation step, metyrapone inhibits cortisol production, resulting in stimulation of ACTH secretion and an increase in precursor adrenal steroids (e.g., 11-deoxycortisol). Patients should be monitored closely for evidence of adrenal insufficiency, and metyrapone should be used only in patients with at least some evidence of adrenocortical function. ACTH stimulation tests using $ACTH_{1\text{-}24}$ (cosyntropin) can accurately evaluate primary adrenocortical insufficiency but may less accurately assess secondary adrenal insufficiency. A variation of the ACTH stimulation test using the low dose of 1 μg has been found to be useful for diagnosing secondary adrenal insufficiency in some studies.

Deficiency of ACTH is treated by replacement with glucocorticoids. Doses need to be individualized and are based largely on clinical criteria in which symptoms of glucocorticoid deficiency are balanced against features of glucocorticoid excess. Typical amounts of hydrocortisone are in the range of 15 to 20 mg/day in divided doses. Such doses are usually doubled in the event of mild-to-moderate illness. Patients should wear MedicAlert tags and be instructed in the warning signs of cortisol deficiency, including nausea, vomiting, abdominal pain, low-grade fever, fatigue, and postural dizziness. Emergency injection kits of hydrocortisone are frequently provided for home use in the event that vomiting precludes taking oral steroids or for severe, sudden stress (e.g., a fracture). Stress doses of steroids should be used during times of illness. Current recommendations call for doses in the range of 50 to 75 mg every 8 hours for severe stress. Mineralocorticoid replacement is not required in patients with ACTH deficiency.

CUSHING'S DISEASE

PATHOBIOLOGY

Cushing's disease results from a pituitary adenoma that causes excess production of ACTH. It should be distinguished from a variety of other causes of *Cushing's syndrome* (glucocorticoid excess), which include adrenal causes of cortisol excess, ectopic production of ACTH and CRH, and physiologic states that result in overproduction of cortisol. Cushing's disease accounts for 60 to 70% of cases of Cushing's syndrome. Ten to 15% of pituitary tumors secrete ACTH. Cushing's disease occurs about eight times more often in women than in men.

Most ACTH-producing pituitary neoplasms, like other pituitary tumors, are monoclonal, implying a primary defect in corticotroph cells. In addition, there are rare cases of corticotroph hyperplasia causing Cushing's syndrome that are secondary to CRH production by either adjacent CRH-producing intrasellar gangliocytomas or ectopic CRH-producing cancers. Most (80 to 90%) of the ACTH-secreting tumors are microadenomas at the time of diagnosis. The clinical features of cortisol excess may allow detection of corticotroph adenomas before they have grown to a larger size. High levels of cortisol may also restrain tumor growth. ACTH-secreting macroadenomas may be locally invasive.

CLINICAL MANIFESTATIONS

The clinical features of Cushing's disease are caused by the effects of excess glucocorticoids and by the hypersecretion of ACTH and other POMC peptide products. The severity of the features of Cushing's disease varies greatly and appears to reflect not only the level of free cortisol but also the duration of the disease and perhaps the sensitivity to glucocorticoid action.

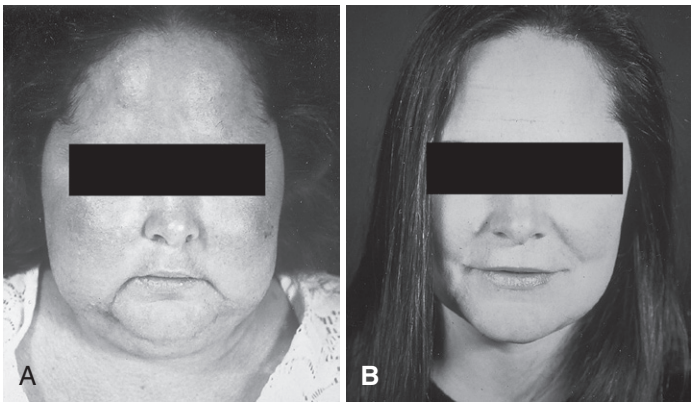

FIGURE 231-2. Clinical features of Cushing's disease. A 25-year-old woman presented with severe Cushing's disease. **A,** Facial features of Cushing's syndrome, including plethora, moon facies, and hirsutism, are evident. **B,** Dramatic resolution of the manifestations of cortisol excess after successful transsphenoidal surgery. (Photographs courtesy of Dr. Beverly M. K. Biller.)

TABLE 231-6 CLINICAL FEATURES OF CUSHING'S DISEASE

GENERAL
Obesity (centripetal distribution)
"Moon facies" and mild proptosis
Increased supraclavicular fat and "buffalo hump"
Hypertension
SKIN
Hyperpigmentation
Facial plethora
Hirsutism
Violaceous striae and thin skin
Capillary fragility and easy bruising
Acne
Edema
MUSCULOSKELETAL
Muscle weakness (proximal)
Osteoporosis and back pain
REPRODUCTIVE
Decreased libido
Oligomenorrhea and amenorrhea
NEUROPSYCHIATRIC
Depression
Irritability and emotional lability
Psychosis
METABOLIC
Hypokalemia and alkalosis
Hypercalciuria and renal stones
Glucose intolerance or diabetes mellitus
Impaired wound healing
Impaired resistance to infection
Granulocytosis and lymphopenia
TUMOR MASS EFFECTS
Headache
Visual field loss
Hypopituitarism

In florid cases of Cushing's disease (Fig. 231-2), the constellation of symptoms and physical features is readily recognized. Early in the disease or in mild cases, it can be challenging to distinguish the clinical features of Cushing's disease from similar traits that are seen in the normal population. Clinical suspicion is of paramount importance. On the other hand, one must be discriminating and not formally evaluate everyone with obesity, hypertension, and glucose intolerance. Of the many features listed in Table 231-6, some are relatively specific for Cushing's disease. For example, the centripetal distribution of fat with the characteristic "buffalo hump," "moon facies," and deposition of fat in the supraclavicular area but not in the extremities, is much more specific than generalized obesity. Striae that are wide (>1 cm) and

purple reflect steroid-induced thinning of the dermis and can be distinguished from the more common "stretch marks." Numerous spontaneous ecchymoses also occur because of thinning of the skin and capillary fragility. Proximal muscle weakness represents another manifestation of glucocorticoid excess. Osteopenia and hypokalemia, when present, provide objective evidence consistent with ACTH excess. Hypokalemia results from the effects of ACTH on mineralocorticoid production but also from the ability of high levels of cortisol to saturate 11β-dehydrogenase, an enzyme in the kidney that inactivates cortisol. As a result, cortisol can "spill over" and act on mineralocorticoid receptors in the distal tubule. The hyperpigmentation associated with Cushing's disease is not as striking as one encounters with Addison's disease or in ectopic ACTH syndrome; but in association with other findings, it should raise the suspicion of Cushing's disease and help to distinguish it from adrenal causes of hypercortisolemia. Hirsutism and acne are caused by the increased production of adrenal androgens and are more prominent in patients with Cushing's disease than in those with adrenal adenomas, in whom glucocorticoids tend to be the predominant product. Oligomenorrhea and amenorrhea probably have several causes, including androgen effects on the reproductive axis and glucocorticoid inhibition of GnRH, which may also account for diminished libido. Hypertension and glucose intolerance are caused by glucocorticoid excess. Immunosuppression, opportunistic infections, and impaired wound healing can lead to considerable morbidity. Neuropsychiatric symptoms, including depression, can be prominent effects of Cushing's disease. Suicide occurs with increased frequency in patients who receive no treatment for Cushing's disease.

DIAGNOSIS

The screening tests and differential diagnosis of Cushing's syndrome represent one of the greatest diagnostic challenges in endocrinology (Chapter 234). The first step is to determine whether a patient truly has cortisol excess. After confirmation of Cushing's syndrome, one must distinguish among (1) adrenal causes of cortisol excess; (2) pituitary causes of ACTH excess (Cushing's disease); (3) ectopic sources of ACTH; and (4) ectopic CRH (Table 231-7).

In screening for hypercortisolism, random cortisol levels are not useful because of diurnal variation of the hormone. The overnight dexamethasone test is the most widely used screening test (see Table 231-5). A normal result of the dexamethasone test excludes Cushing's syndrome. It should be noted, however, that abnormal overnight dexamethasone suppression can be seen in up to 30% of hospitalized patients and in many patients with depression or during alcohol withdrawal. An elevated 24-hour urine free cortisol value provides an alternative, or additional, screening test for hypercortisolism. Often, two sequential specimens are collected because of day-to-day variations in hormone production. The sensitivity and specificity of urinary free cortisol measurements are greater than those of the overnight dexamethasone suppression test, particularly in hospitalized patients. A third test takes advantage of the observation that there is a loss of diurnal variation of cortisol levels in all forms of Cushing's syndrome. This test consists of finding elevation of a midnight cortisol level in the serum or saliva. Kits are available for patients to obtain a late-night salivary cortisol sample.

After demonstrating that cortisol excess is present, the next step is to determine the source of excess ACTH or cortisol. The classic approach is to perform a low-dose, followed by a high-dose, dexamethasone suppression test (see Tables 231-5 and 231-7). The low-dose dexamethasone test excludes or confirms the presence of Cushing's syndrome. On the second day of the test, normal individuals suppress plasma cortisol to less than 5 μg/dL and reduce the urinary free cortisol to less than 20 μg per 24 hours. All forms of Cushing's syndrome fail to suppress according to these criteria.

The high-dose dexamethasone test is one of several means to distinguish ACTH-independent and ACTH-dependent causes of Cushing's syndrome and to discriminate between pituitary and ectopic causes of ACTH-dependent Cushing's syndrome (see Table 231-7). Because adrenal sources of cortisol excess are autonomous and ACTH independent, plasma and urinary cortisol levels are not affected by dexamethasone suppression, even at high doses. In addition, plasma ACTH levels are low in adrenal causes of Cushing's syndrome because the hypothalamic-pituitary axis is suppressed. Pituitary and ectopic causes of Cushing's disease are both ACTH dependent but respond differently to high-dose dexamethasone. Pituitary adenomas have an altered set point for glucocorticoid inhibition but retain a partial ability to respond to high-dose dexamethasone. The exact criteria for dexamethasone suppression in the high-dose test are debated. In most cases of ACTH-producing pituitary adenomas, urinary free cortisol is suppressed below 90% of baseline during the high-dose dexamethasone test.

The ectopic ACTH syndrome (Chapter 186) should be suspected in patients with known malignancies, particularly small cell carcinoma of the lung; bronchial, thymic, or gastrointestinal carcinoids; islet cell tumors; and medullary carcinoma of the thyroid, among others. Plasma ACTH levels are often very high (>200 pg/mL) and can be associated with hyperpigmentation. Clinical features of Cushing's syndrome may be altered by the rapid onset of extreme hypercortisolemia coincident with elements of tumor cachexia. Pronounced weakness, fluid retention, glucose intolerance, hypokalemia, and poor skin integrity are often seen. Ectopic ACTH syndrome is readily recognized in its classic form. However, a subset of tumors, particularly carcinoids (Chapter 240), exhibit dexamethasone suppression that is similar to that seen with pituitary adenomas. When suspected, carcinoids can sometimes be detected by CT or MRI, but many are too small to be seen even with these techniques. Because of these exceptions to the high-dose dexamethasone test, a variety of procedures have been devised in an attempt to further distinguish ectopic and pituitary dependent sources of ACTH. CRH testing may also prove useful, with pituitary tumors exhibiting an increase in ACTH and tumors making ACTH ectopically having little or no response.

In recent years, inferior petrosal sinus sampling has been used to distinguish pituitary and ectopic sources of ACTH when the source of ACTH is not obvious based on the clinical circumstances, biochemical evaluation, and imaging studies. This test requires an experienced radiologist for safe and effective catheterization of the petrosal sinuses. Blood samples are taken simultaneously from the left and right petrosal sinuses and from the periphery before and after CRH stimulation. In the case of ACTH-producing pituitary adenomas, there is a gradient in ACTH levels between the central and peripheral blood specimens. When clinical and biochemical studies suggest the presence of a pituitary adenoma, pituitary imaging should be performed using CT or MRI. Most ACTH-secreting pituitary adenomas are small and scans are normal in more than half of patients.

TREATMENT

Rx

The efficacy of transsphenoidal surgery for Cushing's disease is greatly aided by making the correct diagnosis preoperatively. In experienced hands, surgical cures of ACTH-producing microadenomas occur in 75 to 90% of patients undergoing a first operation. As in other pituitary tumors, complete remissions with macroadenomas are much less common. In the event of surgical remission or cure, postoperative hypocortisolism is to be expected because of suppression of the hypothalamic-pituitary axis. After coverage for steroid withdrawal in the postoperative period, cortisol replacement should gradually be decreased to allow recovery of the hypothalamic-pituitary-adrenal axis; recovery may take up to 1 year.

TABLE 231-7 TESTS USED IN THE DIFFERENTIAL DIAGNOSIS OF CUSHING'S SYNDROME*

ETIOLOGY	OVERNIGHT DEXAMETHASONE SUPPRESSION TEST	PLASMA ACTH	LOW-DOSE DEXAMETHASONE	HIGH-DOSE DEXAMETHASONE	CORTICOTROPIN-RELEASING HORMONE STIMULATION OF ACTH	PETROSAL-TO-PERIPHERAL ACTH RATIO
Normal	Suppression	Normal	Suppression		Normal	
Pituitary	No suppression	Normal or high	No suppression	Suppression	Normal or increased	>2
Ectopic	No suppression	High or normal	No suppression	No suppression	No response	<1.5
Adrenal	No suppression	Low	No suppression	No suppression	No response	

*Classic responses are indicated. Certain cases of ectopic adrenocorticotropic hormone (ACTH) production are suppressed by high-dose dexamethasone or are stimulated by corticotropin-releasing hormone. In these cases, petrosal sinus sampling is the most reliable method for distinguishing pituitary and ectopic sources of ACTH.

If transsphenoidal surgery is unsuccessful, reoperation may be indicated and can result in remission in up to 50% of patients; in this circumstance, consideration should be given to performing a total hypophysectomy at reoperation. If transsphenoidal surgery cannot be performed or has failed, alternative forms of therapy should be used to prevent the long-term consequences of hypercortisolism. Pituitary irradiation is usually the second line of treatment for Cushing's disease. It is more efficacious in children and in younger patients, but even in older adults, remissions can be achieved in 50 to 60% within 2 years. To prevent the continued ravages of hypercortisolism during this period, however, concomitant medical therapy is usually given. Bilateral adrenalectomy represents another alternative for patients with severe hypercortisolism after transsphenoidal surgery. It rapidly and effectively lowers cortisol levels but is associated with relatively high morbidity and mortality rates (as high as 5%) because of the associated metabolic and immune system alterations caused by hypercortisolism. The morbidity has been reduced in recent years by introduction of the laparoscopic approach. After adrenalectomy, patients must be maintained on glucocorticoids and mineralocorticoids and are at risk for the development of Nelson's syndrome (see later).

Medical therapy for Cushing's disease has its primary role in preparation for surgery or control of hypercortisolism during the interval when radiation therapy is taking effect. Because most pituitary adenomas are responsive to changes in cortisol levels, they have a tendency to "escape" from adrenal blockade caused by some therapies by producing higher levels of ACTH. The antifungal agent ketoconazole is highly effective in decreasing glucocorticoid biosynthesis and also inhibits ACTH secretion so that it has become the medical therapy of choice. Alternative medications include metyrapone, mifepristone, etomidate, and mitotane.

NELSON'S SYNDROME

Nelson's syndrome was initially described as the appearance of a pituitary adenoma after bilateral adrenalectomy. In addition to an enlarging pituitary mass, the syndrome is characterized by very high ACTH levels and hyperpigmentation. It is caused by a preexisting ACTH-producing tumor that grows in the absence of feedback inhibition by high levels of glucocorticoids. The incidence of clinically significant Nelson's syndrome after adrenalectomy for Cushing's disease varies from 10 to 50% in different series. Patients with Cushing's disease who have undergone adrenalectomy should be followed with imaging studies and plasma ACTH levels because tumors that cause Nelson's syndrome can be very aggressive. When there is evidence of mass effects or rapid growth, transsphenoidal surgery should be performed. Postoperative irradiation may provide additional benefit, although it appears to be less efficacious than in other ACTH-producing adenomas.

GONADOTROPINS (FOLLICLE-STIMULATING HORMONE AND LUTEINIZING HORMONE)

The pituitary glycoprotein hormones include FSH, LH, and TSH. Chorionic gonadotropin, which is structurally very similar to LH, is made in the placenta. Each of the glycoprotein hormones has a specific β-subunit that forms a noncovalently bound dimer with the common α-subunit. The α- and β-subunits each undergo glycosylation, which is important for correct hormone folding, intracellular transport, and secretion. Glycosylation is also required for biologic activity, presumably because of effects on the tertiary structure of the hormones. The gonadotropins are involved in sexual differentiation, sex steroid production, and gametogenesis. The regulation and physiologic roles of gonadotropins are quite different in males and females.

In males, receptors for FSH are located on Sertoli cells and seminiferous tubules, whereas LH receptors are located on Leydig cells in the testis. LH stimulates androgen production by the Leydig cells. FSH is involved primarily in sperm maturation in the seminiferous tubules. Thus, FSH and LH act together to induce spermatogenesis (Chapter 242).

In females, ovarian FSH receptors are located on granulosa cells, where they induce enzymes involved in estrogen biosynthesis. LH receptors are located predominantly on thecal cells in the ovary and stimulate the production of ovarian androgens and steroid precursors that are transported to granulosa cells for aromatization to estrogens. The pattern of FSH and LH secretion during the menstrual cycle results in follicular recruitment and maturation (largely FSH-mediated), followed by ovulation (largely LH-mediated) and steroid production by the corpus luteum (Chapter 243).

Gonadotropin secretion is regulated primarily by the hypothalamic decapeptide GnRH. The gonadotroph cell is exquisitely sensitive to the pattern of GnRH stimulation. Continuous, rather than pulsatile, exposure to GnRH causes gonadotroph desensitization and suppression of LH and FSH. Gonadotroph sensitivity to GnRH is modulated by sex steroids and probably other hypothalamic peptides, such as neuropeptide Y. Increased GnRH secretion, in combination with a higher density of GnRH receptors and rising estradiol concentrations, accounts in part for the dramatic release of gonadotropins that induces ovulation.

In women, the pattern of GnRH pulse frequency varies across the menstrual cycle (Chapter 243). The combination of GnRH stimulation, in conjunction with ovarian feedback regulation, results in a complex orchestration of positive and negative hormonal signals that converge at the gonadotroph to regulate LH and FSH secretion. The typical 28-day menstrual cycle is divided into follicular and luteal phases that are separated by ovulation on day 14. Unlike chronic exposure to low concentrations of estrogens, which exert negative feedback regulation and inhibit GnRH, the increasing concentration of estrogen before the LH surge exerts positive feedback regulation that results in increased GnRH pulse frequency. Increased GnRH, in combination with increased gonadotroph sensitivity to GnRH, results in the LH-FSH surge. During the luteal phase, the gonadotropin pulse frequency is reduced. In addition to feedback regulation by steroids, ovarian peptides such as inhibin also play a role in control of the reproductive axis. Inhibin causes selective suppression of FSH, without affecting LH secretion. A homodimer of inhibin β-subunits, referred to as *activin*, has opposite actions and selectively stimulates FSH, but its predominant physiologic action is to increase ovarian granulosa cell responsivity to FSH. Circulating inhibin provides one of the negative feedback inputs that leads to FSH suppression as the follicle develops. The perimenopause is characterized by a gradual cessation of ovarian function. After several years of menstrual cycles that are sometimes anovulatory or irregular, menses cease, thereby defining the menopause (Chapter 248). At menopause, the decline in estrogen and progesterone causes loss of feedback inhibition and a marked increase in LH and FSH levels.

In males, the regulation of the hypothalamic-pituitary-gonadal axis is relatively constant. Testosterone inhibits the hypothalamic-pituitary axis, although its actions are mediated, in part, by aromatization to estrogens. Most of the inhibition by gonadal steroids occurs at the hypothalamic level. In contrast to menopause in women, there is no analogous abrupt change in hormone levels in men. There is, however, a gradual decline in testosterone levels associated with an increase in LH and FSH with aging.

HYPOGONADOTROPIC HYPOGONADISM

Clinical features of hypogonadotropic hypogonadism in women are primarily due to estrogen deficiency and include breast atrophy, vaginal dryness, and diminished libido. Hot flashes are uncommon, in contrast to postmenopausal estrogen deficiency. In premenopausal women, normal menstrual cycles provide evidence for an intact hypothalamic-pituitary-gonadal axis. LH and FSH levels should be increased in postmenopausal women, and normal levels may indicate deficiency. Hypogonadism in men causes decreased libido and sexual function. In men, low testosterone without elevation of LH and FSH is consistent with impaired hypothalamic-pituitary reserve. GnRH stimulation can distinguish hypothalamic and pituitary deficiency but may require multiple injections to prime the pituitary.

TREATMENT Rx

In premenopausal women, preparations of estrogen and progestins should be used for hormonal replacement and to allow cyclical growth of the endometrium. Pulsatile GnRH (for GnRH-deficient subjects) has been given to induce ovulation and fertility but is not commonly used at present. Gonadotropin injections are more commonly used. Testosterone can be replaced in men using intramuscular injections that are given at 2- to 4-week intervals. Doses and the intervals between injections should be adjusted on an individual basis using libido and testosterone levels before the next injection as a guide. Oral preparations of androgens should be avoided because of hepatotoxicity. Transdermal patch and gel preparations are also available and maintain more stable testosterone levels but are more expensive. Induction of spermatogenesis requires pulsatile GnRH (for GnRH-deficient subjects) or, more commonly, injections of gonadotropins.

A congenital form of hypogonadotropic hypogonadism is caused by deficiency of GnRH, which in turn causes deficiencies of LH and FSH. When associated with anosmia (absent sense of smell), the condition is referred to

as Kallmann's syndrome (Chapter 230). Pulsatile GnRH has been used to induce puberty and fertility in both males and females with Kallmann's syndrome and other forms of GnRH deficiency, but more commonly, injections of gonadotropins are used.

Secondary hypogonadotropic hypogonadism is relatively common. In most cases, it is reversible and is caused by weight loss, anorexia nervosa, stress, heavy exercise, or severe illness. Reversible forms of secondary hypogonadotropic hypogonadism are caused by GnRH deficiency and are more common in women than men. The condition is ideally treated by correcting the underlying cause. Many women have a discrete threshold for weight or exercise level that will cause loss of menstrual periods. When it is not possible to correct the underlying abnormality, hormonal replacement can be used in women for protection against osteopenia and to cycle the endometrium. Permanent, idiopathic hypogonadotropic hypogonadism can also occur in both sexes and will require hormone replacement.

A variety of pathologic conditions can cause secondary hypogonadotropic hypogonadism, often in association with deficiencies of other pituitary hormones (see Table 231-1). These include hypothalamic lesions and central nervous system irradiation. Pituitary tumors can suppress gonadotropins because of stalk compression and disruption of pulsatile GnRH input as well as by direct destruction of normal pituitary tissue. Hyperprolactinemia can suppress GnRH and lead to reduced gonadotropin levels.

In contrast to the aforementioned causes of hypogonadotropic hypogonadism, which result from GnRH deficiency, primary deficiencies of LH and FSH are uncommon. An acquired form of isolated gonadotropin deficiency is rarely encountered and may have an autoimmune basis. Mutations in the *LHβ* or *FSHβ* genes have been described in case reports and cause selective loss of individual gonadotropins. Inactivating mutations in the GnRH receptor and the LH and FSH receptors causing hypogonadotropic hypogonadism have also been reported.

FOLLICLE-STIMULATING HORMONE– AND LUTEINIZING HORMONE–PRODUCING TUMORS

PATHOBIOLOGY

The majority (70 to 80%) of pituitary tumors classified previously as nonfunctioning adenomas can be shown to produce low levels of intact glycoprotein hormones or their uncombined α- or β-subunits. Biosynthetic defects in the tumor cells account for relatively inefficient hormone secretion as well as the propensity to produce uncombined subunits. FSH is produced more commonly than LH. Elevated levels of free α-subunits are noted more often than increased free β-subunits.

CLINICAL MANIFESTATIONS

Gonadotropin-producing tumors are somewhat more common in men than women and increase in prevalence with age. FSH- and LH-producing tumors do not usually cause a characteristic hormone excess syndrome. The tumors, typically large macroadenomas, present as clinically nonfunctioning tumors with symptoms and signs related to local mass effects. Visual field loss is found in more than 70% of patients. Many are detected incidentally by CT and MRI performed for unrelated indications. Symptoms of hypogonadism with loss of libido are also common. Men with predominantly FSH-secreting tumors may present with testicular enlargement from hypertrophy of the seminiferous tubules but may also be hypogonadal due to low levels of testosterone. These patients must be distinguished from those with primary hypogonadism due to testicular dysfunction. Tumors that primarily secrete LH are rare but can cause increased testosterone levels. Premenopausal women with gonadotropin-producing tumors may experience menstrual irregularity or secondary hypogonadism. Postmenopausal women often show reduced gonadotropin levels because the mass effects of the gonadotropin-producing tumors cause stalk compression, impairing GnRH stimulation of gonadotropins from normal pituitary cells.

DIAGNOSIS

Because of the absence of a clinical syndrome in most patients, almost all gonadotropin-producing pituitary tumors are diagnosed by postoperative immunohistochemistry because they had presented with mass effects. There is no particular clinical benefit to distinguish whether a nonfunctioning adenoma is truly a gonadotroph adenoma. Some patients can have moderately elevated PRL levels that are caused by tumor mass effects. It is important to distinguish this group from patients with true prolactinomas. As noted earlier, many women, including those in the postmenopausal group, have paradoxically low gonadotropin levels. Thus, the absence of elevated gonadotropins does not exclude the diagnosis of a gonadotropin-producing tumor.

TREATMENT Rx

Because the major symptoms of the gonadotropin-producing tumors are due to extrasellar extension and local mass effects, the main aim of treatment is reduction in the size of the tumor. Complete or partial reversal of visual field defects and hypopituitarism can be accomplished by surgery, unless these conditions have been of long standing. Transsphenoidal surgery is rarely curative, however. Patients with significant residual tumor may benefit from radiation therapy. Because most tumors are slow growing, when no tumor is visible postoperatively by MRI, the patient may be followed with yearly monitoring for tumor recurrence using visual fields and CT or MRI. If tumor markers such as free α- or β-subunit levels are available, they can also be used to monitor tumor function. When follow-up studies show tumor regrowth, repeat surgery, radiation therapy, or both are indicated. Medical therapy with dopamine agonists and somatostatin analogues has been successful in only a minority of patients.

THYROID-STIMULATING HORMONE

Like the other glycoprotein hormones, TSH is a heterodimer composed of the common α-subunit and the unique TSH β-subunit. Normal levels of TSH range from 0.4 to 4.0 μU/mL. The detection limit for current TSH assays is less than 0.01 μU/mL, allowing measurement of suppressed TSH levels in patients with hyperthyroidism. Thyroid-stimulating hormone controls thyroid hormone (T_4 and T_3) synthesis and secretion from the thyroid gland. Hypothalamic TRH stimulates TSH synthesis and secretion. Somatostatin and dopamine can inhibit TSH secretion, but their roles in normal physiology have not been clearly elucidated. Thyroid hormones have an inhibitory effect on the production of TRH and TSH and constitute a powerful negative feedback loop acting at both the hypothalamic and pituitary levels. Secretion of TSH is pulsatile, but the amplitude of the pulses is relatively small and does not create the difficulties in measurement of TSH that are encountered with measurements of other pituitary hormones. Because of the integrated nature of the hypothalamic-pituitary-thyroid axis, thyroid function tests are best interpreted when concentrations of TSH, free T_4, and free T_3 levels are known. Except in conditions of secondary hypothyroidism or TSH-secreting pituitary tumors (see later), TSH levels provide an excellent screening test for thyroid dysfunction.

CENTRAL HYPOTHYROIDISM

Central forms of hypothyroidism are due to loss of either TSH or TRH. Three different types of congenital TSH deficiency are caused by genetic mutations. One type involves mutations in the *TSHβ* gene. A second involves mutations in *PIT1*, which causes combined deficiencies of GH, PRL, and TSH (see earlier). A third involves a mutation in the gene for TRH. Acquired, central forms of hypothyroidism are often associated with other pituitary hormone deficiencies, and usually there is no goiter because of low TSH levels.

Tests for TSH deficiency are best performed by analyzing free T_4 levels in combination with TSH. Low free T_4 without elevated TSH is consistent with central hypothyroidism. In some patients with hypothalamic disease, the TSH level is partially elevated in the presence of low levels of free T_4, but the bioactivity of the TSH is reduced. Central forms of hypothyroidism must be distinguished from the sick-euthyroid condition (Chapter 233). Laboratory tests in the sick-euthyroid syndrome progress through several phases but can include prolonged periods when both TSH and free thyroid hormone levels are low. It can be very difficult in these patients to exclude central hypothyroidism unequivocally. In addition to the clinical setting in which thyroid function tests are measured, the presence of normal thyroid function tests before the illness and the absence of known hypothalamic or pituitary disease make true central hypothyroidism unlikely. Increased levels of reverse T_3 are suggestive of sick-euthyroidism, and free T_4 and T_3 may be in the normal or low-normal range in sick-euthyroid patients. When TSH deficiency is documented, thyroid hormone is replaced using daily doses of L-thyroxine (0.05 to 0.15 mg/day). Because TSH cannot be used as an end point, one monitors the patient clinically and with serum levels of free T_4 and T_3.

THYROID-STIMULATING HORMONE–SECRETING TUMORS

TSH-secreting tumors are rare and account for between 1 and 3% of pituitary tumors. As many as 30% of TSH-producing tumors are plurihormonal. GH and PRL are co-secreted most often, perhaps reflecting the common cellular lineage for thyrotrophs, somatotrophs, and lactotrophs. Long-standing severe hypothyroidism can cause thyrotroph hyperplasia and pituitary enlargement. These hyperplastic masses regress with thyroid hormone replacement therapy, however. Most true TSH-producing tumors are relatively autonomous and respond weakly, if at all, to TRH stimulation or thyroid hormone suppression.

TSH-secreting tumors are usually macroadenomas by the time a diagnosis has been made. Consequently, many patients exhibit mass effects of the tumor as well as hyperthyroidism. The clinical features of TSH-secreting tumors resemble those of Graves' disease, except that features of autoimmunity such as ophthalmopathy are absent. Circulating levels of T_4 and T_3 range widely but can be elevated as much as two- to three-fold. Diffuse goiter is present in most patients with TSH-producing tumors, and the 24-hour uptake of radioiodine is elevated.

Because feedback inhibition of TSH is impaired in TSH-producing tumors, TSH levels are inappropriately elevated in the presence of high levels of T_4 and T_3. TSH levels produced by tumors range from the low-normal range to as high as 500 μU/mL, but most levels are minimally elevated. Most TSH-producing tumors (>80%) secrete excess free α-subunit, and its assessment can be very useful in confirming the diagnosis. Thus, the diagnosis can usually be made by demonstrating that a hyperthyroid patient has a detectable serum TSH level associated with excess secretion of the free α-subunit. The finding of a mass lesion on CT or MRI confirms the diagnosis. Several other causes of inappropriate TSH secretion should be considered, including resistance to thyroid hormone and familial dysalbuminemic hyperthyroxinemia and other disorders that alter serum thyroid hormone binding proteins.

TREATMENT

Rx

The goals of therapy are to treat the underlying TSH-secreting tumor and to correct the hyperthyroidism. Transsphenoidal surgery alone is rarely curative because of the large size of most tumors, but it can alleviate mass effects and lower TSH levels. As in other large pituitary tumors, adjunctive irradiation may be required to control tumor growth. Somatostatin analogues have been used as adjunctive medical therapy, and they decrease TSH and α-subunit levels in about 80% of patients with TSH-secreting tumors, but consistent effects on tumor growth have not been demonstrated. Hyperthyroidism caused by TSH-secreting tumors can also be treated using antithyroid drugs or radioiodine.

CLINICALLY NONFUNCTIONING PITUITARY TUMORS

Most clinically nonfunctioning adenomas can be shown to produce low levels of the free α-subunit, free β-subunits of FSH and LH, and intact FSH and LH when analyzed by immunocytochemistry or messenger RNA expression. A smaller fraction can be shown to produce low levels of other pituitary hormones, particularly ACTH or GH, that escaped detection based on routine endocrine testing. Even with detailed analyses of hormone production, a subset (10 to 20%) of nonfunctioning adenomas does not appear to produce any of the known pituitary hormones.

The clinical features and management of nonfunctioning tumors are similar to those for gonadotropin-producing tumors. The major signs and symptoms result from tumor mass effects that cause visual field defects, headache and other neurologic symptoms, and hypopituitarism. Transsphenoidal surgery is the primary mode of treatment, with a goal of debulking the tumor to relieve mass effects. Because there are no serum tumor markers, patients must be followed by CT or MRI in conjunction with visual field tests.

Some pituitary tumors are discovered as incidental findings on CT or MRI scans that were done for other reasons. Such tumors should be screened for hormone oversecretion with measurement of PRL, IGF-1, and a midnight salivary cortisol or an overnight dexamethasone suppression test, but most will be found to be nonfunctioning. If the tumor abuts the optic chiasm, a formal visual field examination should be performed. Over several years, about 10% of incidental microadenomas and 20% of macroadenomas enlarge. Indications for surgery include compression of the optic chiasm with or without visual field defects and significant tumor enlargement. Hypopituitarism is also a relative indication for surgery.

ANATOMY AND HORMONE SYNTHESIS

The hormones of the posterior pituitary, vasopressin and oxytocin, are synthesized in specialized neurons in the hypothalamus, the neurohypophysial neurons. These neurons, notable for their large size, are termed *magnocellular neurons*. In the hypothalamus, magnocellular neurons are clustered in the paired paraventricular and supraoptic nuclei (Fig. 232-1). Vasopressin and oxytocin are synthesized in parvicellular (i.e., small cell) neurons of the paraventricular nuclei, and vasopressin (but not oxytocin) is also synthesized in the suprachiasmatic nucleus.

Transcription of vasopressin and oxytocin messenger RNA and translation of the vasopressin and oxytocin prohormones occur entirely in the cell bodies of the neurohypophysial neurons. The prohormones provasopressin and prooxytocin are packaged along with processing enzymes into neurosecretory granules that are transported out of the perikaryon of the neurohypophysial neurons through microtubules and down the long axons that form the supraopticohypophysial tract and terminate in the posterior pituitary. During transport, the processing enzymes cleave provasopressin into vasopressin (9 amino acids), vasopressin-neurophysin (95 amino acids), and vasopressin glycopeptide, or copeptin (39 amino acids). Pro-oxytocin is similarly cleaved to oxytocin (which differs from vasopressin by only two of nine amino acids) and oxytocin-neurophysin. The neurophysins form neurophysin-hormone complexes that stabilize the hormones. The hormone within the granules is always bound. Stimulatory (e.g., glutamatergic, cholinergic, and angiotensin) neurotransmitter terminals and inhibitory (e.g., γ-aminobutyric acid and noradrenergic) neurotransmitter terminals control the release of vasopressin by the activity of synaptic contacts on the cell bodies. Physiologic release of vasopressin or oxytocin into the general circulation occurs at the level of the posterior pituitary, where, in response to an action potential, intracellular calcium is increased and causes the neurosecretory granules to fuse with the axon membrane, thereby releasing each hormone in the free form in the general circulation. The mature vasopressin and oxytocin are the only biologically active components of the prohormones. Factors that stimulate the release of neurohypophysial hormones also stimulate their synthesis. Because synthesis is delayed, maintenance of a large store of hormone in the posterior pituitary is essential for the instantaneous and massive release of each hormone that is necessary with acute hemorrhage (vasopressin) or during parturition (oxytocin). In most species, sufficient vasopressin is stored in the posterior pituitary to support maximal antidiuresis for several days and to maintain baseline levels of antidiuresis for weeks.

Vasopressin

Vasopressin and Regulation of Osmolality

The primary physiologic action of vasopressin is its function as a water-retaining hormone. The central sensing system (osmostat) for controlling the release of vasopressin is anatomically discrete, located in a small area of the hypothalamus just anterior to the third ventricle (see Fig. 232-1). The osmostat controls the release of vasopressin to cause water retention and also stimulates thirst to cause water repletion. Recent studies have implicated various members of the transient receptor potential vanilloid (TRPV) family of cation channel proteins as "osmo-mechanoreceptors." They are intimately involved in the transduction of osmotic stimuli in the neural cells in the organum vasculosum of lamina terminalis and the surrounding hypothalamus, which regulate osmotic homeostasis.

Osmotic regulation of vasopressin release and osmotic regulation of thirst are usually tightly coupled, but they can be dissociated under pathologic conditions. The primary extracellular osmolyte to which the osmoreceptor responds is sodium. Under normal physiologic conditions, glucose and urea readily traverse neuron cell membranes and do not stimulate the release of vasopressin. Although basal osmolality in normal subjects is between 280 and 295 mOsm/kg H_2O, extracellular fluid osmolality for each individual is maintained within narrow ranges. Increases in plasma osmolality as small as 1 to 2% stimulate vasopressin release. Basal plasma levels of vasopressin are generally 0.5 to 2 pg/mL, which is sufficient to maintain urine osmolality above plasma osmolality and urine volume in the range of 2 to 3 L/day. When vasopressin levels are suppressed below 0.5 pg/mL, maximal urine osmolality decreases to less than 100 mOsm/kg H_2O, and a free water diuresis (or "aquaresis") ensues at levels approaching 800 to 1000 mL/hour (18 to 24 L/day). Increases in plasma osmolality cause a linear increase in plasma vasopressin and a corresponding linear increase in urine osmolality. At a plasma osmolality of approximately 295 mOsm/kg H_2O, urine osmolality is maximally concentrated to 1000 to 1200 mOsm/kg H_2O. Thus, the entire physiologic range of urine osmolality is accomplished by relatively small changes in plasma vasopressin of 0 to 5 pg/mL (Fig. 232-2).

To maintain fluid balance, water must be not only conserved but also consumed to replace insensible water losses and obligate urine output. Thirst is not stimulated until a somewhat higher plasma osmolality (5 to 10 mOsm/kg H_2O) than the threshold for release of vasopressin. Most humans derive sufficient water from habitual fluid intake and catabolism of food to maintain plasma osmolality below the threshold that activates thirst. Therefore, under normal physiologic conditions, water balance (and hence plasma osmolality) is regulated more by secretion of vasopressin than by thirst. However, with severe degrees of dehydration, thirst is essential to restore body water deficits.

Vasopressin acts on V_2 or antidiuretic receptors in the collecting duct cells of the kidney to cause water retention, or antidiuresis. Vasopressin V_2 receptors are G protein–coupled receptors that activate adenylate cyclase, with subsequent increased intracellular cyclic adenosine monophosphate (cAMP) levels upon ligand activation of the receptor. The increased cAMP initiates the movement of aquaporin-2 water channels to the apical (luminal) membrane of the collecting duct cells. These channels allow facilitated, rapid transport of water from the collecting duct lumen into the cell along osmotic gradients. The water then exits the cell through the basolateral membrane, into the kidney medullary circulation through aquaporin-3 and aquaporin-4 water channels. This entire process is termed *antidiuresis*. In the absence of vasopressin, the aquaporin-2 channels are re-internalized from the apical membrane into subapical vesicles. This prevents active reabsorption of water from the collecting duct lumen, resulting in diuresis. In addition to this rapid "shuttling" of the aquaporin-2 channels to regulate water reabsorption on a minute-to-minute basis, vasopressin acts through V_2 receptors to regulate long-term stores of aquaporin-2; that is, increased vasopressin stimulates aquaporin-2 synthesis, and the absence of vasopressin results in decreased aquaporin-2 synthesis. The hypertonic medullary interstitium determines the maximal concentration of the urine, which is isotonic with the inner medulla of the kidney under conditions of maximal antidiuresis (Chapter 117).

Vasopressin and Pressure and Volume Regulation

High-pressure baroreceptors are located in the aorta and carotid sinus, and low-pressure baroreceptors are located in the right and left atria. Stimuli for pressure and volume receptors are carried through the glossopharyngeal (ninth) and vagal (tenth) cranial nerves to the nucleus tractus solitarius in the brain stem. Subsequent secondary and tertiary projections converge on the magnocellular neurons, where they provide inhibitory as well as excitatory inputs. Decreases in blood pressure or intravascular volume stimulate vasopressin release, whereas situations that increase blood volume or left atrial pressure (e.g., negative-pressure breathing) decrease the secretion of vasopressin. The release of vasopressin in response to changes in volume or pressure is less sensitive than the release in response to osmoreceptors, and generally a 10 to 15% reduction in blood volume or pressure is needed to stimulate the release of vasopressin. However, once arterial pressure falls below this threshold, the stimulated response is exponential, and plasma levels of vasopressin are markedly greater than those from osmotic stimulation.

The pressor effects of vasopressin are mediated through a separate receptor subtype, the V_{1a} receptors, located on vascular smooth muscle. For V_{1a} and V_{1b} receptors (located on anterior pituitary corticotroph cells), the mechanism of action of vasopressin is to increase intracellular calcium rather than to stimulate adenylate cyclase. The relatively insensitive regulation of vasopressin secretion by changes in volume and pressure and the modest role of vasopressin to regulate blood pressure are consistent with the notion that the regulation of sodium homeostasis by the renin-angiotensin-aldosterone system is more important for controlling extracellular and blood volume than is the regulation of water homeostasis. However, the pressor effects of

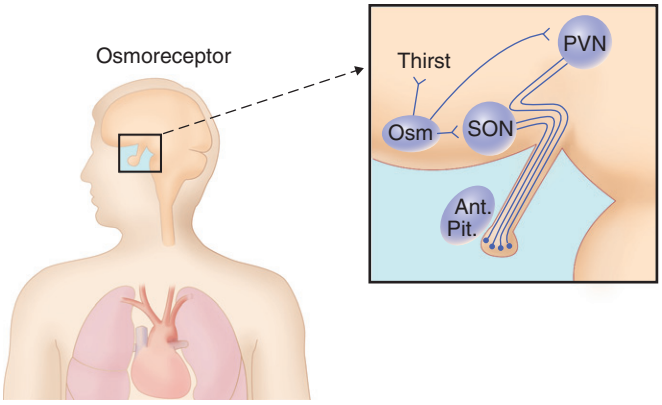

FIGURE 232-1. Sagittal view of the head demonstrating the position of the neurohypophysis. The magnocellular neurons are clustered in two paraventricular nuclei (PVN) and two supraoptic nuclei (SON). Only one nucleus of each pair is illustrated. The supraoptic nuclei are lateral to the edge of the optic chiasm, whereas the paraventricular nuclei are central along the wall of the third ventricle. The axons of the four nuclei combine to form the supraopticohypophysial tract as they course through the pituitary stalk to their storage terminals in the posterior pituitary. The osmostat (Osm) is in the hypothalamus anterior to the third ventricle; the thirst center (Thirst) is distributed across different brain areas. Ant. Pit. = anterior pituitary. (From Buonocore CM, Robinson AG. Diagnosis and management of diabetes insipidus during medical emergencies. *Endocrinol Metab Clin North Am.* 1993;22: 411-423.)

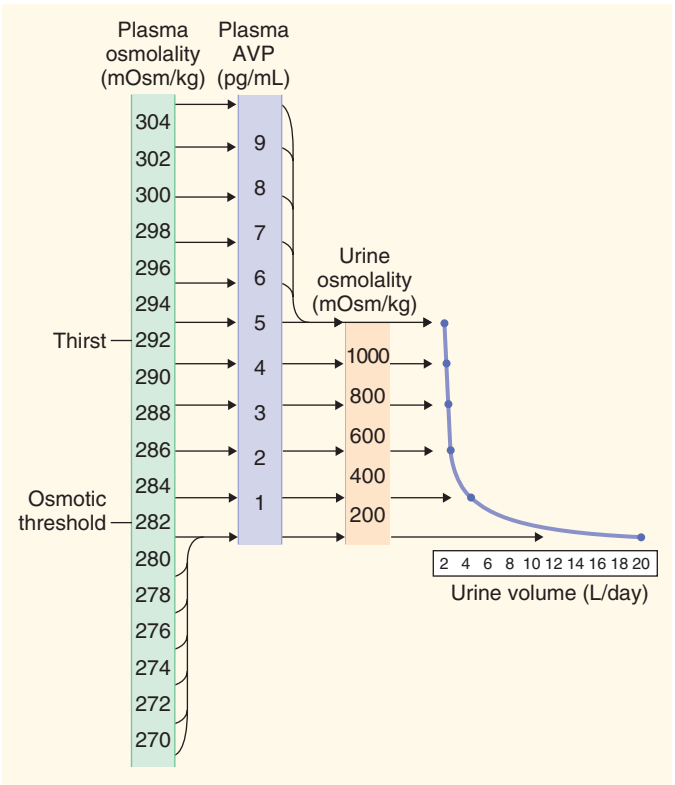

FIGURE 232-2. Idealized schematic of the normal physiologic relationships among plasma osmolality, plasma vasopressin (AVP), urine osmolality, and urine volume. The entire physiologic range of urine osmolality occurs with plasma vasopressin levels from 0 to 5 pg/mL. Increases in plasma osmolality above approximately 290 to 295 mOsm/kg H_2O result in increases in plasma vasopressin but no further concentration of the urine, which is limited by the maximal osmolality in the inner medulla. The relation of volume (calculated on the basis of a constant osmolar load) is inversely exponential to the other parameters. Because of this relationship, urine volume does not change substantially until there is nearly absent vasopressin secretion, after which urine volume increases dramatically. (Calculated from formulas presented in Robertson GL, Shelton RL, Athar S. The osmoregulation of vasopressin. *Kidney Int.* 1976;10:25-37. Figure drawn by J. G. Verbalis, Georgetown University, Washington, DC.)

vasopressin to increase blood pressure can become prominent when other blood pressure regulatory systems are deficient (e.g., autonomic neuropathy or renin-angiotensin-aldosterone system blockade) or in states of pathologic vasodilation (e.g., liver cirrhosis, septic shock).

Vasopressin and Adrenocorticotropic Hormone

Vasopressin in the parvicellular neurons whose axons terminate in the median eminence is released into the pituitary portal capillaries and carried to the anterior pituitary. Anterior pituitary corticotrophs are stimulated through V_{1b} receptors to release adrenocorticotropic hormone (ACTH). Although the major regulator of ACTH secretion is corticotropin-releasing hormone (Chapter 231), vasopressin activates a different signal transduction system in the corticotrophs, so these hormones have synergistic effects in the release of ACTH.

Interaction of Osmotic and Volume Regulation

The vasopressin system has been adapted to optimize mammalian drinking behavior. Water is consumed as available in the absence of stimulated thirst, and then vasopressin regulates water excretion to maintain plasma osmolality. Thirst serves as a backup if dehydration becomes excessive. Similarly, because pressure-volume regulation of vasopressin is less sensitive, modest changes in pressure or volume, which are exacerbated by upright posture, do not interfere with the regulation of osmolality. Yet the pressor effect of high vasopressin serves as a backup if volume depletion or hypotension becomes excessive. Usually, the physiologic regulation of osmolality and pressure-volume are synergistic. Dehydration causes an increase in osmolality and a decrease in volume, both of which stimulate the release of vasopressin. Excess administration of fluid causes a decrease in osmolality and an expansion of volume, both of which inhibit vasopressin secretion. However, other pathologic situations can result in opposing signals for vasopressin secretion (e.g., hyponatremia resulting from diuretic use, with a decreased extracellular fluid volume, or from cardiac failure or cirrhosis, due to a decreased effective arterial blood volume). In these situations, vasopressin secretion represents a balance between the excitatory and inhibitory inputs provided by the osmotic and volume-pressure stimuli.

In addition, other factors can modulate the osmotic release and action of vasopressin. With volume expansion, natriuretic factors such as atrial natriuretic peptide and brain natriuretic peptide are released from atrial myocytes and act at the kidney to induce natriuresis. Atrial natriuretic peptide is also synthesized in the hypothalamus, where it may act to decrease vasopressin secretion. During pregnancy, there is a decrease of plasma osmolality by approximately 10 mOsm/kg H_2O as a result of a resetting of the osmostat, and the osmostat for thirst is reset in parallel. This effect may be mediated by the placental hormone relaxin.

Abnormalities in water and electrolyte balance are common in the elderly. This is due in part to age-related changes in body volume (as much as a 50% decrease in total body water in those older than 75 years) and renal function. The elderly also have a decreased appreciation for thirst. Although there is a normal or even increased ability to secrete vasopressin with age, there is a decreased ability to achieve either maximal urine concentration to retain water or maximal dilution of urine to excrete water. Consequently, the elderly are particularly prone to hypernatremia or hyponatremia with diseases that affect water balance or from the drugs used to treat various diseases.

Oxytocin

Prolactin is the main hormone necessary for milk production, but oxytocin is essential for milk secretion. Suckling stimulates tactile receptors, producing an afferent signal to the hypothalamus that causes the release of oxytocin from the posterior pituitary. Oxytocin binds to oxytocin receptors in the breast and induces contraction of myoepithelial cells around the alveoli and ductules to eject milk. In addition, upregulation of the uterine receptors for oxytocin dramatically increases the response to oxytocin at the end of pregnancy. In all species, there is an interaction of oxytocin with gonadal steroid hormones, prostaglandins, and relaxin. The interaction of these various hormones in a cross-stimulation feed-forward cascade to support parturition is important to ensure survival of the species, so it is understandable that, during parturition, lack of any single hormone (including oxytocin) is generally not sufficient to inhibit delivery. The greatest release of oxytocin occurs with, not before, delivery of the infant, probably secondary to stretching of the vaginal wall. Oxytocin release may be more important to induce uterine contraction to inhibit blood loss after delivery than to initiate parturition. No pathologic syndromes of either increased or decreased secretion of oxytocin have been defined. Women with diabetes insipidus secondary to traumatic damage of the magnocellular neurons often have a normal pregnancy and

delivery and can breast-feed their infants, but in these cases, it may be that oxytocin neurons survive better than vasopressin neurons. Because of the structural similarity between vasopressin and oxytocin receptors, at high plasma levels, oxytocin can activate vasopressin receptors, and vasopressin can activate oxytocin receptors. One example of this is that the administration of oxytocin to induce labor can stimulate V_2 receptors of the kidney and cause water retention and hyponatremia if excess fluids are administered simultaneously.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Excess secretion of vasopressin can be caused by abnormal secretion from the posterior pituitary or by ectopic synthesis and secretion of vasopressin by a tumor. The inappropriate secretion of vasopressin causes renal water retention and volume expansion of body fluids, with a secondary natriuresis and consequent hyponatremia. This disorder is called the *syndrome of inappropriate antidiuretic hormone secretion* and is discussed in Chapter 118.

DIABETES INSIPIDUS

DEFINITION

Diabetes insipidus is the excretion of a large volume of hypotonic, insipid (tasteless) urine, usually manifested by polyuria (increased urination) and polydipsia (increased thirst). The large volume, usually in excess of 50 to 60 mL/kg/day, must be distinguished from increased frequency of small volumes and from large volumes of isotonic or hypertonic urine, both of which have other clinical significance.

PATHOBIOLOGY

Four pathophysiologic mechanisms must be considered in the differential diagnosis of diabetes insipidus.

1. Central diabetes insipidus is caused by the inability to secrete (and usually to synthesize) vasopressin in response to increased osmolality. No concentration of the dilute glomerular filtrate takes place in the renal collecting duct, and consequently, a large volume of hypotonic (i.e., dilute) urine is excreted. This produces an increase in serum osmolality, with stimulation of thirst and secondary polydipsia. Levels of vasopressin in plasma are unmeasurable or inappropriately low for plasma osmolality.
2. Nephrogenic diabetes insipidus is caused by the inability of an otherwise normal kidney to respond to vasopressin. As in hypothalamic diabetes insipidus, the dilute glomerular filtrate entering the collecting duct is excreted as a large volume of hypotonic urine. The rise in plasma osmolality that occurs stimulates thirst and produces polydipsia. Unlike central diabetes insipidus, however, measured levels of vasopressin in plasma are high or appropriate for plasma osmolality.
3. Gestational diabetes insipidus is a rare condition produced by elevated levels or activity of placental cystine aminopeptidase (oxytocinase or vasopressinase) during pregnancy. The rapid destruction of vasopressin produces diabetes insipidus with polyuria and secondary stimulation of thirst with polydipsia. Because of the circulating vasopressinase, plasma vasopressin levels usually cannot be measured.
4. Primary polydipsia is a disorder of excess fluid ingestion rather than of vasopressin secretion or activity. Excessive ingested water produces a mild decrease in plasma osmolality that shuts off the secretion of vasopressin. In the absence of vasopressin action on the kidney, urine does not become concentrated, and a large volume of hypotonic urine is excreted. The amount of vasopressin in plasma is unmeasurable or low but is appropriate for the low plasma osmolality.

Although the pathophysiologic mechanisms for each of these four disorders are distinct, patients in each category usually manifest polyuria and polydipsia. The serum sodium level is normal because the normal thirst mechanism is sufficiently sensitive to maintain water homeostasis in the first three disorders, and the normal kidney has sufficient capacity to excrete the excess water load in the fourth.

CLINICAL MANIFESTATIONS

Central Diabetes Insipidus

The sudden appearance of hypotonic polyuria after transcranial surgery in the area of the hypothalamus or after head trauma with basal skull fracture and hypothalamic damage obviously suggests the diagnosis of central diabetes insipidus. In these situations, if the patient is unconscious and unable to recognize thirst, hypernatremia is a common accompaniment. However, even in patients with more insidious progression of a specific disease or in patients with idiopathic central diabetes insipidus, the onset of polyuria is often relatively abrupt and occurs over several days or weeks. The initial problem is the volume of urine and polydipsia, not the decrease in urine osmolality. Most patients do not report polyuria until urine volume exceeds 4 L/day, and as illustrated in Figure 232-2, urine volume does not exceed 4 L/day until the ability to concentrate the urine is severely limited and plasma vasopressin is nearly absent. As few as 10% of the normal number of vasopressinergic neurons in the hypothalamus can maintain asymptomatic urine volume, but the further loss of these few neurons produces a rapid increase in urine volume and symptomatic polyuria. Urine volume seldom exceeds the amount of dilute fluid delivered to the collecting duct (about 18 to 24 L in humans), and in many cases, urine volume is less because patients voluntarily restrict fluid intake, which causes some mild volume contraction and increased proximal tubular reabsorption of fluid. Patients often express a preference for cold liquids, which are more effective in assuaging thirst. Both thirst and increased urine output persist through the night. Patients with partial central diabetes insipidus have some ability to secrete vasopressin, but this secretion is markedly attenuated at normal levels of plasma osmolality. Therefore, these patients have symptoms and urine volume similar to those of patients with complete central diabetes insipidus. Because most patients with central diabetes insipidus have sufficient thirst to drink fluid to match urine output, few laboratory abnormalities are present at the time of initial evaluation. The serum sodium level may be in the high-normal range, whereas the blood urea nitrogen level may be low secondary to the large urine volume. Uric acid is relatively high due to the modest volume contraction and the lack of action of vasopressin on V_{1a} receptors in the kidney, which stimulate the clearance of uric acid. Uric acid levels greater than 5 mg/dL can distinguish diabetes insipidus from primary polydipsia.

A variant of central diabetes insipidus is the syndrome of osmoreceptor dysfunction. This syndrome has been referred to as *essential hypernatremia* and *adipsic hypernatremia* because such patients have a chronically increased serum sodium concentration and an absence of thirst. Physiologic maneuvers demonstrate that when patients are euvolemic, an increase in plasma osmolality produces neither secretion of vasopressin nor a sensation of thirst. However, vasopressin is still synthesized by the hypothalamus and stored in the posterior pituitary because stimulation of baroreceptors by hypovolemia or hypotension results in the prompt secretion of vasopressin; the kidney is responsive because vasopressin release by volume receptor stimulation causes urinary concentration. Because patients lack thirst, they are chronically dehydrated, with increased serum sodium levels. However, it is the dehydration-induced volume depletion, not the increased osmolality, that eventually stimulates the secretion of vasopressin. The volume of urine output depends on the degree of dehydration-induced secretion of vasopressin. If sufficient fluid replacement is given to return extracellular fluid volume to normal, these patients are unable to regulate vasopressin by osmolality and become polyuric, thereby manifesting their underlying diabetes insipidus.

Central diabetes insipidus can be inherited as an autosomal dominant disease that is typically characterized by an asymptomatic infancy and an onset later in childhood. Most genetic defects are either in the signal peptide of the pre-prohormone or in the neurophysin portion of the prohormone. Mutations involving the vasopressin sequence itself are few. Abnormal packaging of vasopressin and neurophysin might also produce increased degradation of both the mutant and the normal wild-type prohormone and hence inadequate secretion of vasopressin. However, most cases are believed to result from disruption of cleavage from the signal peptide or abnormal folding of the neurophysin, which slows trafficking of the mutant prohormone through the endoplasmic reticulum, leading to neuronal cell dysfunction and death. Because this is a cumulative process, this explains the later onset of central diabetes insipidus with these types of mutations.

Myxedema and adrenal insufficiency both impair the ability to excrete free water by renal mechanisms. The simultaneous occurrence of either of these diseases with central diabetes insipidus (as can occur with a tumor of the hypothalamus or pituitary) may decrease an otherwise large urine output, masking the symptoms of diabetes insipidus. Replacement treatment for the anterior pituitary deficiency, especially glucocorticoids, can then cause a sudden and massive excretion of dilute urine. Similarly, the onset of either hypothyroidism or adrenal insufficiency during the course of diabetes insipidus can decrease the need for vasopressin replacement and in some cases can even cause hyponatremia. Central diabetes insipidus is extremely common

in patients with severe brain ischemia and is usually indicative of brain death. Treatment of the diabetes insipidus along with any coexistent anterior pituitary hormone deficiencies has been advocated to preserve donor organs in such cases.

Nephrogenic Diabetes Insipidus

Nephrogenic diabetes insipidus is caused by mutations of the vasopressin V_2 receptor or the vasopressin-induced water channel aquaporin-2 or by impairments in the signal transduction system linking the V_2 receptor and aquaporin-2. Familial nephrogenic diabetes insipidus is a rare disease, most cases of which (>90%) are due to mutations of the V_2 receptor. More than 100 different V_2 receptor mutations have been described, which can be classified into several different general categories based on differences in transport of the mutant receptor to the cell surface and vasopressin binding or stimulation of adenylate cyclase. Because the gene for the V_2 receptor is located on the X chromosome, this is an X-linked recessive disease. Symptoms are noted only in affected males, who present with vomiting, constipation, failure to thrive, fever, and polyuria during the first week of life. Hypernatremia is found with a hypotonic urine. The phenotype is similar in the less than 10% of patients with mutations of the aquaporin-2 water channel, but because the aquaporin-2 gene is located on chromosome 12, mutations cause autosomal recessive disease; consequently, consanguinity and a family history of the disease in men and women is common, and this disorder should be suspected when the proband is female.

Nephrogenic diabetes insipidus can also be acquired during treatment with certain drugs, such as demeclocycline (which is used to treat inappropriate secretion of vasopressin), lithium carbonate (used to treat bipolar disorders), and fluoride (previously used in fluorocarbon anesthetics), and from electrolyte abnormalities such as hypokalemia and hypercalcemia. All causes of acquired nephrogenic diabetes insipidus have in common the decreased synthesis and function of aquaporin-2 due to impaired vasopressin signaling from V_2 receptor binding and activation. Other diseases of the kidney produce polyuria and inability to concentrate the urine secondary to altered renal medullary blood flow or to other disorders that inhibit maintenance of the hyperosmolar concentrating gradient in the inner medulla. Renal manifestations of such disorders (e.g., sickle cell disease, sarcoidosis, pyelonephritis, multiple myeloma, analgesic nephropathy) are discussed in Chapter 123.

Gestational Diabetes Insipidus

In pregnancy, there is an increased metabolism of vasopressin due to cystine aminopeptidase (oxytocinase or vasopressinase), an enzyme that normally degrades oxytocin and prevents premature uterine contractions. Normally, this is compensated for by increased synthesis of vasopressin. Rarely, women with normal regulation of vasopressin develop diabetes insipidus because of markedly elevated levels of vasopressinase. Some of these patients have accompanying preeclampsia, acute fatty liver, and coagulopathies, but causal relations between diabetes insipidus and these abnormalities have not been identified. In general, diabetes insipidus is not found after the pregnancy ends or in subsequent normal pregnancies.

Polyuria can also manifest in patients who have limited vasopressin reserve (partial central diabetes insipidus) or who respond poorly to vasopressin action (compensated nephrogenic diabetes insipidus). Treatment may be required only during the pregnancy, and the patient often returns to her previous baseline function without the need for therapy when the pregnancy ends. Less commonly, central diabetes insipidus of another cause first becomes symptomatic during pregnancy and then persists, following the usual course of diabetes insipidus.

Primary Polydipsia

Excessive fluid intake also causes hypotonic polyuria and, by definition, polydipsia. This disorder must be differentiated from the various causes of diabetes insipidus. Despite normal pituitary and kidney function, patients with this disorder share many characteristics of both central diabetes insipidus (vasopressin secretion is suppressed as a result of decreased plasma osmolality) and nephrogenic diabetes insipidus (kidney aquaporin-2 expression is decreased as a result of suppressed plasma vasopressin levels). Many different names have been used for this excessive fluid intake, but primary polydipsia is the best descriptor.

Primary polydipsia is sometimes due to a severe mental illness such as schizophrenia, mania, or obsessive-compulsive disorder, in which case it is called *psychogenic polydipsia*. These patients usually deny true thirst and attribute their polydipsia to bizarre motives, such as a need to cleanse the body of poisons. The incidence in psychiatric hospitals can be as high as 42%, and there is no obvious explanation for the polydipsia. Primary polydipsia can also be caused by an abnormality in the osmoregulatory control of thirst, in which case it is termed *dipsogenic diabetes insipidus*. These patients have no overt psychiatric illness and invariably attribute their polydipsia to a nearly constant thirst. Dipsogenic diabetes insipidus is usually idiopathic, but it can also be secondary to organic structural lesions in the hypothalamus identical to those causing central diabetes insipidus, such as neurosarcoidosis of the hypothalamus, tuberculous meningitis, multiple sclerosis, or trauma. Consequently, all polydipsic patients should be evaluated with magnetic resonance imaging (MRI) of the brain before it is concluded that excessive water intake is due to an idiopathic or psychiatric cause. Primary polydipsia can also be produced by drugs that cause a dry mouth or by any peripheral disorder causing marked elevations of renin or angiotensin.

Finally, primary polydipsia is sometimes caused by physicians, nurses, lay practitioners, or health writers who recommend a high fluid intake for valid (e.g., recurrent nephrolithiasis) or unsubstantiated health reasons. These patients lack overt signs of mental illness, but they also deny thirst and usually attribute their polydipsia to habits acquired from years of adherence to a drinking regimen. Laboratory studies in these patients are generally normal, although the serum sodium concentration is sometimes at the low end of the normal range, and the level of uric acid is lower than in patients with other forms of diabetes insipidus.

DIAGNOSIS

Physiologic Diagnosis

Diabetes insipidus should be considered in all patients presenting with significant polyuria (i.e., urine output >50 mL/kg/day). Although osmotic diuresis secondary to hyperglycemia, intravenous contrast agents, or renal injury is a more common clinical cause of polyuria, the medical history, an isotonic urine osmolality, and routine clinical laboratory tests generally distinguish these disorders from diabetes insipidus. A diagnosis of diabetes insipidus can be made when urine osmolality is inappropriately low in the presence of an elevated plasma osmolality as a result of increased serum sodium concentration. These criteria are sometimes met at the initial examination, especially in cases of acute diabetes insipidus occurring after trauma or after surgery with inadequate fluid replacement. In such patients with hypernatremia and hypotonic urine osmolality with normal renal function, one need only administer a vasopressin agonist to differentiate central diabetes insipidus, in which a renal response with decreased urine volume and increased urine osmolality occurs, from nephrogenic diabetes insipidus, in which a subnormal renal response is seen. Sometimes in the postoperative state, a water diuresis occurs as a result of water retention during the surgical procedure. Vasopressin is normally secreted in response to surgical stress, causing fluid administered intravenously during the procedure to be retained. During recovery, vasopressin levels fall, and a diuresis of the retained fluid occurs. In this case, however, the serum sodium level is almost always normal; however, if additional fluid is administered to match the urine output, persistent polyuria might be mistaken for diabetes insipidus. In this situation, the physician should decrease the rate of fluid administered and follow the urine output and serum sodium level. If the urine output decreases and the serum sodium level remains normal, no treatment is necessary; if serum sodium rises above the normal range and the urine remains hypotonic, diabetes insipidus is likely, and the response to a vasopressin agonist can ascertain the type.

Most outpatients with diabetes insipidus are not hypernatremic because the polydipsia produced by a normal thirst response is generally sufficient to maintain water homeostasis. Instead, they present with polyuria, polydipsia, and a normal sodium level. In these patients, further testing is necessary to increase serum osmolality and then measure the plasma vasopressin level or the urinary response to an administered vasopressin agonist. The best described test is the water deprivation test (Fig. 232-3), which should be carried out under controlled observation in the hospital or an appropriately equipped outpatient area. The timing of the test depends on the patient's symptoms. If the patient has marked polyuria during the night, it is best to begin the test during the day because the patient may become dehydrated overnight. However, if the patient has only two or three episodes of nocturia per night, it is best to begin the test in the evening so that the major part of the dehydration takes place when the patient is asleep. In either case, the patient is weighed at the beginning of the test, and all subsequent fluids are withheld. The volume and osmolality (measured directly by freezing point

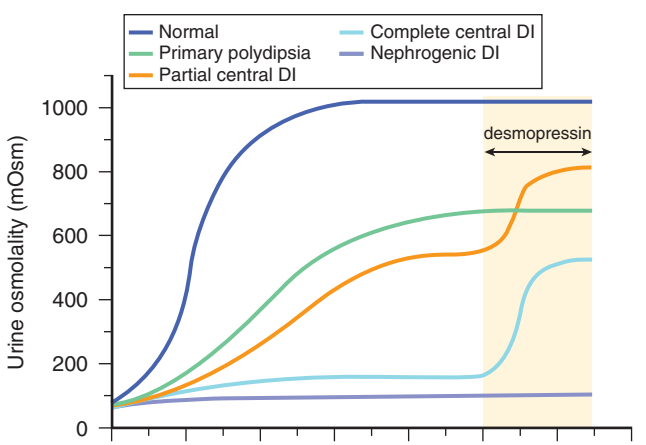

FIGURE 232-3. Responses to the water deprivation test to differentiate various types of diabetes insipidus (DI) and primary polydipsia (as described by Miller M, Dalakos T, Moses AM, et al. Recognition of partial defects in antidiuretic hormone secretion. *Ann Intern Med*. 1970;73:721-729). The response to dehydration reaches a plateau, and the subsequent change in urine osmolality in response to administered desmopressin is illustrated. See the discussion in the text.

depression) of all excreted urine are measured, and the patient is reweighed after each liter of urine output. When three consecutive urine samples have an osmolality differing by no more than 10% and the patient has lost at least 2% of body weight, a blood sample is obtained for the measurement of serum osmolality, sodium, and plasma vasopressin. The patient is then given 2 µg of desmopressin intravenously or intramuscularly and observed for an additional 2 hours.

Adults with normal vasopressin secretion can concentrate their urine to greater than 800 mOsm/kg H_2O and have less than a 10% increase in urine osmolality in response to administered desmopressin. Patients with complete central diabetes insipidus have minimal concentration of the urine with dehydration, and a marked increase in urine osmolality (usually >50%) in response to administered desmopressin. Patients with nephrogenic diabetes insipidus usually have no increase in urine concentration in response to administered desmopressin, although in some cases of acquired nephrogenic diabetes insipidus, some increased urinary concentration (generally <10%) can occur. Nephrogenic diabetes insipidus is best distinguished from central diabetes insipidus by the measurement of vasopressin in plasma; plasma vasopressin levels are normally elevated in cases of nephrogenic diabetes insipidus, especially after dehydration.

In patients with partial central diabetes insipidus and patients with primary polydipsia, the urine is often somewhat concentrated in response to dehydration, but not to the maximum of a normal person. The chronically reduced level of vasopressin downregulates the synthesis of aquaporin-2 water channels, and the large urine volume, regardless of cause, washes out the medullary osmotic gradient that determines the maximal urine concentration. When desmopressin is administered, patients with partial central diabetes insipidus have a further increase (usually >10% but <50%) in urine osmolality, whereas most patients with primary polydipsia have no further increase (i.e., <10%). However, the reliability of distinguishing between these two disorders by the water deprivation test is suboptimal. Some patients with primary polydipsia may not become sufficiently dehydrated to secrete maximal vasopressin and hence have an increase in urine osmolality in response to administered desmopressin. Alternatively, some patients with partial central diabetes insipidus can become sufficiently dehydrated that their maximal concentration of urine is reached during the test, and no further concentration is seen with administered desmopressin. Plasma vasopressin levels at the end of dehydration are better at discriminating between these two disorders, but only at high serum sodium concentrations (>145 mmol/L). Consequently, some investigators advise a limited infusion of hypertonic (3%) sodium chloride solution to achieve these levels if they are not achieved by the water deprivation itself. It is important to maintain adequate follow-up of patients with suspected partial central diabetes insipidus to ensure that, during treatment with vasopressin, a good therapeutic response is obtained. In some difficult cases, the response to treatment with a vasopressin agonist can be an adjunct to the diagnosis. If a decrease in polyuria and thirst with maintenance of normal serum sodium concentration occurs, a diagnosis of partial central diabetes insipidus is confirmed; however, if polydipsia persists and hyponatremia develops, a diagnosis of primary polydipsia is confirmed.

Etiologic Diagnosis

If the water deprivation test confirms that inadequate vasopressin secretion or function is responsible for the polyuria, the underlying cause must be determined. MRI of the hypothalamic-pituitary area is the most important diagnostic tool in these cases. The three areas of interest are the immediate suprasellar region of the hypothalamus, the pituitary stalk, and the posterior pituitary within the sella turcica (see the earlier discussion of anatomy). Most slow-growing tumors confined to the sella do not cause diabetes insipidus. To cause central diabetes insipidus, tumors in the hypothalamic area immediately above the sella must be either sufficiently large to destroy 80 to 90% of the vasopressin cells or located where the paths of the four nuclear groups converge at the origin of the pituitary stalk, just above the diaphragma sellae. Primary tumors, especially craniopharyngioma and suprasellar germinoma; metastatic tumors; and infiltrative diseases can also cause diabetes insipidus by infiltration of the pituitary stalk, which is then thickened on MRI. In addition, on T1-weighted MRI, the vasopressin and oxytocin stored in neurosecretory granules in the posterior pituitary are visualized as a "bright spot" in the sella turcica. Most but not all normal subjects have this bright spot; in most but not all patients with central diabetes insipidus, the bright spot is lost. Thickening of the stalk and absence of the bright spot are therefore especially suggestive of a hypothalamic disease process.

Tumors that cause central diabetes insipidus are most often benign primary intracranial tumors such as craniopharyngioma, ependymoma (suprasellar germinoma), and pinealoma, which arise in the third ventricle. Primary tumors of the anterior pituitary (Chapter 231) cause diabetes insipidus only when substantial suprasellar extension is present. However, rapidly growing intrasellar lesions, such as metastases from carcinomas of the lung, breast, and melanoma or hemorrhage into pituitary adenomas, can cause diabetes insipidus because there is insufficient time for the vasopressin axons to adapt. Metastasis to the hypothalamus can also destroy the supraopticohypophysial tract and produce diabetes insipidus. Granulomatous diseases, such as Langerhans cell histiocytosis, sarcoidosis, tuberculosis, and leukemic infiltrates and lymphomas of the hypothalamus, can cause diabetes insipidus by destroying vasopressin cells. In such patients, the diagnosis is usually suspected on the basis of peripheral manifestations of the respective diseases. Lymphocytic infundibuloneurohypophysitis is an autoimmune disease similar to lymphocytic hypophysitis of the anterior pituitary (Chapter 231) in which lymphocytes infiltrate the neurohypophysis to produce diabetes insipidus. The hallmarks of this process are a thickened pituitary stalk and an absence of the pituitary bright spot in a patient with the abrupt onset of polyuria and polydipsia, particularly a postpartum female. The diagnosis was originally demonstrated by pituitary biopsy but is now generally made by regression of the thickened stalk with continued follow-up. When no cause is found, the diagnosis of exclusion is idiopathic diabetes insipidus, but most such cases are probably caused by an autoimmune disease, and other autoimmune diseases are often recognized in affected patients. When central nervous system disease is suspected but not diagnosed by MRI or general physical examination, cerebrospinal fluid obtained by lumbar puncture may be helpful in identifying tumor cells or markers of tumors or inflammatory processes (e.g., elevated angiotensin-converting enzyme levels in neurosarcoidosis).

TREATMENT Rx

Because excess diuresis of water is the primary manifestation of diabetes insipidus, water replacement in adequate quantities avoids the metabolic complications of this disease. However, oral or intravenous administration of the volume of fluid required to replace urinary losses in diabetes insipidus is difficult and inconvenient. The goal of therapy is to reduce the amount of polyuria and polydipsia to a tolerable level while avoiding overtreatment, which can produce water retention and hyponatremia. The best therapeutic agent for the treatment of hypothalamic diabetes insipidus is the vasopressin agonist desmopressin. Desmopressin is different from vasopressin, in that the amino group of the N-terminal cystine residue has been removed to prolong the duration of action, and D-arginine has been substituted for L-arginine in position 8 to decrease the vasopressor effects. At therapeutic dosages, this agent acts on V_2 or antidiuretic receptors, with minimal activity at V_{1a} or pressor receptors. Desmopressin is available in tablets of 0.1 or 0.2 mg for oral

administration and in either a spray bottle that delivers a fixed dose of 10 µg in 100 µL or a bottle with a rhinal catheter that can deliver 50 to 200 µL (5 to 20 µg) for intranasal administration. When therapy is initiated, it is generally best to begin with a low dose (e.g., half of a 0.1-mg tablet, 5 µg by the rhinal tube, or a single 100 µL spray of 10 µg) at bedtime to allow the patient to sleep through the night, and then determine the duration of action by quantifying the polyuria the next day. The duration of action of a single dose varies from 6 to 24 hours, but in most patients, a good therapeutic response can be achieved on an every-12-hour schedule for the nasal spray or an 8- or 12-hour schedule for the tablets. If patients are never polyuric on a fixed schedule, it may be advisable to delay the administration of a dose once a week to allow diuresis of any accumulated water. Desmopressin is also available for parenteral use in 1-mL vials of 4 µg/mL. Parenteral administration is especially useful postoperatively or when a patient is unable to take the nasal preparation. In hospitalized patients, some physicians add vasopressin directly to a crystalloid solution to infuse doses in the range of 0.25 to 2.7 mIU/kg/hour to cause modest but persistent urinary concentration as a treatment of diabetes insipidus. With any parenteral administration, serum sodium levels should be monitored frequently to prevent the development of hyponatremia.

Some orally administered pharmacologic agents are also useful in treating diabetes insipidus. Chlorpropamide in doses of 100 to 500 mg/day enhances the effect of vasopressin at the renal tubule and is especially useful in patients with partial central diabetes insipidus. An antidiuretic effect is noted in 1 to 2 days, but maximal antidiuresis may not be achieved until after several days of administration. Thiazide diuretics cause sodium depletion and volume contraction and decrease urine volume by increasing proximal tubular reabsorption of glomerular filtrate. Prostaglandin synthase inhibitors (e.g., indomethacin) block the action of prostaglandin E to inhibit the action of vasopressin on the kidney. Although the use of a prostaglandin synthase inhibitor is not a primary treatment for central diabetes insipidus, it can alter the antidiuretic response of other agents. Chlorothiazide, amiloride, and prostaglandin synthase inhibitors are useful to reduce polyuria in nephrogenic diabetes insipidus. However, none of these agents has been approved by the Food and Drug Administration for the treatment of diabetes insipidus; therefore, the prescribing physician should be aware of potential toxicities and side effects. In cases of drug-induced nephrogenic diabetes insipidus, the most direct therapy is discontinuation of the offending agent, if possible. Symptomatic nephrogenic diabetes insipidus is usually treated with a thiazide diuretic, which is enhanced by the coadministration of the potassium-sparing diuretic amiloride. Amiloride can be especially beneficial in cases of nephrogenic diabetes insipidus induced by lithium because the drug decreases the entrance of lithium into cells in the distal tubule. When diuretics are used to treat nephrogenic diabetes insipidus, special attention should be paid to the possibility that the induced dehydration may increase the concentration of other drugs.

Some situations require special attention during therapy. Rarely, if patients with diabetes insipidus are unable to drink or are given a hypertonic solution, severe hypernatremia can develop acutely. Osmotic equilibrium with the intracellular water of neurons and glia produces shrinking of the brain. The brain is in a closed vault (i.e., the skull), and when the brain shrinks, traction on the vasculature of the central nervous system can cause the rupture of blood vessels and subarachnoid or intracerebral hemorrhage. If the hypernatremia persists for a longer time, the neurons accommodate by producing organic osmolytes (previously called *idiogenic osmoles*), which limit the amount of brain shrinkage. Once this adaptation has occurred, a too rapid lowering of osmolality in the extracellular fluid will produce a shift of water into the brain and cause cerebral edema. In this situation, desmopressin can be administered to produce constant antidiuresis, and the amount of water given can be regulated to decrease osmolality by no more than approximately 1 mEq every 2 hours. Postoperatively or after head trauma, diabetes insipidus can be transient (see Prognosis), and the need for long-term maintenance therapy cannot be immediately established. During pregnancy, vasopressinase increases the metabolism of vasopressin but not of desmopressin, so desmopressin is the drug of choice. The vasopressinase activity subsides by a few weeks after delivery, and patients with the onset of partial diabetes insipidus during pregnancy may become asymptomatic after delivery. An additional advantage of desmopressin is that it has little action on the oxytocin receptors of the uterus. During pregnancy, normal plasma osmolality decreases by approximately 10 mOsm/kg H_2O because of changes in serum sodium, so pregnant patients with diabetes insipidus require only enough desmopressin to maintain the serum sodium at this lower level.

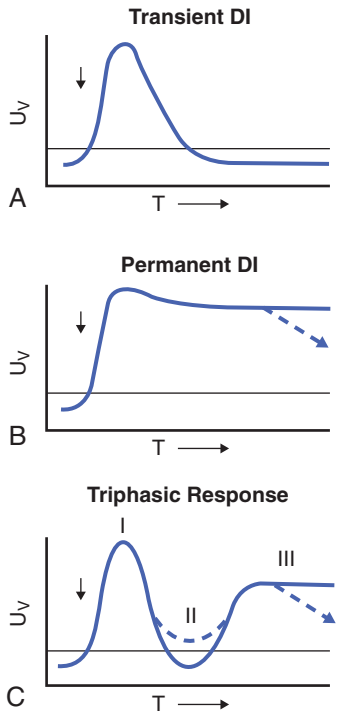

FIGURE 232-4. A to C, Diagrammatic summary of the major patterns of postoperative and post-traumatic diabetes insipidus (DI). The abscissa represents time (T) after the initial injury *(arrow)*; the ordinate represents urinary volume (U_V) relative to a hypothetical "normal" urine output of 2 to 3 L/24 hours *(solid line)*. See the discussion in the text. During the triphasic response (**C**), uncontrolled release of vasopressin from the disconnected or damaged posterior pituitary gland causes an antidiuresis that can lead to water retention and a dilutional hyponatremia. Diabetes insipidus returns as the third phase after the stored hormone in the posterior pituitary has been depleted. (From Verbalis JG, Robinson AG, Moses AM. Postoperative and post-traumatic diabetes insipidus. In: Czernichow AP, Robinson A, eds. *Diabetes Insipidus in Man: Frontiers of Hormone Research*. Basel: S Karger; 1985:247.)

PROGNOSIS

The prognosis of properly treated diabetes insipidus is excellent. Historical complications of bladder hypertrophy and hydroureter secondary to voluntarily decreasing urine frequency are largely unseen with modern therapy. If nephrogenic diabetes insipidus is diagnosed and treated early, intracranial calcification and mental retardation do not occur. When the diabetes insipidus is secondary to a recognized disease process, that disease generally determines the ultimate prognosis. In some specific clinical situations, the course is different and characteristic. The development of diabetes insipidus after surgical or traumatic injury to the neurohypophysis can follow any of several well-defined patterns (Fig. 232-4). In some patients, polyuria develops 1 to 4 days after injury and resolves spontaneously. Less often, the diabetes insipidus is permanent and continues indefinitely. Most interestingly, one can see a "triphasic" response that has been well described after pituitary stalk transection. The first phase of diabetes insipidus is due to axon shock and lack of function of the damaged neurons. This phase lasts several hours to several days and is followed by a second, antidiuretic phase that is due to the uncontrolled release of vasopressin from the disconnected and degenerating posterior pituitary or from the remaining severed neurons. Overly aggressive administration of fluids during this second phase does not suppress the uncontrolled vasopressin release from the damaged neurohypophysis and can lead to hyponatremia. The antidiuresis can last 2 to 14 days, after which diabetes insipidus recurs after depletion of the vasopressin from the degenerating posterior pituitary gland (third phase). Transient hyponatremia without preceding or subsequent diabetes insipidus has been reported after transsphenoidal surgery for pituitary microadenomas. This generally occurs 5 to 10 days postoperatively, and the incidence may be as high as 30% when such patients are carefully observed, although the majority of cases are mild and self-limited. This is due to inappropriate vasopressin secretion by the same mechanism responsible for the triphasic response, except that in these cases, only the second phase occurs ("isolated second phase") because the neural lobe or pituitary stalk damage does not impair vasopressin secretion sufficiently to produce clinical manifestations of diabetes insipidus.

Once a deficiency of vasopressin secretion has been present for more than a few days or weeks, it rarely improves, even if the underlying cause of the neurohypophysial destruction is eliminated. The major exception to this is postoperative diabetes insipidus, in which spontaneous resolution is the rule. Although recovery from diabetes insipidus that persists more than several weeks postoperatively is less common and is distinctly uncommon after 1 year of continued diabetes insipidus, well-documented cases of recovery as long as 10 years after the initiating event have been reported. The reason for

amelioration and resolution is apparent from pathologic and histologic examination of neurohypophysial tissue after pituitary stalk section in both animals and humans. Neurohypophysial neurons that have intact perikarya are able to regenerate axons and form new nerve terminal endings that are capable of releasing vasopressin into nearby capillaries. Potential return of function is another reason for occasionally withholding therapy during long-term treatment. Diabetes insipidus should not be considered idiopathic until at least 4 years of follow-up. During this interval, annual computed tomography or MRI is indicated to search for a tumor or infiltrative process that may not have been detected at the initial examination.

THYROID

MATTHEW KIM AND PAUL LADENSON

EMBRYOLOGY

The embryonic thyroid gland develops from endoderm at the foramen cecum, which migrates caudad and elongates to form two clusters of spherical follicles. The follicles proliferate to form the lobes of the thyroid gland.

Ectopic thyroid tissue can remain at the base of the tongue to form a lingual thyroid, or it may remain along the thyroglossal duct. It can migrate as far inferiorly as the diaphragm. A thyroglossal duct cyst can present as a fluctuant midline cervical mass that elevates with extension of the tongue.

ANATOMY

The adult thyroid gland contains two lobes that wrap along the right and left anterolateral aspects of the trachea midway between the thyroid cartilage and the suprasternal notch. Each lobe is demarcated into upper, middle, and lower poles. The right and left lobes are connected by an isthmus on the anterior aspect of the trachea just below the cricoid cartilage. The normal terminus of the thyroglossal duct can persist as a pyramidal lobe. A pyramidal lobe is often palpably enlarged in diffuse thyroid disorders such as autoimmune thyroiditis and Graves' disease. The adult thyroid gland weighs 15 to 20 g. Each lobe measures approximately 4 cm long, 2 cm wide, and 1.5 cm deep.

After thyroid enlargement, the attachment of the sternothyroid muscle to the trachea limits upward expansion of the superior aspect of each lobe. Lateral and posterior growth may cause inferior expansion that may extend into the superior mediastinum, compressing the trachea and veins at the thoracic outlet. The parathyroid glands usually lie beneath the posterior aspects of each thyroid lobe. The recurrent laryngeal nerves course upward along the tracheoesophageal groove, from which branches pass behind each thyroid lobe to innervate the larynx.

HISTOLOGY

Thyroid tissue is composed of clustered spherical follicles, each containing a single layer of follicular epithelial cells known as *thyrocytes* that surround a lumen containing colloid. The principal component of colloid is thyroglobulin, a thyrocyte-specific protein. Parafollicular C cells, which are derived from neural crest tissue and produce calcitonin, are widely dispersed between follicles.

Microvilli on the luminal surface of thyrocytes play active roles in thyroid hormone synthesis and secretion. Aggregated clusters of follicles are surrounded by dense networks of capillaries innervated by sympathetic and parasympathetic nerve fibers.

PHYSIOLOGY

Thyroid Hormone Synthesis and Secretion

Dietary iodine in the form of iodide (I^-) or iodate (IO_3^-) is absorbed from the gastrointestinal tract and distributed in the extracellular fluid. The median urinary iodide level in an iodine-sufficient population is 10 μg/dL. The average daily intake of iodine in the United States equals the recommended daily intake of 150 μg because of the widespread use of iodized salt. Circulating iodide is actively transported into the thyrocyte by the sodium-iodide symporter. Within the thyrocyte, iodide is rapidly oxidized by H_2O_2 in a reaction catalyzed by thyroid peroxidase. The reactive intermediate formed is covalently bound to tyrosyl residues present in thyroglobulin to generate monoiodotyrosine and diiodotyrosine residues through a process known as *organification*. Thyroid peroxidase also catalyzes the coupling of the monoiodotyrosine and diiodotyrosine residues to generate thyroxine (T_4) and triiodothyronine (T_3). T_4 and T_3 are secreted after proteolysis of thyroglobulin. This hydrolytic process may be inhibited by exposure to excessive amounts of iodide or lithium. In the normal state, approximately100 μg of T_4 and 5 μg of T_3 are directly released into the circulation each day.

Thyroid Hormone Transport and Metabolism

Circulating thyroid hormones are more than 99% bound to three classes of plasma proteins. Thyroxine-binding globulin (TBG) functions as the principal transport protein. Thyroxine-binding prealbumin and albumin make lesser contributions to T_4 and T_3 transport in blood. Pregnancy and exposure to pharmacologic doses of estrogens can increase TBG levels, as can hepatitis, familial TBG excess, and certain medications, including 5-fluorouracil, tamoxifen, and methadone. Conversely, decreased TBG levels may occur with systemic illness, severe hepatic disease, nephrotic syndrome, and treatment with androgens, glucocorticoids, and slow-release nicotinic acid. Whereas total T_4 and T_3 levels rise and fall with changes in TBG, free T_4 and T_3 levels remain constant. Familial dysalbuminemic hyperthyroxinemia is an autosomal dominant disorder characterized by the production of albumin that binds T_4 with a high affinity. Affected individuals may present with high total T_4 levels and normal free T_4 levels. The receptor binding and biologic activity of T_3 is eight-fold greater than that of T_4. More than 80% of the T_3 present in target tissues is derived from T_4 through the action of deiodinase enzymes that convert T_4 to both T_3, which contributes to the pool of T_3 in the circulation, and biologically inactive reverse T_3. The activity of deiodinase may be inhibited by systemic illness; iodide-containing compounds, including amiodarone and radiocontrast agents; glucocorticoid therapy; and selenium deficiency. Type 2 deiodinase is present in the pituitary gland and brain. Type 3 deiodinase is present in the glial cells of the central nervous system. It deactivates thyroid hormone by inner ring monodeiodination, a process that converts T_4 to inactive reverse T_3 (rT_3) and T_3 to inactive diiodothyronine (T_2). Type 3 deiodinase is also expressed in placenta, accounting for the increased thyroxine dose requirement in pregnant women.

Control of Thyroid Function

The growth of thyroid tissue and the synthesis and secretion of thyroid hormones are controlled by the hypothalamus and the pituitary gland. Thyrotropin-releasing hormone (TRH) is synthesized by the hypothalamus and is transported to the pituitary gland, where it binds to receptors on thyrotrophic cells, stimulating the synthesis and secretion of thyroid-stimulating hormone (TSH). TSH is a heterodimeric glycoprotein composed of a unique β-subunit coupled to an α-subunit, identical to that present in follicle-stimulating hormone, luteinizing hormone, and human chorionic gonadotropin (HCG). It is transported in the circulation to the thyroid gland, where it binds to the TSH receptor on thyrocytes. The binding of TSH to the TSH receptor stimulates iodide transport, organification, hydrolysis of thyroglobulin, and secretion of thyroid hormone. Circulating T_4 and T_3 exert negative feedback at the levels of both the hypothalamus and the pituitary gland, inhibiting the synthesis and secretion of TRH and TSH, respectively.

Thyroid Hormone Action

Thyroid hormone binds receptors that are members of the nuclear receptor superfamily, regulating expression of thyroid hormone–responsive genes. Isoforms of the thyroid hormone receptors (α_1, β_1, and β_2) bind to a specific hexameric oligonucleotide sequence in the transcriptional regulatory region of thyroid hormone–responsive genes. For example, T_3 increases expression of the low-density lipoprotein (LDL) receptor, resulting in accelerated LDL cholesterol degradation. In myocardium, T_3 increases myocyte contractility and relaxation by altering myosin heavy chain and sarcoplasmic reticulum adenosine triphosphatase (ATPase), respectively. In the cardiac conducting system, T_3 increases the heart rate by altering sinoatrial node depolarization and repolarization. Other physiologic effects of thyroid hormone include increased mental alertness, ventilatory drive, gastrointestinal motility, and bone turnover. During fetal development, thyroid hormone plays critical roles in brain development and skeletal maturation.

DIAGNOSIS

Physical Examination

Examination of the thyroid begins with inspection of the lower anterior portion of the neck to check for diffuse or asymmetrical gland enlargement, tracheal deviation, lymphadenopathy, and jugular venous distention. Palpation can be performed by an anterior or posterior approach. Anterior palpation can be performed by using the thumb of one hand to locate the isthmus of the gland beneath the cricoid cartilage. The right lobe of the thyroid gland can be palpated by placing the left thumb along the left side of the trachea to brace the contralateral lobe, using the tips of the fingers of the right hand to

laterally retract the right sternocleidomastoid muscle at the level of the isthmus, and using the pads of the fingers of the right hand to explore and define the tissue composing the lobe. The mass of tissue that moves beneath the fingertips when the patient swallows represents the lobe. This maneuver can be reversed to examine the left lobe.

Laboratory Findings

TSH and Thyroid Hormone Levels

TSH is a sensitive indicator of primary thyroid gland dysfunction. Current TSH immunoassays permit the accurate detection of all common causes of thyroid hormone deficiency and excess. Indeed, TSH levels become abnormal when patients' thyroid hormone levels remain within broad reference ranges, conditions termed *subclinical hypothyroidism* and *subclinical thyrotoxicosis*. In most patients with primary thyroid gland dysfunction, measurement of a single TSH level permits an accurate classification of the thyroid status. Limitations of TSH testing occur when there is TSH-mediated secondary thyroid dysfunction, reduced biologic activity of T_3 or TSH itself, temporary disequilibrium of the hypothalamic-pituitary-thyroid axis, or analytic problems affecting the TSH immunoassay.

Measurements of T_4 and T_3 levels confirm the significance of an abnormal TSH level, define the severity of thyroid dysfunction, and provide a clue to the underlying cause. Whereas assays that measure total T_4 and T_3 levels are accurate, their results do not distinguish between large plasma protein–bound and free fractions of each hormone. Consequently, congenital and acquired derangements of TBG (and, less commonly, transthyretin and albumin) can alter total but not free T_4 and T_3 levels. These conditions can be misdiagnosed as abnormal thyroid function unless a discordance in TSH is noted or one of these underlying conditions is suspected (Tables 233-1 and 233-2). There are several methods of estimating unbound T_4 and T_3 levels. Free T_4 and free T_3 immunoassays are widely employed for this purpose and yield reliable results in common conditions that alter plasma protein levels, such as estrogen-induced TBG excess. Free T_4 measurement after equilibrium dialysis of serum is the most accurate approach, but it is technically demanding and not readily available in most settings.

Other Laboratory Tests

Measurement of thyroid autoantibody titers can be useful in the evaluation of thyroid dysfunction. Antithyroid peroxidase and antithyroglobulin antibody titers can confirm a diagnosis of autoimmune thyroiditis. Thyroid-stimulating immunoglobulin activity levels can be measured to evaluate Graves' disease. The erythrocyte sedimentation rate can be helpful in the diagnosis of subacute thyroiditis. Serum thyroglobulin and calcitonin levels are used as tumor markers when observing patients treated for differentiated and medullary thyroid cancers, respectively.

Imaging

Anatomic Imaging

Ultrasonography provides detailed views that help measure the size of the thyroid gland, characterize its texture, and identify structural abnormalities, including solid nodules and simple or partially cystic nodules. Diffuse heterogeneity may suggest autoimmune thyroiditis. Certain characteristics of nodules—including the appearance of capsules, vascularity, and patterns of calcification—can alter the probability of malignancy but do not confirm or exclude thyroid cancer with certainty. Imaging of surrounding structures may identify cervical lymphadenopathy not detectable on physical examination.

The value of computed tomography (CT) and magnetic resonance imaging (MRI) is their ability to delineate tracheal deviation, narrowing, and substernal extension of the thyroid into the mediastinum. Cervical CT scanning can also help define and localize regional lymphadenopathy. Positron emission tomography (PET) plays a role in the localization of residual thyroid cancer.

Functional Imaging

Radionuclide scanning takes advantage of the fact that gamma ray–emitting tracers transported into thyrocytes by the sodium-iodide symporter can generate images that reflect the regional activity of thyroid tissue. Technetium -99m (^{99m}Tc) and iodine-123 (^{123}I) are commonly used. ^{99m}Tc-pertechnetate is rapidly trapped by thyrocytes, and ^{99m}Tc scans can be acquired 20 to 30 minutes after injection. ^{123}I and ^{131}I thyroid scans generate images that provide a more accurate representation of regional thyroid tissue function and can indicate whether a nodule is hypofunctioning (cold), hyperfunctioning (hot), or equivalent in function to extranodular tissue (warm). Radionuclide imaging no longer plays a central role in the differential diagnosis of most thyroid nodules. When it is necessary, ^{123}I is the preferred tracer because of its lower thyroidal and whole body radiation dose.

Thyroid Uptake

The fraction of an administered radioactive iodine or technetium dose taken up and retained by the thyroid gland during a defined period represents an index of the gland's activity. Typically, technetium pertechnetate uptake ranges from 0.5 to 3%; radioiodine uptake usually ranges from 8 to 28%. These fractional thyroid uptakes can be useful in the differential diagnosis of thyrotoxicosis. Radioiodine uptake values are also used to calculate effective ^{131}I doses for the treatment of hyperthyroidism and thyroid cancer.

HYPOTHYROIDISM

DEFINITION

Primary hypothyroidism (termed *myxedema* when it is severe) refers to hormone deficiency caused by intrinsic dysfunction of the thyroid gland that disrupts the synthesis and secretion of T_4 and T_3 (Table 233-3). Overt hypothyroidism is characterized by an elevated TSH level, usually greater than 10 mIU/L, in conjunction with a free T_4 level below the lower limit of the reference range. In subclinical hypothyroidism, the TSH level is only modestly elevated; the free T_4 level remains in the low-normal to normal range.

Secondary or central hypothyroidism refers to deficient thyroid gland function that is the result of inadequate stimulation by TSH. This is due, in turn, to production of either insufficient or ineffective TSH from a number of congenital or acquired pituitary and hypothalamic disorders (Chapter 231).

TABLE 233-1 CAUSES OF EUTHYROID HYPERTHYROXINEMIA (INCREASED TOTAL T_4, NORMAL TSH, NORMAL FREE T_4)

- Increased synthesis of thyroxine-binding globulin
  - Pregnancy
  - Hepatitis
  - Acute intermittent porphyria
  - Drugs
    - Estrogens
    - Tamoxifen
    - Raloxifene
    - Methadone
    - 5-Fluorouracil
- Increased binding of thyroid hormone to albumin
  - Familial dysalbuminemic hyperthyroxinemia
- Increased binding of thyroid hormone to transthyretin
  - Hereditary variants
  - Pancreatic neuroendocrine tumors

TABLE 233-2 CAUSES OF EUTHYROID HYPOTHYROXINEMIA (DECREASED TOTAL T_4, NORMAL TSH, NORMAL FREE T_4)

- Increased metabolism of thyroid hormone
  - Drugs
    - Phenytoin
    - Phenobarbital
    - Carbamazepine
    - Rifampin
- Decreased synthesis of thyroxine-binding globulin
  - Severe liver disease
  - Malnutrition
  - Drugs
    - Androgens
    - Danazol
    - L-Asparaginase
- Increased clearance of thyroxine-binding globulin
  - Nephrotic syndrome
  - Protein-losing enteropathy
- Decreased binding of thyroid hormone to thyroxine-binding globulin
  - Drugs
    - Salicylates (high dose)
    - Phenytoin (high dose)
    - Furosemide (intravenous)

TABLE 233-3 ETIOLOGIES OF HYPOTHYROIDISM

PRIMARY HYPOTHYROIDISM
Insufficient functioning thyroid tissue
Congenital absence of thyroid tissue
Autoimmune destruction of thyroid tissue
Autoimmune thyroiditis (Hashimoto's thyroiditis)
Surgical removal of thyroid tissue
Radioablation of thyroid tissue by radioactive iodine or external beam radiation
Infiltrative destruction of thyroid tissue
Hemochromatosis
Scleroderma
Amyloidosis
Impaired thyroid hormone synthesis
Iodine deficiency
Congenital enzymatic defects that disrupt thyroid hormone synthesis
Drug-mediated inhibition of thyroid hormone production and release
Thionamides
Amiodarone
Lithium
Aminoglutethimide
SECONDARY HYPOTHYROIDISM
Insufficient secretion of TRH or TSH
Hypothalamic disorders
Tumor (lymphoma, germinoma, glioma)
Irradiation
Inflammation (sarcoidosis, vasculitis)
Hypopituitarism
Mass lesions
Pituitary surgery
Pituitary radiation
Hemorrhagic apoplexy (Sheehan's syndrome)
Infiltration (hemochromatosis, tuberculosis, fungal infection)
Lymphocytic hypophysitis
Thyroid hormone resistance syndrome

EPIDEMIOLOGY

Primary hypothyroidism is common—present in 5% of individuals. Mild hypothyroidism is present in as many as 15% of older adults. Hypothyroidism is more commonly diagnosed in women. It is more prevalent among whites and Latinos. Secondary hypothyroidism is rare, representing less than 1% of cases.

PATHOBIOLOGY

Dietary iodine deficiency is an important cause of primary hypothyroidism in children in certain underdeveloped countries. The most common cause of primary hypothyroidism in developed countries is autoimmune (or Hashimoto's) thyroiditis, a condition in which altered T-cell-mediated immunity causes destruction of thyroid tissue and impaired gland function. The condition is characterized by a lymphocytic infiltrate and fibrosis. Circulating antithyroid antibodies directed against thyroid peroxidase and thyroglobulin are markers of the disease, but glandular inflammation is principally the result of altered T-cell-mediated function. There is a genetic predisposition to the condition. Linkage studies suggest a polygenic basis. Patients with autoimmune thyroiditis may have other endocrine and nonendocrine autoimmune disorders. It may be a component of the type 2 polyglandular autoimmune syndrome associated with autoimmune adrenal insufficiency and type 1 diabetes mellitus. It is less commonly a component of the type 1 syndrome, which includes adrenal insufficiency, hypoparathyroidism, and chronic mucocutaneous candidiasis (Chapter 239). Other nonendocrine autoimmune conditions associated with autoimmune thyroiditis include atrophic gastritis, pernicious anemia, systemic sclerosis, Sjögren's syndrome, celiac disease, and vitiligo. Individuals treated with interferon-α may develop autoimmune thyroiditis with transient or permanent hypothyroidism.

Surgical resection of thyroid tissue predictably leads to hypothyroidism. Radioactive iodine therapy for treatment of hyperthyroidism commonly destroys sufficient thyroid tissue to cause postablative hypothyroidism. External beam radiation therapy for head and neck cancer can cause thyroid gland failure. Exposure to certain pharmacologic and radiocontrast agents that contain large amounts of iodine, such as amiodarone, radiocontrast dyes, some expectorants, and topical disinfectants, can disrupt thyroid hormone production. Lithium inhibits secretion of T_4 and T_3, leading to hypothyroidism in 10% of treated patients. Other pharmacologic agents reported to cause hypothyroidism include stavudine, thalidomide, sunitinib, and aminoglutethimide.

There are a number of other rare causes of primary hypothyroidism (see Table 233-3). Congenital hypothyroidism can be due to agenesis or dysgenesis of the thyroid gland, or to mutations in genes encoding the enzymes catalyzing thyroid hormone synthesis. Infiltrative disorders can disrupt thyroid function, including hemochromatosis, amyloidosis, systemic sclerosis, and invasive fibrous thyroiditis (also known as *Riedel's thyroiditis*). The thyroid gland inflammation that occurs with subacute thyroiditis and painless (postpartum) thyroiditis causes transient hypothyroidism, from which most patients recover.

Secondary or central hypothyroidism may be caused by a number of disorders that impair normal hypothalamic or pituitary control of the thyroid gland (Chapter 231). Infiltrative disorders affecting the hypothalamus that can interfere with TRH secretion include sarcoidosis, hemochromatosis, and histiocytosis. Masses that impinge on the pituitary stalk can impede TRH delivery through the hypophysial portal system. Compression of thyrotrophic cells by pituitary adenomas and other masses in the sella turcica can inhibit synthesis and secretion of TSH. Surgery and radiation therapy to treat pituitary adenomas can destroy thyrotrophic cells, leading to secondary hypothyroidism that develops as a component of pan-hypopituitarism. Other disorders that may be associated with secondary hypothyroidism include lymphocytic hypophysitis, pituitary metastases from primary malignant neoplasms, apoplexy, infarction caused by hemorrhage at the time of delivery in women (also known as *Sheehan's syndrome*), and head trauma.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Symptoms of hypothyroidism include fatigue, lethargy, weight gain despite poor appetite, cold intolerance, hoarseness, constipation, weakness, myalgias, arthralgias, paresthesias, dry skin, and hair loss. Females may develop precocious puberty, menorrhagia, amenorrhea, and galactorrhea. Affected individuals may experience depressed mood with limited initiative and sociability. Cognitive deficits can range from mild lapses in memory to delirium, dementia, seizures, and coma. The nonspecific nature of most of these symptoms makes it difficult to determine which patients presenting with them have hypothyroidism rather than other causes. In most cases, hypothyroidism is insidious in onset, making its recognition difficult. Symptoms that are new, progressive, or present in combination are more likely to be due to hypothyroidism.

The physical findings associated with hypothyroidism vary according to the age at onset and disease severity. Children may present with delayed linear growth despite weight gain, precocious or delayed puberty, and pseudohypertrophy of muscle. Adults can present with bradycardia, diastolic hypertension, and mild hypothermia. The skin may be coarse, dry, yellow, and cool to the touch as a result of peripheral vasoconstriction. Diffuse thinning of scalp hair accompanied by thinning of the lateral eyebrows may occur. The nails may be brittle. Examination of the chest may reveal distant heart sounds. The extremities may reveal diffuse nonpitting edema caused by the deposition of glycosaminoglycans. Neurologic examination may reveal slow, dysarthric speech and diffuse slowing of deep tendon reflexes with a marked delay in the terminal relaxation phase.

Examination of the neck may reveal a range of findings. Healed cervical incisional scars in this region indicate a history of surgical resection of thyroid tissue. The thyroid gland may be normal in size, diffusely enlarged, or atrophic to the point where it may be difficult to palpate with any degree of certainty. It may be soft and smooth with a lobular texture or firm and irregular with a variegated nodular texture.

Other Routine Test Abnormalities

Blood tests may reveal anemia, hyponatremia, hypoglycemia, and elevated creatine phosphokinase, prolactin, homocysteine, triglyceride, and total and LDL cholesterol levels. Electrocardiography may show sinus bradycardia with low voltage in the limb leads. Chest radiography may show a widened cardiac silhouette, and echocardiography may confirm a pericardial effusion.

DIAGNOSIS

Suspected primary hypothyroidism is confirmed by an elevated TSH level (Fig. 233-1). Established reference ranges for TSH levels typically extend from 0.5 to 4.5 mIU/L. However, the distribution of values within this range is skewed toward the lower half, such that the mean TSH level is estimated

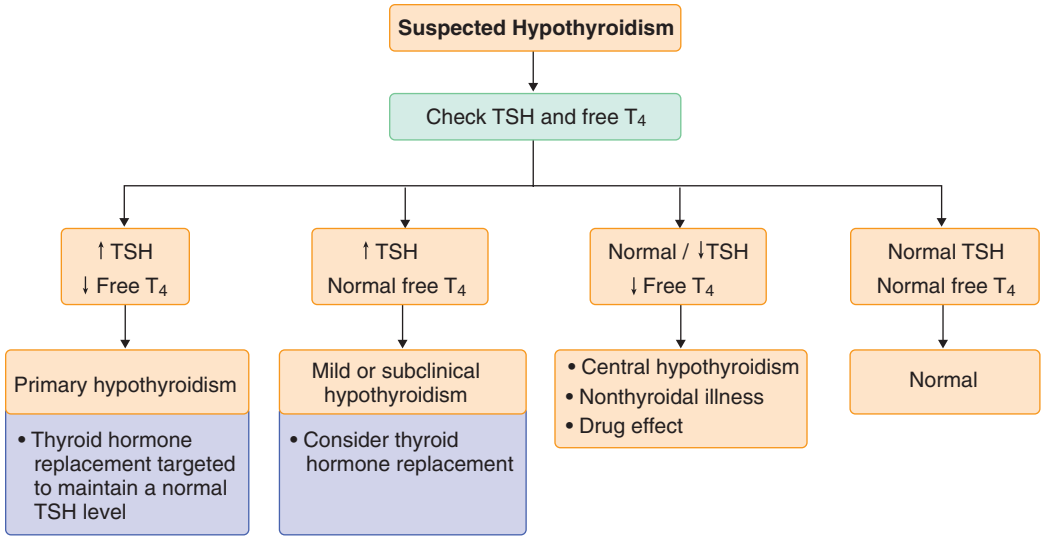

FIGURE 233-1. Laboratory assessment of suspected hypothyroidism.

to be 1.5 mIU/L. Measurement of the free T_4 level confirms the diagnosis of primary hypothyroidism and characterizes its severity. A low free T_4 level in conjunction with a persistently elevated TSH level represents overt primary hypothyroidism, whereas a low-normal free T_4 level with an elevated TSH level is termed *mild primary hypothyroidism*. Other uncommon causes of isolated TSH elevation should be considered in appropriate settings, including recovery from severe systemic illness, renal failure, and adrenal insufficiency.

Testing to determine the underlying cause of primary hypothyroidism is usually unnecessary. The condition can almost always be ascertained from the patient's history; if not, autoimmune thyroiditis is usually the cause. When confirmation is required (e.g., to convince a patient that the condition is permanent), serum antithyroid antibodies may be assessed. Measurement of antithyroid peroxidase antibody is a more sensitive test than antithyroglobulin antibody for this purpose. However, 10% of patients with histologically documented autoimmune thyroiditis have no circulating antithyroid antibodies.

When clinical findings such as the presence of a sellar mass, previous pituitary surgery or irradiation, or other pituitary axis hormone deficiencies suggest the possibility of secondary hypothyroidism, the TSH level cannot be relied on to provide an accurate index of thyroid function. In these settings, the serum free T_4 level must be assessed, and a low or even low-normal free T_4 level can confirm the diagnosis. The TSH level in patients with secondary hypothyroidism can be low, normal, or even modestly elevated.

TREATMENT

Rx

The goals of thyroid hormone replacement therapy are straightforward: to replace endogenous thyroid hormone production, to avoid iatrogenic thyrotoxicosis, and, rarely, to treat systemic complications of severe hypothyroidism. Levothyroxine sodium (hereafter thyroxine) is the hormonal preparation of choice. Thyroxine has a number of favorable pharmacokinetic characteristics. It is well absorbed, and its plasma protein binding gives it a 7-day half-life, permitting daily dosing. Thyroxine is physiologically deiodinated to the more biologically active T_3 in peripheral tissues. However, thyroxine is a narrow therapeutic index drug, and doses differing by as little as 12% can have clinical consequences. Tablets of multiple dose strengths ranging from 25 to 300 µg are available. Regulatory standards ensure pharmaceutical equivalence in terms of mass of thyroxine, but bioavailability may differ by as much as 12% among different preparations. Consequently, adherence to a single thyroxine formulation is advisable.

The optimal dose of thyroxine for replacement therapy is related to lean body weight, with most adults requiring a daily dose of 1.8 µg/kg. The dose requirement for elderly adults is typically lower (e.g., 1.0 µg/kg/day) because of reduced metabolic clearance. Patients with postsurgical or postablative hypothyroidism usually require a higher daily dose than patients with autoimmune thyroiditis, who may have some residual gland function. Patients with coexisting malabsorptive disorders may require higher and variable doses. Certain medications, mineral supplements, and foods can interfere with thyroxine absorption, including ferrous sulfate, calcium carbonate, aluminum hydroxide, sucralfate, cholestyramine, and soy-containing foods (Table 233-4). Thyroxine doses should be separated from these substances by 4 hours or longer.

TABLE 233-4 INTERFERENCE WITH THYROXINE REPLACEMENT THERAPY

FACTORS CONTRIBUTING TO UNDERREPLACEMENT
Inadequate prescribed dose
Limited compliance
Decreased absorption due to ingestion of agents that bind thyroxine
Ferrous sulfate
Calcium carbonate
Aluminum hydroxide
Sucralfate
Cholestyramine
Soy protein
Increased metabolism of thyroxine
Pregnancy
Drugs
Phenytoin
Phenobarbital
Carbamazepine
Rifampin
Diminishing residual thyroid function
Changing formulations
FACTORS CONTRIBUTING TO OVERREPLACEMENT
Excessive prescribed dose
Factitious ingestion of additional doses
Decreased metabolism of thyroxine due to aging
Increasing residual thyroid function
Changing formulations

Thyroxine dose requirements may increase as a result of accelerated metabolic clearance in several circumstances. Patients with nephrotic syndrome and other systemic illnesses that lead to rapid clearance of thyroid hormone require higher daily doses. Dose requirements increase by an average of 75% in most pregnant women, probably as a result of placental metabolism of thyroxine. Simultaneous treatment with phenytoin, phenobarbital, carbamazepine, or rifampin also typically accelerates thyroxine metabolism. One third of postmenopausal women beginning estrogen replacement therapy have increased dose requirements.

Most adults without known or suspected coronary artery disease can be started on a full replacement dose of thyroxine. The initial dose can be calculated on the basis of the patient's weight and age, rounding down to the nearest available dose strength. For patients with primary hypothyroidism, adequacy of thyroxine therapy can be assessed by TSH measurement 4 to 6 weeks after therapy is started. The target TSH level for most individuals should be the lower half of the reference range (i.e., 1.0 to 2.0 mIU/L). Once an adequate dose has been established, the TSH level should be checked annually. In patients with secondary hypothyroidism, the serum free T_4 level should be monitored 2 to 4 weeks after the thyroxine dose is started or adjusted, with a target free T_4 level in the upper half of the reference range.

Management of Complications

Complications of thyroxine therapy are limited to iatrogenic thyrotoxicosis and, rarely, adverse effects of restoring euthyroidism. Typical symptoms and

signs of thyrotoxicosis accompany overtreatment. Even a modestly excessive thyroxine dose can induce bone mineral loss, especially in postmenopausal women, and it can increase the risk of atrial fibrillation in older individuals. In patients with underlying coronary artery disease, the positive chronotropic and inotropic effects of thyroxine may exacerbate myocardial ischemia. Adults with known or suspected ischemic heart disease should be started on a low dose that is titrated upward in small increments once tolerance is ensured (e.g., starting with 25 µg daily, then increasing the dose by 12.5 to 25 µg every 4 to 6 weeks). In some cases, β-blocker therapy may need to be intensified to counter the induction of myocardial ischemia. Deliberate suboptimal dosing of thyroxine should be avoided. If necessary, coronary revascularization may be required before euthyroidism can be fully restored. Coexisting adrenal insufficiency associated with hypopituitarism or the type 2 polyglandular autoimmune syndrome may be unmasked when cortisol clearance is accelerated by a return to the euthyroid state. Other adverse effects that infrequently occur with thyroxine therapy include transient hair loss, acute sympathomimetic symptoms that resolve with dose reduction and slow advancement, and pseudotumor cerebri in children.

A minority of patients with thyroxine-treated hypothyroidism continue to report bothersome symptoms despite biochemical evidence of adequate thyroid hormone replacement. Some of these patients improve with a higher thyroxine dose that restores the serum free T_4 level to the upper limit of normal. Eight trials have now shown that combined T_3 and T_4 therapy—whether as desiccated thyroid or combined synthetic hormones—is not superior to T_4 alone.

Subclinical and Mild Hypothyroidism

Whether individuals diagnosed with subclinical hypothyroidism (i.e., an elevated or high-normal TSH level with a free T_4 level within the reference range) benefit from thyroxine therapy is controversial. Proponents argue that treatment with thyroxine relieves symptoms, lowers cholesterol, avoids the emergence of overt hypothyroidism, and is relatively safe. Detractors counter that these purported benefits have not been confirmed in any adequately powered, randomized controlled trials. In practice, many providers opt for a trial of therapy in mildly hypothyroid patients who are symptomatic, have underlying hypercholesterolemia, or demonstrate a high likelihood of progressing to overt hypothyroidism. Predictors of progressive thyroid failure include age older than 65 years, TSH level higher than 10 mIU/L, and the presence of circulating antithyroid antibodies, indicating underlying autoimmune thyroiditis.

Myxedema Coma

Severe hypothyroidism can culminate in myxedema coma, a life-threatening condition characterized by hypothermia, bradycardia, hypotension, altered mental status, and multisystem organ failure. Risk factors include advanced age, poor access to health care, and other underlying major organ system diseases. Most patients have long-standing thyroid hormone deficiency. Treatment should include thyroxine (1.8 µg/kg/day, with or without a 500-µg loading dose). Some experts advocate coadministration of triiodothyronine in divided doses to compensate for impaired conversion of T_4 to T_3. No controlled trials have been performed to evaluate the relative benefits and risks of these different approaches. Glucocorticoids should be administered in stress doses after a cosyntropin stimulation test has been performed to check for evidence of concomitant adrenal insufficiency (Chapter 234). Care should be taken to avoid exposure to potent sedative or analgesic agents that may exacerbate altered mental status. Hypothermia should be treated with external warming to reduce the risk of circulatory collapse.

Nonthyroidal Illness

In patients with severe nonthyroidal illness, a characteristic constellation of thyroid function test changes occurs that often appears to be consistent with hypothyroidism (see Fig. 233-1). The T_3 level usually declines as a result of decreased extrathyroidal T_4-to-T_3 conversion. With increasingly severe disease, total T_4 and free T_4 levels also decline. TSH levels are usually low to low-normal. During the course of recovery, the TSH level can rise above the upper limit of the normal range, producing a profile that can be mistaken for primary hypothyroidism. Clinical correlation is essential to assess thyroid function in severely ill patients (e.g., a history of preexisting thyroid or pituitary disease, the presence of a goiter, or features suggesting other elements of hypopituitarism). Because no benefit of thyroid hormone treatment has been shown for these patients, observation with retesting 6 to 8 weeks after recovery is the preferred approach.

THYROTOXICOSIS

DEFINITION AND EPIDEMIOLOGY

Thyrotoxicosis is a systemic syndrome caused by exposure to excessive thyroid hormone (Table 233-5). Its prevalence is 1 in 2000 adults, affecting 1% of all individuals during the course of their lifetime.

TABLE 233-5 ETIOLOGIES OF THYROTOXICOSIS

HYPERTHYROIDISM
Antibody-mediated stimulation of thyroid tissue
Graves' disease
Autonomously functioning thyroid tissue
Toxic multinodular goiter
Toxic adenoma
Iodine exposure
Autonomously functioning heterotopic thyroid tissue
Struma ovarii
Metastatic differentiated thyroid cancer
Excessive secretion of TSH
TSH-secreting pituitary adenoma
NONHYPERTHYROID THYROTOXICOSIS
Ingestion of exogenous thyroid hormone
Pharmacologic
Levothyroxine
Liothyronine
Combination preparations
Nonpharmacologic
Dietary supplements
Improperly processed meat products
Inflammation causing release of endogenous thyroid hormone
Subacute thyroiditis
Autoimmune thyroiditis

PATHOBIOLOGY

Hyperthyroidism develops when there is excessive synthesis and secretion of thyroid hormone caused by thyrotropic stimulus or autonomous function of thyroid tissue. Strictly speaking, *hyperthyroidism* refers to those forms of *thyrotoxicosis* that are caused by excessive production of thyroid hormone by the thyroid gland (see Table 233-5). The two terms are often used interchangeably. In Graves' disease, the most common cause of hyperthyroidism, the thyroid gland is stimulated by autoantibodies that bind to and activate the TSH receptor. Excessive secretion of TSH causes hyperthyroidism in patients with rare TSH-secreting pituitary adenomas (Chapter 231). HCG, a glycoprotein with high TSH homology, can cause transient gestational hyperthyroidism during pregnancy when a choriocarcinoma or a germ cell tumor produces variant forms of HCG that are more active, or when mutant TSH receptors bind HCG more avidly, as occurs in familial gestational thyrotoxicosis.

Autonomous production of thyroid hormone occurs when thyrocytes function independently of TSH receptor activation. This can occur as a result of growth of a benign functioning thyroid adenoma or growth of multiple autonomously functioning nodules forming a toxic multinodular goiter; in rare cases, it can occur when patients with well-differentiated thyroid cancer present with functioning metastases. In some toxic adenomas, somatic mutations in the TSH receptor gene lead to constitutive activation. In patients whose thyroid glands have the potential for autonomous function, exposure to excessive amounts of iodine in the form of amiodarone or iodinated contrast agents can provoke hyperthyroidism.

Transient thyrotoxicosis can also be caused by inflammatory conditions that release an excessive amount of thyroid hormone stored in the gland (see the section on thyroiditis). These include subacute thyroiditis, which is believed to be caused by a viral infection; acute or suppurative thyroiditis, caused by bacterial infection; radiation-induced thyroiditis; and pharmacologic thyroiditis, precipitated by exposure to amiodarone. Autoimmunity can also provoke an inflammatory thyroiditis that causes transient thyrotoxicosis. This commonly occurs in the setting of lymphocytic thyroiditis (also known as *silent, painless,* or *postpartum thyroiditis*). It rarely occurs in the setting of autoimmune thyroiditis (also known as *Hashimoto's thyroiditis*).

In rare cases, excess thyroid hormone can be secreted by ectopic thyroid tissue located anywhere from the base of the tongue to the mediastinum, or by heterotopic thyroid tissue that develops as part of an ovarian teratoma (a condition known as *struma ovarii*).

Thyrotoxicosis can also be caused by ingestion of excessive amounts of thyroid hormone. This is most often the result of the prescription of excessive doses of pharmacologic preparations of thyroid hormone, but it can rarely be due to surreptitious or accidental ingestion.

CLINICAL MANIFESTATIONS

Symptoms and Signs

The classic symptoms of thyrotoxicosis include weight loss despite a hearty appetite, heat intolerance, palpitations, tremor, and hyperdefecation (increased frequency of formed bowel movements). Thyrotoxicosis can escape early detection because of its presentation with common nonspecific symptoms such as fatigue, insomnia, anxiety, irritability, weakness, atypical chest pain, or dyspnea on exertion. Delayed recognition may also occur when atypical symptoms such as headache, weight loss, periodic paralysis, or nausea and vomiting dominate the clinical picture. Elderly patients may present with apathetic thyrotoxicosis typified by weight loss and the absence of sympathomimetic symptoms and signs.

Signs of thyrotoxicosis include resting tachycardia; systolic hypertension with a widened pulse pressure; warm, moist skin with a velvety texture; onycholysis; and a staring gaze with lid lag (noted to be present when a rim of sclera is visible between the upper eyelid and the superior margin of the iris on downward gaze). Cardiac examination may reveal a prominent apical impulse and a systolic flow murmur. Neurologic findings may include a restless, impatient demeanor; pressured speech; proximal muscle weakness; distal hand tremor; and brisk deep-tendon reflexes.

Clinical findings often provide a strong indication of the underlying cause. In Graves' disease, the gland is diffusely enlarged, with a smooth or slightly lobulated contour, and may manifest an audible bruit. Ophthalmopathy and dermopathy are also unique to Graves' disease. In patients with toxic nodular goiter, one or more discrete nodules may be appreciated. In subacute thyroiditis, the gland is modestly enlarged, extremely tender, and firm. A history of recent pregnancy suggests possible painless thyroiditis. Recent exposure to amiodarone, other iodine-containing compounds, interferon-α, or pharmacologic preparations of thyroid hormone may suggest the characteristic forms of thyrotoxicosis associated with these agents.

Graves' Disease

DEFINITION

Graves' disease is an autoimmune disorder characterized by a variable combination of hyperthyroidism, ophthalmopathy (also known as *thyroid eye disease*), and dermopathy.

EPIDEMIOLOGY

Graves' disease is more common among women, but it also affects men. It can develop at any time during life, but the onset most often occurs between 30 and 60 years of age.

PATHOBIOLOGY

The proximate cause of hyperthyroidism in Graves' disease is the production of thyroid-stimulating immunoglobulins (autoantibodies) that bind to and activate the TSH receptor, promoting thyroid hormone secretion and growth of the thyroid gland. Thyrotropin (TSH) receptor antibodies of the stimulating variety are the hallmark of hyperthyroidism in Graves' disease. Other thyroid autoantibodies commonly identified in the setting of Graves' disease include antithyroid peroxidase antibodies, antithyroglobulin antibodies, and anti-TSH receptor antibodies that block TSH binding. The fundamental pathogenesis of Graves' disease remains unknown. A genetic predisposition is implicated by a higher incidence in monozygotic twins and first-degree relatives of affected individuals. Environmental factors implicated in triggering the onset of Graves' disease include exposure to cigarette smoke, high dietary iodine intake, stressful life events, and certain antecedent infections.

CLINICAL MANIFESTATIONS

Affected individuals usually present with thyrotoxicosis and a thyroid gland that is diffusely enlarged with a rubbery consistency, smooth contour, definable pyramidal lobe, and audible bruit or palpable thrill due to increased blood flow. When it is clinically evident, thyroid eye disease usually presents within a few months of onset. In rare cases, it may develop long before, long after, or without any biochemical confirmation of hyperthyroidism.

PROGNOSIS

The hyperthyroidism associated with this condition often follows a persistent and progressive course, but one fourth of patients with Graves' disease demonstrate spontaneous disease remission.

FIGURE 233-2. Graves' ophthalmopathy. A, A 59-year-old woman with excess proptosis, moderate eyelid edema, and erythema with moderate eyelid retraction affecting all four eyelids. Conjunctival chemosis (edema) and erythema with bilateral edema of the caruncles, with prolapse of the right caruncle, are evident. **B,** A 40-year-old woman with excess proptosis, minimal bilateral injection, and chemosis with slight erythema of the eyelids. She also had evidence, on slit lamp examination, of moderate superior limbic keratoconjunctivitis. (From Bahn RS. Graves' ophthalmopathy. *N Engl J Med*. 2010;362:726-738. OPHTHALMOPATHY

DEFINITION

Thyroid eye disease is a distinctive disorder characterized by inflammation and swelling of the extraocular muscles and orbital fat, eyelid retraction, periorbital edema, episcleral vascular injection, conjunctival swelling (chemosis), and proptosis (also called *exophthalmos*). Swelling of soft tissues within the confines of the orbits precipitated by fibroblast growth and inflammatory cell infiltrate can cause proptosis, entrapment of extraocular muscles, and compression of the optic nerve.

CLINICAL MANIFESTATIONS

Affected individuals typically complain of a change in eye appearance, ocular irritation, foreign body sensation, dryness, and, ironically, excessive tearing. More severe involvement may cause exposure keratitis with corneal ulceration, diplopia, and blurred vision. On examination, patients may have a staring gaze; a rim of sclera visible between the upper eyelid and the superior margin of the iris during downward gaze (lid lag); signs of conjunctival inflammation; periorbital edema; and abnormalities of conjugate gaze, color vision, and visual acuity (Fig. 233-2). The precise degree of proptosis can be measured by an exophthalmometer. Orbital imaging with CT scanning or ultrasonography can confirm the diagnosis, which must sometimes be distinguished from other causes of bilateral and unilateral proptosis.

TREATMENT Rx

Treatment of mild thyroid-related eye disease focuses on protecting the cornea from exposure and desiccation with moisturizing drops and ointment, glasses, and sometimes taping the eyelids closed at bedtime. High-dose systemic glucocorticoid therapy can attenuate orbital inflammation. Orbital irradiation may be helpful in controlling inflammatory symptoms in some patients. Persistent corneal exposure, diplopia, altered vision due to optic nerve compression, and cosmetic issues may require surgery to decompress the orbits and readjust the extraocular muscles. Immunosuppressive agents and plasmapheresis have been used in severely affected patients, with anecdotal success.

DERMOPATHY

Infiltrative dermopathy, the least common complication of Graves' disease, is precipitated by the deposition of glycosaminoglycans in the dermis of the skin. Affected individuals usually present with mildly pruritic, orange peel–like thickening of the skin along the anterior aspects of the shins, commonly

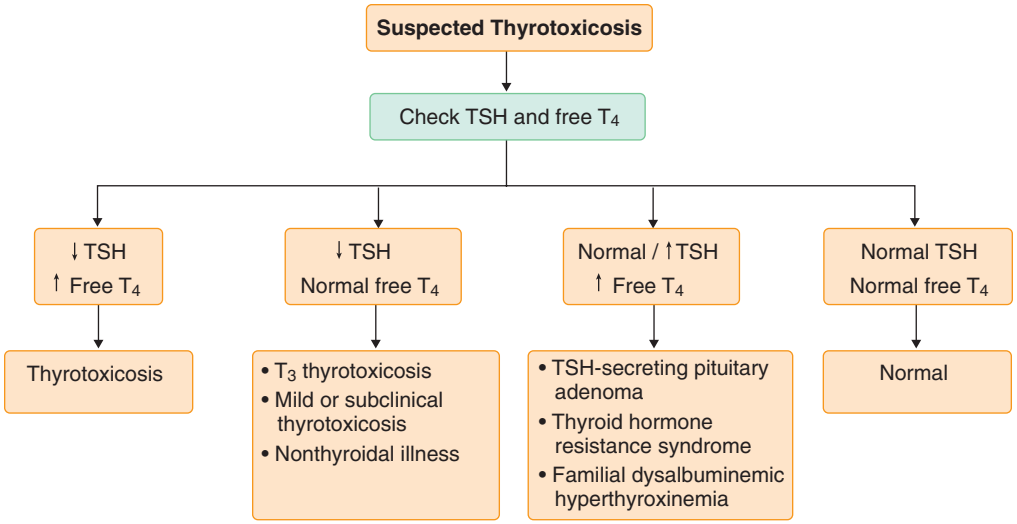

FIGURE 233-3. Laboratory assessment of suspected thyrotoxicosis.

known as *pretibial myxedema*. The dorsal aspects of the feet and fingers, the extensor surface of the elbows, and the face are more rarely affected.

The diagnosis can be confirmed by skin biopsy. Treatment of early infiltrative dermopathy with topical glucocorticoids under an occlusive wrap may limit its progression. Treatments involving the use of intradermal or systemic glucocorticoids, long-acting somatostatin analogues, and even surgical resection of soft tissue have shown limited success.

Toxic Adenoma

A toxic adenoma is a solitary, autonomously functioning thyroid neoplasm that synthesizes and secretes excessive amounts of thyroid hormone independent of TSH stimulation. These neoplasms are almost always benign. Most grow large enough to be palpated by the time they present with thyrotoxicosis. Somatic gene mutations causing constitutive activation of the TSH receptor and the stimulatory subunit of the guanine nucleotide ($G_s\alpha$) have been identified in a subset of toxic adenomas. Hyperthyroidism caused by a toxic adenoma does not remit spontaneously, except in unusual cases complicated by hemorrhagic infarction of the neoplasm.

Toxic Multinodular Goiter

A toxic multinodular goiter is composed of multiple autonomously functioning thyroid nodules that synthesize and secrete excessive amounts of thyroid hormone. In some patients with nontoxic multinodular goiters, hyperthyroidism can be precipitated by exposure to excessive amounts of iodine. Most affected individuals have a goiter with multiple palpable thyroid nodules. Progressive enlargement may go undetected when there is substernal extension of nodular tissue. Toxic multinodular goiter is more common among older individuals.

TSH-Secreting Pituitary Adenoma

TSH-secreting pituitary adenomas represent less than 1% of all functioning pituitary tumors (Chapter 231). By the time of diagnosis, most patients have developed macroadenomas that are larger than 1 cm in diameter. Smaller microadenomas may also be identified. Patients may present with typical clinical manifestations of thyrotoxicosis, a diffuse goiter, symptoms and signs precipitated by an expanding sellar mass, syndromes associated with cosecretion of other anterior pituitary hormones (growth hormone, prolactin, or adrenocorticotropic hormone), or symptoms and signs of hypopituitarism. The key to suspecting the condition is usually recognition of an inappropriately nonsuppressed TSH level in a patient with thyrotoxicosis. The diagnosis is confirmed in most cases when laboratory testing reveals an elevated circulating level of the pituitary glycoprotein α-subunit in conjunction with a radiographically definable sellar mass.

DIAGNOSIS

Laboratory Findings

Abnormalities detected in routinely ordered laboratory tests are often the first clues to the presence of thyrotoxicosis. Thyrotoxic patients may have hypercalcemia or hypercalciuria, increased alkaline phosphatase levels, modestly elevated transaminase levels, and low or declining total and LDL cholesterol levels. When they are measured, ferritin and angiotensin-converting enzyme levels are often increased. Electrocardiography typically reveals resting sinus tachycardia or atrial tachyarrhythmias, particularly atrial fibrillation with a rapid ventricular response. In severe cases, chest radiography may reveal cardiomegaly.

In most patients with suspected thyrotoxicosis, the diagnosis can be determined by measurement of TSH (Fig. 233-3). Sensitive TSH immunoassays with a detection limit of less than 0.02 mIU/L can accurately discriminate between clearly suppressed TSH levels, characteristic of all common forms of thyrotoxicosis, and mildly suppressed levels that fall just beneath the reference range, as may occur in otherwise sick and elderly euthyroid individuals. Only the rare conditions associated with TSH-mediated hyperthyroidism (TSH-secreting pituitary tumors and isolated pituitary resistance to thyroid hormone) yield false-negative TSH results in screening for thyrotoxicosis. In these conditions, serum free T_4 and T_3 levels are not elevated on subsequent testing.

Measurement of serum free T_4 and total or free T_3 levels confirms a diagnosis of thyrotoxicosis, defines its severity, and occasionally provides a clue to its underlying cause. Overt thyrotoxicosis is characterized by free T_4 or T_3 levels above the upper limit of the reference range, whereas mild or subclinical thyrotoxicosis is characterized by a suppressed TSH level with free T_4 and T_3 levels within the normal reference range. When only the free T_4 or T_3 concentrations are elevated, the terms *T_4 toxicosis* and *T_3 toxicosis* are applied, respectively.

Differential Diagnosis

Once thyrotoxicosis is confirmed, it is important to define its underlying cause to determine the most appropriate treatment. The relative degrees of T_4 and T_3 elevation sometimes can be helpful. Predominantly T_3 toxicosis is typical of Graves' disease and can also occur with toxic nodular goiter. In contrast, predominantly T_4 toxicosis is more typical of subacute or painless thyroiditis. T_4 toxicosis is also more common in patients with iodine-induced hyperthyroidism.

Other laboratory tests are sometimes helpful in differential diagnosis. Antithyrotropin-receptor antibodies are pathognomonic of Graves' disease. Levels of antithyrotropin-receptor antibodies are especially high in thyroid dermopathy and correlate positively with the clinical features and prognosis of Graves' ophthalmopathy. An elevated erythrocyte sedimentation rate is typically seen in subacute thyroiditis.

Imaging studies can be helpful for the differential diagnosis. The fractional thyroidal uptake of radiotracer within the thyroid gland on scintigraphic scanning often helps establish a definitive diagnosis (Table 233-6). Thyroid ultrasonography can confirm the presence of solitary or multiple thyroid nodules. Chest radiography and CT scanning may help delineate a substernal goiter.

TREATMENT

Rx

Selection of the most effective treatment for a specific condition causing thyrotoxicosis requires an understanding of the underlying pathophysiologic process and natural history. For example, toxic multinodular goiter does not

TABLE 233-6 RADIOGRAPHIC EVALUATION OF SUSPECTED THYROTOXICOSIS

ETIOLOGY	FRACTIONAL 24-HOUR RADIOIODINE UPTAKE (%)	THYROID SCAN APPEARANCE
Graves' disease	35-95	Diffuse increased homogeneous uptake; visible pyramidal lobe extending from isthmus
Toxic adenoma	20-60	Solitary focus of intense uptake; suppression of uptake in remainder of thyroid
Toxic multinodular goiter	20-60	Patchy heterogeneous foci of increased uptake interspersed with regions of diminished uptake
Subacute thyroiditis	0-2	Minimal to absent uptake
Autoimmune thyroiditis	0-2	Minimal to absent uptake; patchy heterogeneous uptake during recovery
Iodine-induced hyperthyroidism	0-2	Minimal to absent uptake
Exogenous thyroid hormone intoxication	0-2	Minimal to absent uptake
Metastatic differentiated thyroid cancer	0-5	Focal uptake in metastases
TSH-secreting pituitary adenoma	30-80	Diffuse increased homogeneous uptake

remit and requires radioiodine treatment or surgery; subacute thyroiditis subsides spontaneously and requires only temporizing symptomatic therapy.

β-Blockers

β-Blockers help alleviate the sympathomimetic manifestations of thyrotoxicosis, regardless of the underlying cause. Palpitations, tremor, and anxiety can often be promptly controlled. However, other clinical features of thyrotoxicosis, including weight loss, heat intolerance, and fatigue, are not ameliorated by these agents. In thyrotoxic patients with marked sinus tachycardia or atrial fibrillation with a rapid ventricular response rate, β-blockers can be used as rate-controlling agents. Propranolol also partially inhibits extrathyroidal conversion of T_4 to T_3, which may be of added benefit in patients with severe thyrotoxicosis.

Propranolol can be started at a dose of 20 to 40 mg every 8 hours and titrated upward to a maximal daily dose of 240 mg on the basis of symptom control. Sustained-release propranolol or longer-acting β-blockers, such as metoprolol and atenolol, can also be used. Esmolol can be used when a short-acting parenteral agent is required. β-Blockers should be used with caution in thyrotoxic patients with a history of heart failure, obstructive pulmonary disease, or Raynaud's phenomenon.

For patients with transient forms of thyrotoxicosis (subacute thyroiditis, autoimmune thyroiditis, or exogenous thyroid hormone intoxication), a β-blocker may be the only treatment required. In patients with more sustained conditions, such as Graves' disease or toxic nodular goiter, β-blockers provide prompt initial relief of symptoms while definitive treatment with antithyroid drugs, radioiodine, or surgery is implemented.

Antithyroid Drugs

The thionamides inhibit thyroid hormone biosynthesis by competitively inhibiting iodine organification and iodotyrosine coupling. These agents are used for the treatment of thyrotoxicosis caused by the overproduction of thyroid hormones. Because the thionamides block only new thyroid hormone synthesis, glandular stores of preexisting thyroid hormone must be exhausted before they are fully effective. This may require 3 to 8 weeks in patients with Graves' disease or toxic multinodular goiter. Although antithyroid drugs can provide long-term control of hyperthyroidism, they are most appropriately used when there is a possibility that the underlying condition will remit, as in Graves' disease, or when thyrotoxicosis must be attenuated before radioiodine treatment or surgery.

Two thionamide agents are currently available: methimazole and propylthiouracil. Methimazole can be taken as a single daily dose because of its longer half-life and higher effective intrathyroidal concentration. This can bolster patients' adherence and drug effectiveness. Propylthiouracil also inhibits its extrathyroidal conversion of T_4 to T_3, an effect that may be beneficial in patients with severe complicated thyrotoxicosis. Propylthiouracil is preferred for pregnant women with thyrotoxicosis because it crosses the placental barrier less readily than methimazole does. However, the shorter half-life of propylthiouracil necessitates the administration of three or four daily doses. Concerns about the potential risk of severe hepatotoxicity associated with the use of propylthiouracil have prompted the recommendation that it not be used as a first-line agent to treat hyperthyroidism in children or adults. It is still recommended for the treatment of thyrotoxicosis that develops during the first trimester of pregnancy, however.

For patients with mild to moderate hyperthyroidism, methimazole is usually started at a dose of 10 to 30 mg once daily and increased to as much as 90 mg/day. For patients with more severe hyperthyroidism, thyrotoxicosis complicated by cardiac disease, or concomitant pregnancy, propylthiouracil can be started at a dose of 50 to 200 mg every 6 to 8 hours. Methimazole can be given rectally if necessary. The anticipated duration of treatment depends on the underlying cause. In patients with toxic multinodular goiter, antithyroid drugs are generally used only to restore euthyroidism in anticipation of definitive therapy. An effective dose can be continued for 6 to 24 months in a patient with Graves' disease before it is tapered off to determine whether there has been a remission of the patient's autoimmune thyroid disease. Patients most likely to respond are those who present with mild clinical and biochemical hyperthyroidism, a small thyroid gland, and no active ophthalmopathy.

Patients treated with antithyroid drugs should have thyroid function tests every 3 to 12 weeks during dose titration to monitor for iatrogenic hypothyroidism. Common side effects include rash, pruritus, fever, and arthralgias, which affect 5% of thionamide-treated patients. Agranulocytosis and hepatitis are rare but potentially fatal adverse reactions to thionamide medications. Their presentations are relatively sudden in onset and unpredictable. Monitoring of leukocyte counts and liver function test results is not useful as a preventive measure. Patients who are prescribed antithyroid drugs should be cautioned about manifestations of these adverse reactions and should be instructed to discontinue treatment and seek medical attention if they develop a high fever, pharyngitis, jaundice, or abdominal pain.

Radioactive Iodine

The selective uptake and concentration of iodide in thyrocytes permits the use of radioactive iodine to treat hyperthyroidism. Once it is concentrated in the gland after oral administration, ^{131}I destroys thyroid tissue, effectively controlling hyperthyroidism. The dose of ^{131}I can be calculated on the basis of the fractional uptake of radioiodine, but the outcome of dosimetry is not superior to that achieved with the administration of 10 mCi. Patients can be treated on an outpatient basis, with precautions taken to prevent the exposure of others. Approximately three quarters of patients are cured with a single dose of radioiodine.

The principal side effect of radioactive iodine therapy is postablative hypothyroidism, which develops in most individuals receiving treatment for Graves' disease and a lesser proportion of patients treated for toxic nodular goiter. Lifelong monitoring of thyroid function is required because patients develop postablative hypothyroidism at a rate of 3% per year. Another less common complication is a transient exacerbation of thyrotoxicosis, which occurs in one quarter of patients during the first month after treatment as a result of radiation thyroiditis. Long-term follow-up studies have shown that radioiodine-treated patients with Graves' disease do not have any greater risk of thyroid cancer or other malignant neoplasms. However, hyperthyroid children and adolescents treated with radioactive iodine are more likely to develop benign nodules. Among hyperthyroid women treated with radioiodine, the incidences of infertility, spontaneous abortion, and children with birth defects are not increased. Diagnostic or therapeutic radioactive iodine is contraindicated in women during pregnancy, and treated women should avoid pregnancy until euthyroidism has been confirmed 3 to 6 months after administration of a dose.

Other Drugs

A saturated solution of potassium iodide (SSKI) or Lugol's solution transiently inhibits the synthesis and release of thyroid hormone from the gland. It may be used to accelerate recovery after radioactive iodine treatment, to prepare patients for thyroidectomy, and to augment other treatments used to control severe thyrotoxicosis (see later). Iodinated radiocontrast agents inhibit the release of thyroid hormone while blocking peripheral conversion of T_4 to T_3. Lithium carbonate also inhibits the release of thyroid hormone. Rarely, these agents are used in combination with thionamides to treat patients with severe thyrotoxicosis. They may also help provide temporary control of hyperthyroidism when severe allergies preclude the continued use of thionamides. Cholestyramine can be used to bind thyroid hormone in the gut to interrupt enterohepatic circulation in cases of suspected exogenous thyroid hormone intoxication.

Surgery

Surgery has a limited role because of its potential to injure the adjacent recurrent laryngeal nerves and parathyroid glands. Resection of a toxic adenoma by lobectomy is curative and often preserves sufficient normal thyroid tissue for euthyroidism to be maintained. Consequently, it is often recommended in younger individuals. Toxic multinodular goiters causing compressive

symptoms or cosmetic disfigurement may be appropriately managed with surgical resection. Although surgery is seldom recommended for the treatment of hyperthyroid Graves' disease, it may be appropriate when other modalities are contraindicated, such as when there has been an adverse reaction to an antithyroid drug in pregnancy, when a thyroid nodule is thought to be malignant, or when hyperparathyroidism also requires surgical intervention.

Specific Treatment Scenarios

Pregnancy

Pregnant patients with hyperthyroidism present special challenges. Diagnosis requires a careful assessment of symptoms, especially heat intolerance, palpitations, and vomiting, which also occur during normal pregnancy. The serum total T_4 level is elevated because of increased TBG, and the TSH level can be suppressed in the first trimester as a result of HCG-mediated thyroid stimulation. Diagnostic radioiodine studies are contraindicated. After diagnostic confirmation, hyperthyroidism must be treated because it is associated with an increased risk of spontaneous abortion, premature labor, low birthweight, and toxemia. β-Blockers should be used only transiently to treat severe symptoms. Propylthiouracil is the preferred thionamide for treatment of Graves' disease during the first trimester of pregnancy because it crosses the placenta less readily than methimazole and because methimazole has been rarely linked to congenital malformations (i.e., choanal atresia and cutis aplasia). However, owing to the risk of very rare but potentially fatal propylthiouracil-related hepatitis, methimazole is preferred after the first trimester. Because Graves' disease often remits later in pregnancy, antithyroid drug dose requirements often decline as gestation progresses. Measurement of maternal thyroid-stimulating immunoglobulin levels can help predict the risk of an infant's developing neonatal Graves' disease.

Subclinical and Mild Hyperthyroidism

Patients with mild hyperthyroidism (i.e., a suppressed serum TSH with normal free T_4 and T_3 levels) may have symptoms that justify treatment. In patients with a serum TSH level suppressed to less than 0.1 mIU/L, bone mineral loss can lead to osteoporosis, particularly in postmenopausal women. Atrial fibrillation occurs more commonly in mildly hyperthyroid patients aged 60 years and older with TSH suppression below normal. It is less clear, however, whether younger, asymptomatic patients with modestly suppressed TSH levels (e.g., 0.1 to 0.5 mIU/L) require anything more than periodic monitoring.

Thyrotoxic Crisis

Thyrotoxic crisis, also known as *thyroid storm*, is a potentially life-threatening syndrome that is usually the end result of severe and sustained thyrotoxicosis. It can affect patients with other medical conditions that render them vulnerable to the cardiovascular, neuropsychiatric, and gastrointestinal effects of exposure to excessive amounts of thyroid hormone. Thyrotoxic crisis typically develops in the setting of inadequately treated Graves' disease and may be precipitated by intercurrent illness, surgery, or treatment with radioactive iodine. Affected individuals present with fever, atrial tachyarrhythmias, congestive heart failure, nausea and vomiting, diarrhea, and seizures. Mental status changes can include agitation, delirium, psychosis, and coma. Prompt recognition and treatment in a monitored setting are crucial. A multifaceted treatment regimen should incorporate antipyretics, β-blockers, thionamides, iodinated contrast agents, and glucocorticoids, as well as aggressive evaluation and management of underlying medical problems.

THYROIDITIS

Subacute (de Quervain's) Thyroiditis

PATHOBIOLOGY

Transient thyrotoxicosis results from the uncontrolled release of thyroid hormone from the inflamed gland. After 2 to 8 weeks, when the supply of stored hormone is exhausted, thyrotoxicosis resolves spontaneously. Hypothyroidism ensues because the gland's biosynthetic capabilities remain impaired. This is also transient (lasting approximately 1 month), with subsequent restoration of normal thyroid function in most patients.

CLINICAL MANIFESTATIONS

Subacute thyroiditis is characterized by painful enlargement of the thyroid, systemic inflammatory symptoms, and transient thyrotoxicosis that is often followed by transient hypothyroidism. The histologic pattern shows inflammatory cell infiltrates that are believed to be the result of a viral infection. Many patients with subacute thyroiditis report antecedent upper respiratory infections.

Patients usually present with pain localized to the thyroid or radiating to the throat, ears, or jaw. Constitutional symptoms, including fever, chills, sweats, and malaise, are generally present. On occasion, these features may dominate the presentation. Examination of the thyroid typically reveals an exquisitely tender, modestly enlarged, and woody, hard gland.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of thyroid pain must be considered in the evaluation of patients presenting with pain and tenderness localized to the lower anterior neck. In addition to subacute thyroiditis, potential causes of thyroid pain include acute (suppurative) thyroiditis; hemorrhage into an existing thyroid nodule; and rapid growth of anaplastic thyroid cancer, diffusely infiltrating thyroid cancer, or thyroid lymphoma.

Laboratory Findings

Laboratory testing in patients with subacute thyroiditis reveals a profile of overt thyrotoxicosis. Elevated T_4 levels are usually proportionately higher than T_3 levels. Patients typically have an elevated erythrocyte sedimentation rate during the acute phase. The fractional uptake of radioiodine is typically less than 2% at 24 hours (see Table 233-6).

TREATMENT Rx

High-dose aspirin or naproxen sodium can be used to treat thyroid pain and systemic inflammatory symptoms. Patients who fail to respond may require glucocorticoid therapy, but it must be tapered over several weeks to prevent a relapse, prolonging the overall course of the illness. Symptoms ascribed to transient thyrotoxicosis may respond to treatment with a β-blocker continued for a limited course of 1 to 3 weeks. Patients who progress to symptomatic hypothyroidism may then need short-term thyroxine replacement therapy, but most do not require long-term thyroid hormone replacement.

Lymphocytic (Postpartum, Painless, Silent) Thyroiditis

EPIDEMIOLOGY

Lymphocytic thyroiditis occurs most commonly in postpartum women, affecting as many as 6% of women 2 to 12 months after delivery or termination. Rarely, this condition occurs in non-postpartum women or in men. Predisposing factors include a history of previous episodes of postpartum thyroiditis, type 1 diabetes mellitus, and circulating antithyroid autoantibodies.

PATHOBIOLOGY

This painless inflammation of the thyroid gland can cause transient thyrotoxicosis followed by transient or persistent hypothyroidism. Each of these phases of thyroid dysfunction typically lasts 2 to 8 weeks. This condition is believed to reflect transient autoimmunity.

DIAGNOSIS

The diagnosis of lymphocytic thyroiditis is often overlooked when nonspecific symptoms of thyrotoxicosis (e.g., weight loss, insomnia, anxiety) or hypothyroidism (e.g., fatigue, depression) are misinterpreted as common postpartum complaints. The thyroid gland is nontender and either normal in size or modestly enlarged. Once it is considered, a diagnosis of lymphocytic thyroiditis can be readily confirmed or excluded by laboratory testing, which reveals a suppressed TSH level during phases of thyrotoxicosis and an elevated TSH level during phases of hypothyroidism. This condition must be distinguished from Graves' disease, which can also present in the same time frame after delivery. Relative degrees of T_4 and T_3 elevation can sometimes provide a clue to which condition is present; lymphocytic thyroiditis is typically characterized by predominant increases in T_4 levels. Fractional uptake of radioiodine is either absent or very low in the setting of lymphocytic thyroiditis but increased in active Graves' disease, thus providing a useful diagnostic test (see Table 233-6).

TREATMENT Rx

Lymphocytic thyroiditis can often be managed with reassurance and observation alone. Symptomatic thyrotoxicosis can be treated with a limited course of β-blocker therapy. Overt hypothyroidism may require transient thyroxine replacement.

PROGNOSIS

Whereas most affected patients eventually return to a euthyroid state, 25% develop persistent hypothyroidism due to classic autoimmune thyroiditis.

Acute (Suppurative) Thyroiditis

Infection of the thyroid gland is a rare condition that typically presents with severe thyroid pain, fever, and other systemic manifestations of infection. Bacterial infection of thyroid tissue can be the result of direct spread of gram-positive or gram-negative pathogens through fistulas communicating with the piriform sinus or the skin. Hematogenous spread of bacterial, mycobacterial, fungal, or parasitic organisms, especially *Pneumocystis carinii,* can occur in immunocompromised individuals. On examination, affected patients are typically febrile, with asymmetrical swelling of a thyroid that is tender, warm, and fluctuant to firm in consistency beneath erythematous skin. Ultrasonography may reveal an abscess that can be aspirated to identify a pathogen. Patients with suppurative thyroiditis require prompt treatment with appropriate antibiotics. Surgical drainage of abscesses may be required.

Other Forms of Thyroiditis

Certain drugs can cause thyroid gland inflammation. Amiodarone can produce a painless thyroiditis associated with thyrotoxicosis. Whenever possible, this should be distinguished from the iodine-induced form of thyrotoxicosis that can also be associated with amiodarone therapy. The former is optimally treated with glucocorticoid therapy, whereas the latter is managed with antithyroid drugs. Interferon-α can provoke a painless thyroiditis associated with transient thyrotoxicosis. This must be differentiated from interferon-α–induced Graves' disease because the former is managed with β-blockers and the latter with antithyroid drugs.

Riedel's thyroiditis or struma is characterized by fibrotic replacement of the thyroid, with adherence and infiltration of adjacent structures that causes local compressive symptoms. In this idiopathic condition, the thyroid is substantially enlarged, hardened, and fixed. Affected patients may also develop mediastinal and retroperitoneal fibrosis, sclerosing cholangitis, or orbital pseudotumor. Diagnosis requires open biopsy. Surgical excision is difficult or impossible. Glucocorticoid therapy and tamoxifen therapy have been anecdotally reported to be effective.

GOITER

DEFINITION

Goiters can be classified as diffuse or nodular, nontoxic or toxic (i.e., associated with thyroid hormone overproduction), and benign or malignant. Thyroid enlargement can be the result of thyrocyte proliferation stimulated by circulating factors (e.g., TSH and thyroid-stimulating autoantibodies) or local growth factors (e.g., epidermal growth factor), infiltration of the gland by inflammatory or malignant cells, or benign or malignant neoplastic changes within the gland itself. In a patient with a goiter, three clinical issues must be considered: local compressive or cosmetic problems, gland hyperfunction or hypofunction, and potential malignancy.

EPIDEMIOLOGY

Dietary iodine deficiency represents the most common cause of goiter worldwide. It is encountered in the United States only among immigrants from iodine-deficient regions. Younger patients present with diffuse or simple goiters that shrink in response to adequate iodine supplementation. In older individuals, iodine-deficient goiters become multinodular and do not decrease in size with iodine repletion. Excessive iodine exposure can provoke thyrotoxicosis in these patients.

PATHOBIOLOGY

Benign multinodular goiter or adenoma can be the result of genetic defects that lead to dyshormonogenesis, including mutations in the thyroglobulin, thyroid peroxidase, dual oxidase, and pendrin genes. Similarly, exposure to goitrogenic substances in foodstuffs, water, or drugs (e.g., lithium carbonate) that inhibit the normal steps in thyroid hormone synthesis can lead to goiter. In most patients the underlying cause is unknown.

Autoimmune thyroiditis typically produces a modest goiter as a result of glandular infiltration with lymphocytes, inflammatory changes in thyrocytes, and fibrosis. The hypothyroid state caused by autoimmune thyroiditis results in increased TSH, which further stimulates thyroid enlargement. Graves' disease is also characterized by diffuse thyroid enlargement due to the action of thyroid-stimulating immunoglobulins. Other forms of thyroiditis can present with goitrous enlargement of the thyroid gland, including subacute, lymphocytic, and acute (suppurative) thyroiditis (see earlier sections).

Malignant neoplasms that involve the gland diffusely, including thyroid lymphoma and infiltrative papillary, medullary, and anaplastic thyroid cancers, may present as rapidly enlarging goiters (see later sections). Affected patients often experience local pain and symptoms related to tumor expansion.

DIAGNOSIS

Clinical Examination

The first step in evaluating a suspected goiter is to confirm whether swelling represents enlargement of the thyroid. Redundant skin and subcutaneous fat in the lower anterior neck can be mistaken for an enlarged thyroid. These findings can usually be distinguished from true thyroid enlargement by palpating a normal thyroid beneath the misleading soft tissue and by observing that the fullness does not rise and fall with deglutition. Ultrasonography may help resolve uncertainty.

A patient's history can provide important clues to the underlying cause. A childhood history may confirm previous iodine deficiency. Symptoms of hypothyroidism may suggest autoimmune thyroiditis, whereas clinical evidence of thyrotoxicosis may suggest Graves' disease or toxic multinodular goiter. Clinical findings may lead to recognition of one of the various forms of thyroiditis (e.g., pain in subacute thyroiditis or postpartum status in lymphocytic thyroiditis). Symptoms suggesting the invasion of adjacent structures may raise concerns about malignant disease or Riedel's thyroiditis.

Careful examination of the thyroid is informative. Diffuse enlargement favors one of the forms of thyroiditis, Graves' disease, or a diffusely infiltrating malignant neoplasm. Nodular enlargement is more likely to reflect a benign multinodular goiter or malignant neoplasm. The precise size of the gland should be documented. Dysphonia, tracheal deviation, cervical lymphadenopathy, and venous engorgement in the neck should be noted. Subtotal obstruction of the thoracic outlet may be revealed by having the patient touch his or her hands together above the head (Pemberton's maneuver) while checking for signs of facial plethora and cervical venous distention.

Laboratory Findings

A TSH level determines whether there is primary hypothyroidism or thyrotoxicosis. Elevated antithyroid peroxidase antibody titers can confirm suspected autoimmune thyroiditis. In asymptomatic patients with a modest diffuse goiter, no further evaluation may be indicated. Other blood tests (e.g., erythrocyte sedimentation rate for subacute thyroiditis or calcitonin for medullary thyroid cancer) can be useful when clinical clues suggest specific diagnoses.

Imaging

Cervical ultrasonography is usually the best imaging technique to define the character and extent of a goiter limited to the neck. It can help determine whether a goiter is diffuse or nodular, whether the thyroid is impinging on other cervical structures, and whether lymphadenopathy is present. When a goiter extends posteriorly or beneath the sternal notch into the thorax, CT or MRI may be required. The administration of iodine-containing radiocontrast dye should be avoided in the evaluation of patients with goiters because the stable iodide load may interfere with subsequent radioiodine imaging or therapy. Thyroid uptake studies may help define whether quantitative tracer uptake is subnormal or supranormal. Radioiodine scanning can help determine whether a superior mediastinal mass is thyroid tissue. Barium swallow radiographs with fixed-diameter markers and pulmonary function testing with flow-volume loops can help determine whether symptoms are directly related to compression of the esophagus or trachea, respectively. Laryngoscopy is useful to evaluate vocal cord function in patients with potential recurrent laryngeal nerve involvement.

TREATMENT Rx

Once thyroid dysfunction and malignant disease have been excluded, asymptomatic patients with goiters can be observed, with periodic clinical assessment. Ultrasonography can be relied on as a reproducible technique for monitoring the size of an enlarged thyroid gland. Thyroxine therapy to suppress TSH levels is effective in shrinking goiters in only a minority of patients. Furthermore, chronic thyroid hormone treatment carries the risks of symptomatic thyrotoxicosis, atrial fibrillation, and bone mineral loss.

Patients with benign multinodular goiters causing local compressive symptoms or cosmetic concerns can be treated with surgery or radioactive iodine therapy. Surgery is often preferred when a patient has substantial gland enlargement causing compressive complications, especially when there is substernal extension of the goiter or acute obstructive symptoms. When surgery is contraindicated by the patient's health status, radioactive iodine therapy has been shown to reduce goiter size by an average of 50% over 12 to 24 months.

THYROID NODULES

EPIDEMIOLOGY

Thyroid nodules are common, being detected by palpation in 6% of women and 2% of men. Contemporary high-resolution ultrasonography identifies thyroid nodules in as many as 50% of all adults. Although the majority of these represent small, benign adenomatoid nodules or cysts, 5 to 10% of thyroid nodules are malignant. Less commonly, thyroid nodules are clinical problems by virtue of being hyperfunctioning or causing local compressive symptoms or cosmetic dissatisfaction.

DIAGNOSIS

Thyroid nodules are usually noted by the patient or the physician in the absence of any other complaints. It is also common for thyroid nodules to be detected incidentally on imaging procedures, such as carotid ultrasonography and cervical spine CT or MRI. Symptoms of compression or invasion of adjacent tissues suggest that a nodule may be malignant. These include pain in the lower anterior neck, cough or dyspnea due to tracheal compression, hemoptysis due to tracheal invasion, dysphonia due to recurrent laryngeal nerve encasement, and dysphagia or odynophagia due to esophageal compression. Certain other symptoms and signs lead to the consideration of specific underlying conditions. A toxic adenoma should be suspected in a patient with a thyroid nodule and the classic clinical manifestations of thyrotoxicosis. Hypothyroid symptoms and signs suggest autoimmune thyroiditis with asymmetrical thyroid enlargement. Hypercalcitoninemia associated with the metastatic spread of medullary thyroid cancer can cause pruritus, flushing, and diarrhea. The clinical assessment should also include symptoms and signs related to common sites of thyroid cancer metastasis, such as chest pain, dyspnea, bone pain, and neurologic findings. Thyroid nodules rarely can be due to metastasis from other primary malignant neoplasms, including kidney, colon, and breast cancer.

History

A special predisposition to thyroid cancer is suggested by a personal history of therapeutic neck irradiation in childhood. Family history can be informative if relatives have had medullary or papillary thyroid cancers, which are familial in 50% and 10% of cases, respectively. The possibility of medullary thyroid cancer should also be considered when there is a personal or family history of clinical problems associated with multiple endocrine neoplasia type 2 (MEN 2) syndrome, including hyperparathyroidism and pheochromocytoma (Chapter 239).

Physical Examination

Physical examination of the thyroid nodule should seek to define its size, consistency, surface texture, mobility, and tenderness. The presence of malignant disease is suggested by fixation and ipsilateral regional adenopathy or vocal cord paresis. Multinodularity of the gland may reflect benign nodular goiter, but it is not sufficiently reassuring to dispense with further diagnostic testing. This is particularly true for a so-called dominant nodule, which is larger, enlarging faster, or more symptomatic than others present in the thyroid.

Laboratory Findings

Routine laboratory testing includes measurement of TSH levels to identify patients with hyperthyroidism or hypothyroidism. When the TSH level is low or undetectable, the possibility of a benign autonomously functioning toxic adenoma can be pursued with radionuclide thyroid scanning (see Table 233-6). If an elevated TSH level indicates primary hypothyroidism, antithyroid peroxidase antibody titers can confirm whether the patient has autoimmune thyroiditis. Ultrasonography can distinguish asymmetrical enlargement caused by autoimmune thyroiditis from a discrete nodule. Calcitonin levels should be measured in patients with a known or suspected family history of MEN 2 or familial medullary thyroid cancer. Serum thyroglobulin measurement is not helpful in distinguishing benign from malignant thyroid abnormalities.

Imaging

Cervical ultrasonography is not required before biopsy, but it can help confirm that a mass is within the thyroid, accurately define its size, classify it as cystic or solid, and determine whether additional nodules are present. Ultrasonography occasionally reveals other suspicious findings, such as fine calcifications, irregular nodule borders, and cervical adenopathy.

Radionuclide scanning with radioiodine or technetium pertechnetate is helpful only in selected cases. In patients with a thyroid nodule and a suppressed TSH level, scanning can confirm that the nodule is hyperfunctioning or "hot," in which case biopsy is usually not required. CT, MRI, and PET are generally unnecessary in the evaluation of patients with thyroid nodules. Furthermore, administration of iodinated radiocontrast dye can interfere with the subsequent management of patients who prove to have thyroid cancer.

Invasive Evaluation

Fine-Needle Aspiration Biopsy

Fine-needle aspiration biopsy is the most accurate test to exclude or confirm malignant disease in patients with a nodule and a normal TSH level (Fig. 233-4). Most solid nodules and complex cysts larger than 1.0 to 1.5 cm in diameter should be sampled. Although aspiration can be directed by palpation alone when a nodule is readily definable, ultrasonography provides more certain guidance for the sampling of poorly localized lesions, often revealing additional nodules that should be assessed.

The cytologic assessment of aspirated material must first confirm that there is adequate material for assessment (e.g., six clumps of 10 cells on two slides). Biopsies with inadequate specimens, which are more common in cystic lesions, must be repeated. Ultrasonographic guidance and on-site preliminary cytologic assessment can improve the yield of biopsy. In accordance with the recently developed Bethesda System for Reporting Thyroid Cytopathology, a sampled nodule can be categorized as benign, malignant, or indeterminate (suspicious).

Benign nodules typically yield samples containing clusters of normal-appearing follicular epithelial cells with colloid. Pure colloid cysts may have scant epithelium. This classification is highly accurate, with a false-negative rate of less than 1% in sonographically directed biopsy specimens, and surgical resection is not required. In most cases, conservative observation based on yearly clinical or sonographic reassessment can be recommended. Further enlargement during observation should prompt repeated biopsy. If a nodule is determined to be benign, a trial of thyroxine therapy to suppress the TSH level to the low but detectable range (e.g., 0.1 to 0.5 mIU/L) can be considered, although this approach is likely to shrink nodules in less than 50% of cases. Surgical resection should be considered if a cytologically benign nodule continues to grow, causing compressive symptoms or cosmetic disfigurement.

Cytologic material classified as malignant typically contains abundant epithelial cells with atypical nuclear features and scant or absent colloid. This is also a highly reliable finding, with 97 to 99% of such lesions found to be thyroid cancers on subsequent resection. Consequently, bilateral thyroidectomy is indicated in patients without contraindications to operation. Samples that contain sparser quantities of epithelial cells with similar atypical nuclear features may be classified as suspicious for malignancy. More than 60 to 75% of nodules falling into this category represent thyroid cancers.

One in five biopsies yields adequate but diagnostically indeterminate cytologic material. Specific findings that classify an indeterminate nodule as suspicious for a follicular neoplasm include abundant follicular or Hürthle cells in microfollicles, with little or no colloid and minor degrees of nuclear atypia, potentially indicative of papillary cancer. Although the majority of such indeterminate nodules are benign follicular adenomas, 15 to 30% are thyroid carcinomas. Consequently, surgery is advisable in most otherwise healthy patients with nodules that fall within this diagnostic category. Unilateral thyroid lobectomy has the advantage of a lower incidence of surgical complications and postoperative hypothyroidism when the lesion is benign, but it necessitates a subsequent completion thyroidectomy for most patients who prove to have cancer. For patients with no clinical features of malignancy, particularly middle-aged or older women with multinodular glands, in whom the prevalence of malignancy is 5% or less, vigilant observation with serial sonography is an alternative.

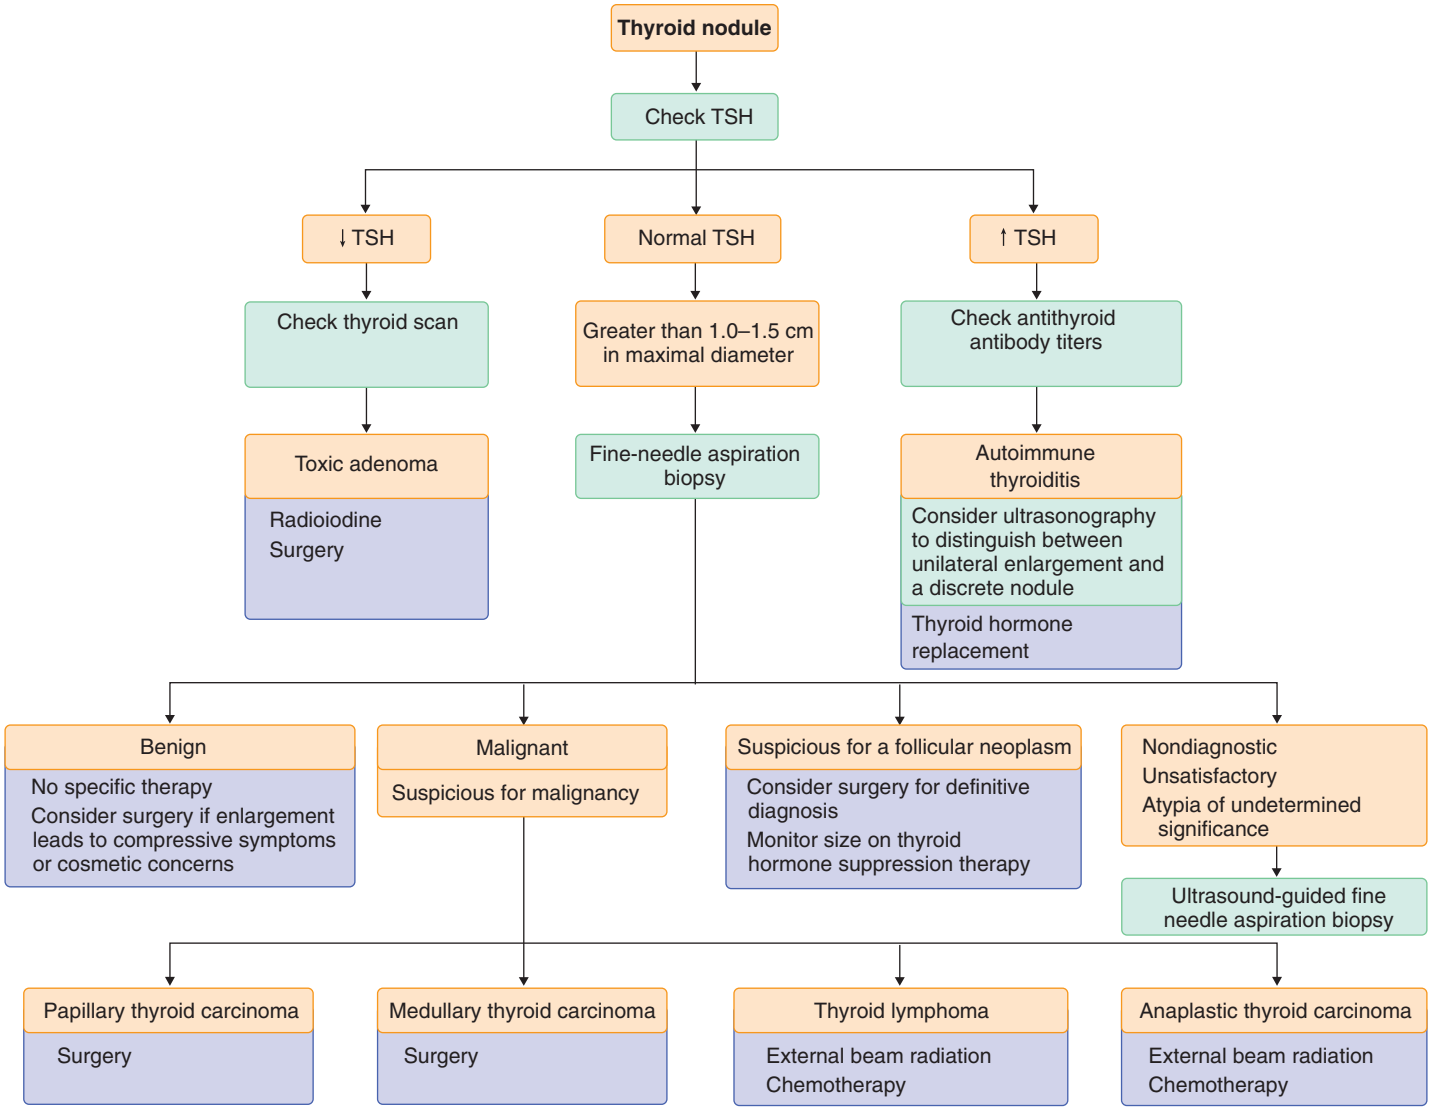

FIGURE 233-4. Evaluation of a thyroid nodule.

Biopsy samples that reveal nuclear or architectural features considered to be abnormal but not clearly suspicious for malignancy or a follicular neoplasm are classified as demonstrating atypia of undetermined significance. Nodules that initially fall into this category have been estimated to harbor malignancy at rates ranging from 5 to 15%. Repeat sampling may provide a more definitive diagnosis to guide further management in 75 to 85% of cases.

THYROID CANCER

Cancers of the thyroid gland have a spectrum of behavior that ranges from incidentally detected and clinically inconsequential microcarcinomas to aggressive and virtually untreatable anaplastic malignant neoplasms. When thyroid cancer is diagnosed early, treatment is effective for most types. Most thyroid cancers present as thyroid nodules that are either asymptomatic or associated with local cervical symptoms or adenopathy. Less often, thyroid cancers first present with manifestations of metastatic disease, such as a pulmonary mass or bone pain.

Papillary and Follicular (Epithelial) Thyroid Carcinomas

Papillary and follicular thyroid cancers arise from follicular epithelium and often retain responsiveness to TSH, produce thyroglobulin, and concentrate iodide. They are distinguished by their histopathologic appearances and characteristic patterns of progression. Hürthle cell carcinoma of the thyroid is composed of thyrocytes with abundant cytoplasm and behaves like a follicular thyroid cancer, although it typically does not retain iodine-concentrating ability.

EPIDEMIOLOGY

Approximately 34,000 new cases of thyroid cancer are diagnosed annually in the United States. Thyroid cancer is three times more common in women, in whom its incidence is currently rising fasting than that of any other malignancy. There are estimated to be 350,000 U.S. thyroid cancer survivors, who require lifelong follow-up for recurrence. Papillary thyroid carcinoma is the most common form of thyroid cancer, representing 90% of cases. The mean age at diagnosis is 45 years, but papillary thyroid carcinoma does occur in children and increases in incidence with age.

PATHOBIOLOGY

Irradiation of the thyroid gland in childhood is a risk factor, as evidenced by the epidemics of thyroid cancer that follow both external beam radiation therapy for benign childhood conditions and radioiodine exposure after nuclear incidents. A substantial body of evidence now implicates *RET/PTC* and *B-Raf kinase* gene mutations that activate the MAP kinase signaling pathway in the pathogenesis of papillary thyroid cancer. Most papillary thyroid carcinomas are slow growing and either remain confined to the gland or metastasize to cervical lymph nodes. Papillary microcarcinomas are a common incidental pathologic finding in 5% of thyroid glands excised for other reasons. Some papillary thyroid carcinomas are more aggressive, with extension into adjacent tissues, extensive nodal involvement, and distant metastatic spread, most commonly to the lungs. This is more common in older patients.

Follicular and Hürthle cell thyroid carcinomas account for 10% of all thyroid cancers. When these tumors show histologic evidence of invading only the tumor capsule, they are termed *minimally invasive* and generally

behave like papillary thyroid carcinomas. However, follicular and Hürthle cell carcinomas with vascular invasion are more likely to be associated with distant metastatic disease, which most commonly involves the lungs and skeleton.

TREATMENT

Rx

Treatment of epithelial thyroid cancer entails surgery, often followed by radioiodine ablation of remnant thyroid tissue. Total or near-total thyroidectomy with selective central compartment lymph node resection is usually the appropriate initial surgical procedure. Thyroid surgery can be complicated by hypoparathyroidism or recurrent laryngeal nerve injury, which causes hoarseness if it is unilateral and airway obstruction if it is bilateral. The rationale for bilateral surgery is the frequent presence of bilateral disease in papillary thyroid cancer and the lower risk of recurrence. In addition, there is greater accuracy in detecting residual disease after the eradication of all remaining normal thyroid tissue.

Follow-up

Postoperatively, ^{131}I administration can ablate the small amount of normal thyroid tissue that usually remains. This tissue, if it is not destroyed, leaves patients with circulating thyroglobulin and iodine-concentrating tissue, thus decreasing the utility of TBG measurements to detect recurrence. In nonrandomized trials, radioiodine has been associated with a lower rate of tumor recurrence in patients with advanced disease at presentation (see later), but there is no clear clinical benefit for patients with lower stages of disease. TSH stimulation of residual thyroid tissue is essential for effective radioiodine therapy. This can be accomplished either by the administration of recombinant thyrotropin or by the temporary withdrawal of thyroid hormone therapy to promote endogenous TSH production.

Thyroxine therapy is appropriate for all patients with treated thyroid cancer, regardless of the extent of surgery and whether they received radioiodine ablative therapy. Thyroid hormone therapy is intended to suppress the patient's circulating TSH level to reduce the likelihood of thyroid tumor recurrence. In determining the extent to which the TSH level should be suppressed, the patient's risk of cancer recurrence must be balanced against potential complications such as bone mineral loss in postmenopausal women and atrial fibrillation in older patients.

Long-term monitoring of patients entails periodic clinical assessment, measurement of thyroglobulin levels, radioiodine imaging in the early postoperative phase, and occasional use of ultrasonography. Clinically, patients should be assessed for local neck symptoms or recurrent cervical masses, as well as for optimization of thyroid hormone therapy. For patients with treated epithelial thyroid cancers, thyroglobulin is a more specific tumor marker if all remaining normal thyroid tissue has been ablated. For patients with undetectable thyroglobulin levels on TSH-suppressive thyroid hormone therapy, thyroglobulin measurement after recombinant TSH stimulation can sometimes reveal residual disease. Radioiodine scanning after TSH stimulation can be helpful in patients who have previously undergone radioiodine ablation, but once iodine imaging is normal, it offers little or no advantage over measurement of stimulated thyroglobulin levels. This is particularly true in recurrent papillary thyroid cancers, which often lose the ability to concentrate iodine. Unfortunately, thyroglobulin testing is impossible in the 20% of patients who have circulating thyroglobulin autoantibodies that interfere with thyroglobulin immunoassays. Because most epithelial thyroid cancer recurrences are in cervical nodes or soft tissues, ultrasonography is useful for postoperative monitoring, particularly in patients who presented with extensive cervical disease or who have persistent detectable serum thyroglobulin. CT scanning of the chest should be employed to detect intrathoracic disease in patients whose findings suggest recurrence outside the neck. In patients with substantial detectable thyroglobulin levels (>10 ng/dL) and normal findings on standard imaging studies, PET scanning can identify sites of residual disease in more than 50% of patients.

Localization of recurrent cervical disease is usually an indication for comprehensive compartmental neck dissection. Distant and nonresectable metastases that are iodine avid, which occur more commonly in patients with invasive follicular thyroid cancer, can be treated with repeated doses of ^{131}I. Symptomatic hilar node and bone metastases can be treated palliatively with external beam radiation therapy. Surgery can be employed for isolated metastatic disease sites. Conventional chemotherapy has limited efficacy in the treatment of differentiated thyroid cancer, but newer biologic agents targeting the molecular pathogenesis of these tumors hold promise. For example, in a phase II study of patients with progressive disease, treatment with the multikinase inhibitor motesanib produced stable disease in 67% of patients, and stability was sustained for 24 weeks or longer in 35% of cases.

PROGNOSIS

The TNM (tumor, node, metastasis) staging system is commonly used to stage epithelial thyroid cancers. In addition to tumor size, extent of node involvement, and presence of distant metastatic disease, the age of the patient at presentation is an important predictor of outcome. Patients younger than 45 years have a better prognosis than older individuals. The overall age-adjusted 10-year survival rates for patients with papillary and follicular thyroid cancer are 98% and 92%, respectively. However, disease recurrence is relatively common, (e.g., one third of patients with papillary thyroid cancer). Consequently, patients with treated thyroid cancer must be monitored for recurrent disease.

Medullary Thyroid Carcinoma

PATHOBIOLOGY

Medullary thyroid carcinoma (Chapter 254) arises from the thyroid's parafollicular C cells. It accounts for less than 5% of all thyroid cancers. It may occur as sporadic medullary cancer or as a component of the MEN 2a syndrome, MEN 2b syndrome, or familial medullary thyroid cancer syndrome. These inherited syndromes are autosomal dominant disorders caused by mutations of the *ret* proto-oncogene. In patients with no known family history, genetic testing at the time of diagnosis indicates a prevalence of 6%.

Patients with medullary thyroid cancer typically present with a thyroid nodule, cervical adenopathy, distant disease, or clinical manifestations of markedly elevated circulating calcitonin levels that may include flushing, diarrhea, and pruritus. Features of the other elements of MEN 2a (e.g., hypertension) or MEN 2b (e.g., marfanoid habitus, submucosal neuromas) should be sought.

TREATMENT

Rx

Initial treatment is surgical resection of the thyroid and regional lymph nodes, which are involved in 50% of patients at the time of diagnosis. The high risk of extrathyroidal disease and the limited availability of secondary treatment options mandate aggressive initial surgery, including central neck compartment dissection, unilateral or bilateral modified neck dissection, and even superior mediastinal exploration to extirpate suspicious lymphadenopathy. The risk for the development of medullary thyroid carcinoma is so high in children with inherited *ret* proto-oncogene mutations that prophylactic thyroidectomy is advisable during childhood. Distant metastases involving the liver are present in a small minority of patients and can often be established by laparoscopically guided liver biopsy.

Follow-up

Because medullary thyroid carcinoma cells produce calcitonin and carcinoembryonic antigen, these tumor markers can be measured serially to monitor patients for recurrence and progression of disease. Surgery can be repeated to treat significant cervical and mediastinal node disease. External beam radiation therapy has been used for nonresectable cervical disease, but its value has not been established in controlled trials. Radioiodine therapy is ineffective, and thyroid hormone therapy is intended only to maintain euthyroidism. Somatostatin analogues can be used to control the diarrhea and flushing associated with hypercalcitonemia.

Anaplastic Thyroid Carcinoma

Anaplastic thyroid carcinoma is a rare, histologically undifferentiated and clinically aggressive malignant neoplasm that typically arises in older patients, one fourth of whom present with evidence of a preceding differentiated thyroid cancer. Affected patients present with a rapidly enlarging mass in the anterior or lateral neck associated with pain, tenderness, and compressive symptoms including dysphagia, dysphonia, and stridorous dyspnea. Fine-needle aspiration biopsy of the mass usually yields large, pleomorphic, undifferentiated cells, but open surgical biopsy is sometimes required to confirm the diagnosis.

Most cases are unresectable at presentation because of invasion of cervical structures. Surgery is not curative and should aim to secure the patient's airway. A percutaneous gastrostomy tube is often placed to ensure adequate nutrition in the face of esophageal impingement. Conventional therapy consisting of combined external beam radiation therapy and chemotherapy with doxorubicin with or without cisplatin produces an initial response in 25% of patients. Those with disease limited to the neck may have extended survival, but almost all patients relapse within a few months and succumb to their disease, with median survival ranging from 3 to 7 months. Current research is focused on the use of targeted antiangiogenic agents to treat unresponsive disease.

Thyroid Lymphoma

Lymphoma rarely arises in the thyroid gland, typically presenting in older persons as a rapidly enlarging and painful diffuse goiter. Patients often have a preceding history of autoimmune thyroiditis. The diagnosis is further suspected when fine-needle aspiration biopsy yields abundant lymphocytes without other cellular features of autoimmune thyroiditis. Immunohistochemical staining and flow cytometry of sampled material can characterize a monoclonal lymphocyte population. Surgical biopsy is sometimes required to establish the diagnosis. In 50% of cases, lymphoma is primary to the thyroid gland, and it is usually an intermediate-grade non-Hodgkin's–type lymphoma (Chapter 191).

Surgical resection of the thyroid is not indicated, but elective tracheostomy should be considered as a prophylactic measure when tracheal compression is imminent. Most patients respond to treatment with combined external beam radiation therapy and chemotherapy. Disease-free survival rates vary with the disease stage at diagnosis and the initial response to combination therapy.

ADRENAL CORTEX

LYNNETTE K. NIEMAN

The adrenal glands weigh 6 to 8 g in adults (Fig. 234-1). Each contains a cortex, which makes steroid hormones, and a medulla, which produces catecholamines. Diseases of the adrenal medulla are discussed in Chapter 235. In the adrenal cortex, production of the three major classes of steroids occurs in specific zones: the outermost layer, the glomerulosa, produces mineralocorticoids, primarily aldosterone; the middle layer, the fasciculata, produces glucocorticoids, primarily cortisol; the innermost layer, the reticularis, produces adrenal "androgens," primarily dehydroepiandrosterone (DHEA) and its sulfated conjugate (DHEA-S) (Fig. 234-2). This division reflects the fact that certain critical enzymes are restricted to specific zones, resulting in the ability or inability to synthesize specific end products.

FUNCTION

The actions and regulation of these steroid classes differ. Mineralocorticoids act through the renal mineralocorticoid receptor to promote the reabsorption of sodium and the secretion of potassium. Aldosterone secretion is stimulated primarily by hyperkalemia and angiotensin II (which itself is stimulated by hypovolemia and excess renin). These agents increase the production of aldosterone synthase to restore homeostasis through this feedback loop. Aldosterone production is stimulated to a much smaller degree by adrenocorticotropic hormone (ACTH).

Cortisol and other glucocorticoids act through the glucocorticoid receptor type 2 and its isoforms. The actions of this class of steroids are much broader, including effects on carbohydrate handling, lipid and calcium metabolism, and the immune and nervous systems. Cortisol production is regulated primarily by ACTH, which is secreted in a circadian rhythm in response to corticotropin-releasing hormone (CRH) so that cortisol levels are highest in the morning and fall to a nadir around midnight. Cortisol coordinates ACTH production through negative feedback at the pituitary (ACTH) and hypothalamus (CRH). Vasopressin secretion also plays a role in stimulating ACTH release.

DHEA and DHEA-S are the most abundant products of the adrenal gland. They exert their estrogenic and androgenic effects as prohormones, being converted to estrogens and testosterone in the peripheral tissues and activating the androgen and estrogen receptors. There is no known regulator of DHEA synthesis, but its production declines with age.

DISORDERS OF ADRENAL FUNCTION

Most disorders of the adrenal cortex reflect overproduction or underproduction of the products of a single synthetic zone—cortisol, aldosterone, or testosterone or estrogen (Fig. 234-3). The congenital adrenal hyperplasias are an exception and present with both overproduction and underproduction. Abnormal secretion is suggested by clinical features of each disorder and is reflected in plasma or urine levels of the relevant hormones or by the consequent increases or decreases in feedback systems, which form the basis of the biochemical diagnostic tests.

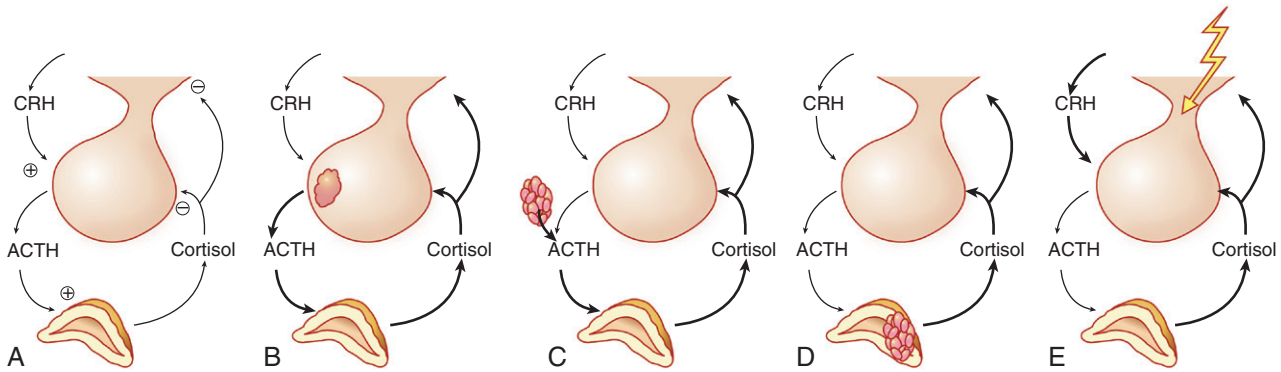

FIGURE 234-3. Physiology of the adrenal axis in health, Cushing's syndrome, and pseudo-Cushing states. A, In healthy individuals, cortisol production is stimulated by the increased hypothalamic release of corticotropin-releasing hormone (CRH), which then travels down the pituitary stalk to stimulate adrenocorticotropic hormone (ACTH) secretion and release by corticotropes. Circulating ACTH stimulates adrenal gland production and secretion of cortisol. Cortisol then functions in a negative feedback mechanism to inhibit both CRH and ACTH. **B,** In Cushing's disease, a pituitary tumor releases excessive amounts of ACTH, which results in increased cortisol secretion by the adrenal glands. **C,** In ectopic ACTH secretion, a nonpituitary ACTH-secreting tumor releases excessive amounts of ACTH, which results in increased cortisol secretion by the adrenal glands. **D,** In ACTH-independent adrenal forms of Cushing's syndrome, the adrenal tumor autonomously releases excess amounts of cortisol. In all forms of Cushing's syndrome, the negative feedback effects of excessive cortisol inhibit endogenous CRH and ACTH secretion, so that circulating ACTH levels reflect the underlying tumor (levels are normal or increased) or independent cortisol production (levels are suppressed). **E,** In pseudo-Cushing states, central stimulation increases CRH secretion, which in turn increases ACTH and hence cortisol production. In this setting, the negative feedback effects of excessive cortisol inhibit endogenous CRH and ACTH secretion, so that cortisol levels are ultimately constrained, albeit at an increased level.

Glucocorticoid Excess: Cushing's Syndrome

CLINICAL MANIFESTATIONS

Cushing's syndrome is a symptom complex that reflects excessive tissue exposure to cortisol. Classic features of Cushing's syndrome include weight gain, plethora, hypertension, and striae (Table 234-1). Not all patients have all features; the number and severity of features correlate roughly with the duration and severity of hypercortisolism. Because many of the signs and symptoms are nonspecific, the diagnosis may be confused with psychiatric disorders, polycystic ovary syndrome, the metabolic syndrome, simple obesity, fibromyalgia, or acute illness. However, because worsening hypercortisolism may precipitate hypertension, glucose intolerance, infections, psychiatric disturbances, impaired cognition, and hypercoagulability, it is important to identify this treatable disorder to prevent its associated morbidity and mortality.

Changes in mood and cognition are useful markers of hypercortisolism. These include irritability, crying, and restlessness; depressed mood; decreased libido; insomnia; anxiety; and decreased concentration and impaired memory.

TABLE 234-1 THE FREQUENCY OF CLINICAL SIGNS AND SYMPTOMS OF CUSHING'S SYNDROME

SIGN OR SYMPTOM	PERCENTAGE
Decreased libido in men and women	100
Obesity or weight gain	97
Plethora	94
Round face	88
Menstrual changes	84
Hirsutism	81
Hypertension	74
Ecchymoses	62
Lethargy, depression	62
Striae	56
Weakness	56
Electrocardiographic changes or atherosclerosis	55
Dorsal fat pad	54
Edema	50
Abnormal glucose tolerance	50
Osteopenia or fracture	50
Headache	47
Backache	43
Recurrent infections	25
Abdominal pain	21
Acne	21
Female balding	13

DIAGNOSIS

Clinical Examination

Cushing's syndrome screening is most likely to be positive in the presence of signs that are typical of glucocorticoid excess, such as abnormal fat distribution in the supraclavicular and temporal fossae, proximal muscle weakness, wide (>1 cm) purple striae, and new irritability, decreased cognition, and decreased short-term memory. Testing is indicated when clinical features have progressed over time. For example, oligomenorrhea is more suggestive of Cushing's syndrome if a woman previously had regular menses. Serial seven subtractions and recall of three cities (or objects) are useful bedside strategies to identify deficits in cognition and memory.

Laboratory Findings

Exogenous administration of glucocorticoid should be excluded before screening for endogenous Cushing's syndrome. Two different screening tests should be abnormal to establish the diagnosis.

Urine, Saliva, and Serum Cortisol Measurements

Urine free cortisol (UFC) excretion during 24 hours is a good screening test. Specific, structurally based assay techniques, such as high-performance liquid chromatography and tandem mass spectrometry, are the "gold standard." The upper-normal limit of these tests is much lower and more specific than that of antibody-based assays, in which other steroids may cross-react.

UFC excretion also may be increased in the so-called pseudo-Cushing states, including psychiatric disorders (depression, anxiety disorder, obsessive-compulsive disorder), chronic pain, severe exercise, alcoholism, uncontrolled diabetes, and morbid obesity. Here, it is hypothesized that higher brain pathways stimulate CRH release and activation of the entire hypothalamic-pituitary-adrenal axis. Cortisol negative feedback inhibition on CRH and pituitary ACTH release restrains the resulting hypercortisoluria to less than four-fold greater than normal. Thus, Cushing's syndrome cannot be diagnosed with certainty unless values reach this threshold. Conversely, patients with Cushing's syndrome may have normal UFC excretion because of intermittent hypercortisolism or altered renal metabolism of cortisol. If UFC is only mildly elevated and clinical features are minimal, it is best to treat any pseudo-Cushing state and to remeasure UFC excretion with the expectation that it will normalize. Alternatively, if UFC values are normal but clinical suspicion is high, repeated measurement might disclose intermittent hypercortisolism.

Measurement of plasma cortisol at midnight distinguishes pseudo-Cushing states from Cushing's syndrome with 95% diagnostic accuracy; a level greater than 7.5 μg/dL is required for the diagnosis of Cushing's syndrome. Measurement of salivary cortisol at bedtime or at midnight works just as well and is more convenient. However, the criteria for its interpretation differ, so each assay must be validated before it is used for this purpose.

Dexamethasone Suppression Tests

The dexamethasone suppression test is a simple screening test that takes advantage of the negative feedback effect of glucocorticoids to reduce ACTH (and hence serum cortisol). Dexamethasone 1 mg is given orally between 11:00 PM and midnight, and plasma cortisol is measured between 8:00 and 9:00 the next morning. The test has an 8% false-negative rate in patients with Cushing's disease and a 30% false-positive rate in chronic illness, obesity, psychiatric disorders, and normal individuals. As a result, Cushing's syndrome cannot be diagnosed by this test alone unless the result is extremely abnormal.

The 2-day, 2-mg dexamethasone suppression test discriminates patients with a pseudo-Cushing state if plasma cortisol end points of less than 1.4 or 2.2 μg/dL are used. Dexamethasone 500 μg is given orally every 6 hours for eight doses, and plasma cortisol is measured 2 hours after the last dose. The test has excellent sensitivity (90 to 100%) and specificity (97 to 100%) for discriminating Cushing's syndrome, but it is costly and requires excellent patient compliance. The immediate subsequent administration of CRH (1 μg/kg body weight intravenously) and the measurement of cortisol 15 minutes later increased the sensitivity and specificity to 100% in a small study of 58 patients, with values above 1.4 μg/dL indicating Cushing's syndrome. Although this combined dexamethasone-CRH test has high diagnostic accuracy, it has the same disadvantages as the 2-day dexamethasone suppression test and the added cost of CRH testing. Because of these drawbacks, these tests are usually reserved for patients with ambiguous or confusing results on other screening tests. CRH is available commercially (Acthrel), with Food and Drug Administration–approved labeling for the differential diagnosis of Cushing's syndrome. Its use in the dexamethasone-CRH test is an off-label use.

Any dexamethasone test may give false results in patients with abnormal metabolic clearance of the drug. Agents that induce the cytochrome P-450 CYP3A4 enzymes (alcohol, rifampin, phenytoin, phenobarbital) increase dexamethasone clearance, whereas renal or hepatic failure decreases it. Measurement of a dexamethasone level can determine whether its clearance has been altered.

Differential Diagnosis

The causes of endogenous Cushing's syndrome can be divided broadly into ACTH-dependent (80%) and ACTH-independent (20%) forms (Table 234-2). Hypercortisolism from autonomously functioning adrenal tumors suppresses ACTH, whereas in primary disorders of ACTH excess, the adrenal glands respond to ACTH. Plasma ACTH concentration distinguishes between these causes. ACTH is usually less than 10 pg/mL in primary adrenal disorders but is also suppressed by exogenous steroids, whether they are prescribed intentionally (iatrogenic Cushing's syndrome) or taken factitiously. Patients in the latter group often have had multiple surgical procedures and do not reveal that they are self-administering steroids. As a result, patients must be queried closely about exogenous steroid administration, recognizing that parenteral, inhaled, and topical steroids can all cause glucocorticoid excess. Patients with endogenous Cushing's syndrome and low ACTH concentrations undergo adrenal imaging to identify the site of adrenal abnormality. Nonautonomous adrenal tissue atrophies when ACTH support is subnormal. Because of this, the common ACTH-independent forms of Cushing's syndrome—adrenal adenoma and carcinoma—present as a unilateral adrenal mass, with atrophy of the adjacent and contralateral tissue on magnetic resonance imaging or computed tomography.

Bilateral forms of primary adrenal disease are rare and may present with small or large adrenal nodules. Primary pigmented nodular adrenal disease occurs primarily in children and young adults and is characterized by small to normal-sized adrenal glands containing small (<5 mm) black-brown cortical nodules. About half these patients have additional features, termed Carney's complex, which are often inherited in an autosomal dominant fashion. The clinical features of Carney's complex include myxomas of the skin, breast, and heart; spotty pigmentation, such as lentigines and blue nevi; and other endocrine overactivity, such as acromegaly and testicular tumors. Some of these patients have mutations leading to a truncated form of protein kinase A regulatory 1α subunit. The resultant increase in protein kinase A activation by cyclic adenosine monophosphate presumably allows tumor formation. Bilateral nodular hyperplasia with Cushing's syndrome can occur in the setting of McCune-Albright syndrome, mostly in infants. Massive macronodular adrenal disease generally presents after age 40 years with huge adrenal glands and aberrant expression of "illicit" receptors for various ligands (gastric inhibitory polypeptide, β-adrenergic, vasopressin), which presumably mediates autonomous cortisol production.

A normal or elevated plasma ACTH level (>15 pg/mL; 3.3 pmol/L) is consistent with an ACTH-producing tumor. Intermediate ACTH concentrations between 5 and 15 pg/mL (1.1 to 3.3 pmol/L) are not diagnostic. In these patients, suboptimal cortisol responses to CRH stimulation may identify the minority of cases of ACTH-independent Cushing's syndrome with borderline basal ACTH values. In addition, a suppressed plasma DHEA-S value supports the diagnosis of an ACTH-independent disorder.

Cushing's disease, an ACTH-secreting pituitary adenoma, is the most common cause of Cushing's syndrome. It is more common in women than in men (6:1 ratio), with a mean age at onset in the fourth decade. ACTH also may be secreted ectopically by a variety of neuroendocrine tumors, as shown in Table 234-3 (see also Chapter 186).

Pituitary magnetic resonance imaging shows a tumor in only about 40 to 50% of patients with Cushing's disease, but it is obtained routinely in patients with ACTH-dependent disease to exclude a macroadenoma or abnormal anatomy before petrosal sinus sampling or surgery. Biochemical tests must be used to distinguish among the ACTH-dependent causes of Cushing's syndrome, and they must be performed after a 6- to 8-week period of sustained hypercortisolism sufficient to suppress normal corticotrope function.

TABLE 234-2 ETIOLOGY OF CUSHING'S SYNDROME

EXOGENOUS	ENDOGENOUS
Most common cause of Cushing's syndrome	ACTH independent—autonomous adrenal activation (20% of all cases)
Glucocorticoid or ACTH driven	Adrenal adenoma (40-50%)
May be factitious or iatrogenic	Adrenal carcinoma (40-50%)
	Primary pigmented nodular adrenal disease
	McCune-Albright syndrome
	Massive macronodular adrenal disease
	Gastric inhibitory polypeptide or food induced
	ACTH dependent—adrenal activation by excessive ACTH (80% of all cases)
	Corticotrope adenoma (80%)
	Ectopic ACTH secretion (20%)
	Ectopic CRH secretion (rare)

ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone.

TABLE 234-3 THE INCIDENCE AND TYPES OF TUMORS CAUSING THE SYNDROME OF ECTOPIC ACTH SECRETION

TUMOR TYPE	PERCENTAGE
Carcinoma of lung (small cell or oat cell)	19-50
Carcinoid of bronchus	2-37
Carcinoid of thymus	8-12
Pancreatic tumors, carcinoid and islet cell	4-12
Pheochromocytoma, neuroblastoma, ganglioma, paraganglioma	5-12
Medullary carcinoma of the thyroid	0-5
Miscellaneous*	<1

*Miscellaneous tumors reported to secrete ACTH in 1 to 10 cases include carcinoma of the ovary, prostate, breast, thyroid, kidney, salivary glands, testes, gallbladder, esophagus, and appendix; gastric carcinoid and renal carcinoid; acute myeloblastic leukemia; melanoma; and cloacogenic carcinoma of the anal canal.
ACTH = adrenocorticotropic hormone.

Inferior petrosal sinus sampling is the best test to distinguish between a pituitary and an ectopic source of excess ACTH; worldwide, the overall sensitivity and specificity are about 94%. The test involves catheterization of a peripheral vein and the petrosal sinuses draining the pituitary gland, simultaneous measurement of ACTH levels at each site before and after administration of CRH, and calculation of the central-to-peripheral ACTH ratio at each time point. Ratios of more than 2 before CRH administration or more than 3 after CRH administration are consistent with Cushing's disease.

Although it is accurate in experienced hands, inferior petrosal sinus sampling carries a small risk of stroke, is expensive, and is not widely available. Other tests, such as the CRH test and the 8-mg dexamethasone suppression test, may be useful if both responses indicate Cushing's disease. In this setting, the likelihood of ectopic ACTH secretion is low. However, the diagnosis is not clear if both responses are negative or if they are mixed.

If endocrine tests suggest ectopic ACTH secretion, imaging is obtained to localize the tumor (see also Chapter 186). Computed tomography and magnetic resonance imaging of the chest are the best initial screens because these tumors are most often in the thoracic cavity. Octreotide scintigraphy is a useful adjunctive test. Measurement of serum calcitonin and gastrin and measurement of plasma or urine catecholamines may identify medullary carcinoma of the thyroid, gastrinoma, and pheochromocytoma. The process can be repeated every 6 to 12 months; tumors that make ACTH ectopically have a spectrum of malignant potential, and annual screening should continue, regardless of treatment for hypercortisolism.

TREATMENT

Surgical Therapy

The optimal treatment of Cushing's syndrome is surgical resection of the lesion that is producing excessive ACTH or cortisol. In ACTH-dependent Cushing's syndrome, if this is unsuccessful or cannot be done, bilateral adrenalectomy is an option. Medical therapy can also be used for patients with occult ectopic ACTH-secreting tumors and in combination with pituitary irradiation to treat Cushing's disease.

Transsphenoidal resection of a microadenoma is the optimal therapy for a patient with Cushing's disease, with up to a 90% chance of cure in the hands of an experienced neurosurgeon. A successful outcome is less likely if the initial surgery is not curative, in cases of recurrence, and for macroadenomas. Controversy exists about the criteria for remission; although a low postoperative cortisol level is encouraging, it does not preclude later recurrence. If recurrence develops, additional resection or alternative therapy should be considered.

Radiation Therapy

Radiation therapy to the pituitary gland, with adjunctive medical therapy to normalize cortisol levels, is a good option for Cushing's disease patients who cannot undergo surgery, for those in whom the risk of Nelson's syndrome is deemed great, and for those with recurrent disease. This is usually delivered in 200-rad daily increments to a total dose of 4500 cGy. The disadvantage of radiotherapy is the length of time needed for a full response—up to 10 years—and the possibility of hypopituitarism. There is less experience with high-energy radiosurgery, such as the gamma knife, which has the advantage of requiring only one or two treatments. Adrenalectomy is preferable if rapid normalization of hypercortisolism is needed, and this option may be chosen by patients who have concerns about radiation-induced hypopituitarism and loss of reproductive function.

Medical Therapy

Combination Surgical and Medical Therapy

Medical therapy alone is rarely appropriate for Cushing's disease because it requires close monitoring and adjustment of dose and has low long-term efficacy.

Patients with ectopic ACTH secretion can be cured if the tumor can be removed and is not metastatic. Otherwise, adrenalectomy or medical therapy is chosen. Adrenalectomy is appropriate when the patient cannot tolerate the cost, medical toxicity, or adverse psychological effects of long-term medical therapy and monitoring; if the patient requires rapid correction of hypercortisolism; or if maximal daily doses of ketoconazole (1600 mg) and metyrapone (2 g) given in combination do not render the patient eucortisolemic.

Nonmalignant primary adrenal causes of Cushing's syndrome are cured by resection of the abnormal tissue. Laparoscopy is the preferred approach. Surgery is the mainstay in the treatment of adrenal cancer; multiple operations may be needed to resect primary lesions, local recurrences, and hepatic, thoracic, and intracranial metastases. Adjuvant adrenolytic therapy with mitotane may provide a chemotherapeutic benefit.

Mineralocorticoid Excess

DIAGNOSIS

Patients with mineralocorticoid excess often have few clinical symptoms apart from fatigue and muscle weakness or cramps related to hypokalemia. Most often the condition is suspected because of hypertension, especially if it occurs at an early age in association with spontaneous hypokalemia or is difficult to control. Mineralocorticoid excess can result from primary adrenal disease, in which aldosterone (or another mineralocorticoid) is produced autonomously (and renin levels are low), or it may be due to nonadrenal causes as a result of elevated renin values, which stimulate aldosterone secretion. The latter situations include states of contracted arterial volume, such as congestive heart failure or cirrhosis with ascites, decreased renal arterial blood flow, and tumor production of renin (Table 234-4).

RENIN-INDEPENDENT MINERALOCORTICOID EXCESS

DIAGNOSIS

Although most of these conditions result from excessive aldosterone production by one or both adrenal glands, excessive production of other mineralocorticoids or constitutive activation of the renal sodium channel must be excluded. In these latter conditions, both aldosterone and renin values are low, resulting in the so-called syndrome of apparent mineralocorticoid excess. In this setting, diagnostic information is obtained by history (licorice ingestion) or measurement of other mineralocorticoids (see Table 234-4).

The diagnosis of primary hyperaldosteronism rests on the demonstration of an increased plasma aldosterone value greater than 15 pg/mL with an increased ratio (>20) of aldosterone to plasma renin activity. Salt loading, by one of four possible tests, is used to confirm primary hyperaldosteronism by demonstrating a lack of aldosterone suppression. The plasma aldosterone concentration should decrease to less than 5 ng/dL in normal individuals.

TABLE 234-4 CAUSES OF MINERALOCORTICOID EXCESS

PRIMARY HYPERALDOSTERONISM: HIGH ALDOSTERONE, LOW RENIN
Aldosterone-producing adenomas (30-50%)
Bilateral zona glomerulosa hyperplasia
Familial hyperaldosteronism
Type 1: glucocorticoid-remediable hyperaldosteronism—this results from formation of a chimeric gene containing the regulator portion of 11β-hydroxylase (normally regulated by ACTH) and the synthetic region of aldosterone synthase; as a result, ACTH stimulates aldosterone synthase and hence aldosterone production
Type 2: adrenal adenomas or hyperplasia expressed in a familial pattern
Aldosterone-producing adrenal carcinoma
Ectopic aldosterone secretion (rare): kidney, ovary
SECONDARY HYPERALDOSTERONISM: HIGH ALDOSTERONE, HIGH RENIN
Renovascular hypertension and aortic stenosis
Diuretic use
Renin-secreting tumors
Severe cardiac failure
APPARENT MINERALOCORTICOID EXCESS: LOW ALDOSTERONE, LOW RENIN
Licorice ingestion: licorice (candy or flavored tobacco) containing glycyrrhetinic acid (or similar compounds such as carbenoxolone) inhibits renal 11β-hydroxysteroid dehydrogenase type 2, reducing cortisol conversion to cortisone and enabling cortisol to act as an endogenous mineralocorticoid
Severe hypercortisolism: similar in mechanism to licorice ingestion; very high cortisol levels are thought to overwhelm the ability of 11β-hydroxysteroid dehydrogenase type 2 to convert cortisol to cortisone in the kidney; cortisol itself then acts as a potent mineralocorticoid
Liddle's syndrome: mutation of the β or γ subunit of the collecting tubule sodium channel leads to a constitutive increase in sodium reabsorption and potassium excretion
11β-Hydroxylase deficiency form of congenital adrenal hyperplasia: 11-deoxycortisol accumulates because of an inability to convert it to cortisol
17-Hydroxylase deficiency form of congenital adrenal hyperplasia: deoxycorticosterone and corticosterone are increased

Differential Diagnosis

Having made the diagnosis of aldosterone-dependent mineralocorticoid excess, one must differentiate between the two most common adrenal causes—hyperplasia and adenoma—after excluding potential rare causes of hyperaldosteronism. Glucocorticoid-suppressible hyperaldosteronism is a rare cause of aldosterone excess caused by a genetic swap of the promoter for *CYP11B1* (11β-hydroxylase) with that of *CYP11B2* (aldosterone synthase), forming a chimeric gene in which ACTH stimulates aldosterone synthase. Glucocorticoid-suppressible hyperaldosteronism should be suspected in the setting of familial hyperaldosteronism, particularly if there is a history of cardiovascular accidents at an early age. Serum 18-hydroxycortisol and 18-oxocortisol concentrations are elevated in glucocorticoid-suppressible hyperaldosteronism, and gene testing confirms the diagnosis (see *http://www.brighamandwomens.org/gra*).

For the more common conditions, adrenal computed tomography scans may show nonfunctioning nodules and falsely suggest an adenoma. The responses to physiologic maneuvers, such as upright posture, and salt loading with oral or intravenous sodium tend to be preserved in patients with hyperplasia, but there is significant overlap among groups of patients. The best diagnostic test involves the measurement of cortisol and aldosterone in bilateral adrenal venous effluent and a peripheral vein before and during an ACTH infusion. Cortisol is used to evaluate catheter placement in the adrenal veins, as levels from the two sides should be similar. When an adenoma is present, the aldosterone-to-cortisol ratio on one side is usually at least five-fold greater than the other, which may be similar to the periphery, indicating suppression. Bilateral hyperplasia tends to produce similar values on each side.

TREATMENT Rx

Treatment of primary hyperaldosteronism includes laparoscopic resection for adenomas. Afterward, hypokalemia generally resolves, but hypertension persists in up to 65% of patients. The mineralocorticoid antagonist spironolactone or amiloride is used to treat patients unable to undergo surgery or those with hyperplasia. Antihypertensive agents are continued. Eplerenone is a newer, more selective mineralocorticoid antagonist (with fewer side effects of sexual dysfunction and gynecomastia compared with spironolactone). It is currently approved by the Food and Drug Administration for the treatment of hypertension and congestive heart failure.

Androgen Excess

DEFINITION

Women with excess circulating androgens or increased sensitivity to androgens present with complaints of hirsutism, acne, and anovulation or infertility. When testosterone is secreted in great excess, women may virilize and exhibit a deepened voice, clitorimegaly, masculinized body habitus, and alopecia.

DIAGNOSIS

The adrenal causes of hyperandrogenism—congenital adrenal hyperplasia, Cushing's disease, adrenal cancer, and androgen-producing adrenal adenoma—are uncommon. Most women have no clear-cut cause (idiopathic hirsutism) or polycystic ovary syndrome. Rarely, androgen-secreting ovarian tumors, hyperprolactinemia, glucocorticoid resistance, or exogenous drugs cause hyperandrogenism. Patients with an adrenal source of hyperandrogenism usually have increased serum levels of DHEA-S or androstenedione, in contrast to the testosterone excess that is more typical of an ovarian source. DHEA and DHEA-S are weak androgens that can be converted locally to testosterone in the hair follicles. Because DHEA and DHEA-S levels decline throughout adult life, these values must be interpreted within age-specific normal ranges. Although a tumor is more likely if DHEA-S is greater than 500 μg/dL or testosterone is greater than 200 ng/mL, it is not excluded at lower levels.

Imaging identifies nearly all adrenal tumors but may miss a small intraovarian one. UFC may be elevated in patients with virilizing adrenal carcinoma or Cushing's disease (see earlier) and in those with glucocorticoid resistance. By contrast, androgen-secreting adrenal adenomas do not have glucocorticoid excess. In women suspected of having nonclassic forms of congenital adrenal hyperplasia, precursor and product hormones should be measured before and after ACTH to confirm the diagnosis.

TREATMENT Rx

Treatment of adrenal causes of hyperandrogenism varies according to the disorder. Tumors are resected. Late-onset congenital adrenal hyperplasia is treated by glucocorticoids to normalize ACTH and hence androgen levels (typically, dexamethasone 0.125 to 0.375 mg at bedtime).

Mixed Mineralocorticoid and Glucocorticoid Deficiency: Adrenal Insufficiency

PATHOBIOLOGY

Primary Adrenal Insufficiency

Autoimmune Destruction

Autoimmune destruction is the most common cause of primary adrenal insufficiency in industrialized countries and may occur alone or, rarely, in association with autoimmune polyglandular syndromes. These syndromes tend to present either in childhood (type 1), in association with hypoparathyroidism and mucocutaneous candidiasis, or in adulthood (type 2), in association with insulin-dependent diabetes mellitus, autoimmune thyroid disease, alopecia areata, and vitiligo. The glands are small on imaging.

Adrenoleukodystrophy

Adrenoleukodystrophy, a rare (1 in 25,000) X-linked condition, is characterized by a deficiency of peroxisomal membrane adrenoleukodystrophy protein, which transports activated acyl-coenzyme A derivates into the peroxisomes, where they are shortened by β-oxidation. This deficiency results in the accumulation of very long chain fatty acids in the central nervous system and other tissues and increased plasma $C_{26:0}$ fatty acids. Incomplete penetrance of the genetic defect and variable accumulation of very long chain fatty acids in the adrenal gland, brain, testis, and liver account for the clinical phenotypes, which differ by age and presentation.

Infection

Infections cause about 15% of primary adrenal insufficiency. Typical infections include tuberculosis and systemic fungal diseases (histoplasmosis, coccidioidomycosis, blastomycosis), in which the adrenal tissue is replaced by caseating granulomas. End-stage AIDS-associated opportunistic infections, such as cytomegalovirus or *Mycobacterium avium-intracellulare,* may reduce adrenal function. Adrenal tissue may be replaced by bilateral metastases (most commonly primary carcinoma of the lung, breast, kidney, or gut) or primary lymphoma, although adrenal insufficiency is uncommon. Intraadrenal hemorrhage may also lead to insufficient steroidogenesis. Hemorrhage typically occurs in a stressed, hospitalized patient receiving long-term prophylactic anticoagulation and is often accompanied by back pain. The adrenal glands tend to be large on imaging.

Congenital Adrenal Hyperplasias

The congenital adrenal hyperplasias are a disparate group of diseases caused by a genetic deficiency of one of the enzymes needed for adrenal steroidogenesis. Patients with nearly complete deficiency of an enzyme required for cortisol synthesis present in infancy with adrenal insufficiency and salt-wasting crisis. This is most problematic in patients with mutation of the 21-hydroxylase (*CYP21*) or 11β-hydroxylase (*CYP11B1*) gene. The increase in ACTH levels caused by cortisol deficiency drives the intact steroidogenic pathways so that there is excessive production of the steroids just proximal to the enzymatic block—17-hydroxyprogesterone and 11-deoxycortisol, respectively, in 21-hydroxylase and 11β-hydroxylase deficiency. The increased levels of precursor steroids enable increased adrenal androgen synthesis, so that severely affected girls may be virilized in utero. Girls and women with nonclassic congenital adrenal hyperplasia present later. They have greater enzyme activity, so that cortisol production is adequate, but increased ACTH levels cause hyperandrogenism.

Rare Causes

Other rare causes of primary adrenal insufficiency include ACTH resistance, congenital adrenal hypoplasia, Smith-Lemli-Opitz syndrome, and amyloidosis. Patients with primary adrenal insufficiency should undergo further evaluation to determine its cause (Table 234-5). Detection of antibodies to 21-hydroxylase identifies nearly all patients with idiopathic disease. In a male

TABLE 234-5 CAUSES OF ADRENAL INSUFFICIENCY AND ANCILLARY TESTS

SPECIFIC CAUSES	SUGGESTIVE CLINICAL FEATURES	USEFUL ANCILLARY TESTS
Primary adrenal insufficiency	Hyperpigmentation, orthostatic hypotension	Hyperkalemia, elevated ACTH
Idiopathic autoimmune destruction	Most common cause (80%) in developed countries; with or without other endocrinopathies, as below	Antibodies to 21-hydroxylase are present; on imaging, adrenal glands are small
Polyglandular failure type 1	Hypoparathyroidism, mucocutaneous candidiasis, vitiligo; age <20 yr	
Polyglandular failure type 2	Insulin-dependent diabetes, autoimmune thyroid disease, alopecia areata, vitiligo; age >40 yr	On imaging, adrenal glands are small
Infections: tuberculosis, systemic fungal diseases, AIDS-associated opportunistic infections (e.g., cytomegalovirus)	15% of patients in U.S. series	Adrenal glands tend to be large on CT and may be calcified
Space-occupying adrenal lesions	Metastases from carcinoma of lung, breast, kidney, gut; lymphoma or hemorrhage (heparin use)	Abnormal shape of adrenal glands on CT; evidence of hemorrhage
Bilateral adrenalectomy or treatment with steroidogenesis inhibitors		Ketoconazole, mitotane, aminoglutethimide, trilostane, and metyrapone reduce cortisol levels
Adrenoleukodystrophy	X-linked—screen males; in childhood, cognitive and gait disturbances; in adults, spastic paraparesis	Deficiency of peroxisomal very long chain acyl-coenzyme A synthetase leads to elevated plasma $C_{26:0}$ fatty acid levels
Secondary adrenal insufficiency		
Suppression of the adrenal axis by exogenous or endogenous glucocorticoids	Medication history; history of Cushing's syndrome	Adrenal glands are small on imaging
Structural lesions of the hypothalamus or pituitary gland (tumors, destruction by infiltrating disorders, x-irradiation, and lymphocytic hypophysitis)	Other pituitary deficiencies	Adrenal glands are normal or small on imaging; MRI or CT may show pituitary or hypothalamic lesion
Isolated ACTH deficiency		
Head trauma		

ACTH = adrenocorticotropic hormone; AIDS = acquired immunodeficiency syndrome; CT = computed tomography; MRI = magnetic resonance imaging.

with negative results, measurement of very long chain fatty acids will detect adrenoleukodystrophy. Taken together, this strategy identifies the cause in nearly all adult patients with idiopathic adrenal insufficiency. Patients with autoimmune disease should be tested for other endocrine deficiencies, and those with adrenoleukodystrophy require neurologic evaluation.

Secondary Adrenal Insufficiency

Suppression of the Pituitary Axis

Suppression of the hypothalamic-pituitary-adrenal axis by exogenous or endogenous glucocorticoids is the most common cause of secondary adrenal insufficiency. This phenomenon depends on the dose, duration, and schedule of glucocorticoid administration. Thus, adrenal suppression is unusual with "replacement" doses of glucocorticoid that are roughly equivalent to daily production (e.g., total daily doses of 20 mg hydrocortisone, 5 mg prednisone, or 0.3 to 0.5 mg dexamethasone). At higher doses, adrenal suppression is usually not seen until after 3 weeks of administration, and a single morning administration is less suppressive than are divided doses given during the day. When potentially suppressive doses of glucocorticoids are stopped, symptoms of adrenal insufficiency may occur within 48 hours, and the entire axis may not recover for up to 18 months. During this time, the patient should receive replacement glucocorticoid treatment and/or supplemental steroids at times of physiologic stress, depending on the degree of impairment (see later).

Lesions of the Hypothalamus or Pituitary

Secondary adrenal insufficiency also may result from structural lesions of the hypothalamus or pituitary gland that interfere with CRH production or transport or with corticotrope function. These causes include tumors, trauma, destruction by infiltrating disorders, x-irradiation, and lymphocytic hypophysitis. In general, these are not reversible conditions. Patients with secondary adrenal insufficiency not ascribed to glucocorticoid use should undergo imaging of the pituitary and hypothalamus to exclude a structural or infiltrating lesion, as well as tests of other pituitary function to exclude additional deficiencies.

CLINICAL MANIFESTATIONS

The clinical presentation of adrenal insufficiency reflects the cause and duration of this uncommon condition. Primary adrenal insufficiency eventually destroys the entire adrenal cortex, with loss of both glucocorticoid and mineralocorticoid activity. By contrast, secondary adrenal insufficiency reflects an inability of the hypothalamic-pituitary unit to deliver CRH or ACTH, thus reducing trophic support to otherwise normal glands. As a result, only cortisol production decreases, because mineralocorticoid production is not very ACTH dependent.

The characteristic clinical presentation of acute primary adrenal insufficiency includes orthostatic hypotension, agitation, confusion, circulatory collapse, abdominal pain, and fever. These features are most likely to be caused by hemorrhage, metastasis, or acute infection and can lead to death if not treated. In contrast, the typical history and clinical findings of chronic primary adrenal insufficiency include a longer history of malaise, fatigue, anorexia, weight loss, joint and back pain, and darkening of the skin (especially in the creases of the hands, extensor surfaces, recent scars, buccal and vaginal mucosa, and nipples). Patients may crave salt and may develop unusual food preferences, such as drinking the brine from pickles. Associated biochemical features for both presentations include hyponatremia, hypoglycemia, hyperkalemia, unexplained eosinophilia, and mild prerenal azotemia.

Chronic secondary adrenal insufficiency presents in a similar way, but without hyperpigmentation or mineralocorticoid abnormalities.

DIAGNOSIS

Biochemical testing confirms the diagnosis of adrenal insufficiency. A morning serum cortisol measurement is an inexpensive but relatively insensitive screening test for adrenal insufficiency in patients who are not acutely ill. Adrenal insufficiency is virtually excluded by values greater than 19 μg/dL (524 nmol/L) and is likely if the value is less than 3 μg/dL (83 nmol/L). However, because of the pulsatile nature of cortisol secretion, both healthy individuals and patients with adrenal insufficiency may have results in the intermediate range of 3 to 19 μg/dL, requiring additional evaluation.

Patients with acute adrenal insufficiency should be evaluated for sepsis or for hemorrhage or metastasis in the adrenal glands. Imaging of the glands and other testing may reveal an infectious cause. Individuals thought to have congenital adrenal hyperplasia should undergo additional measurement of ACTH-stimulated precursor and product hormones to delineate the site of enzymatic deficiency. In acute adrenal insufficiency, a serum cortisol value is generally inappropriately normal or subnormal in the setting of hypotension (in which cortisol values are usually well above 18 μg/dL). There is controversy about the best test for the diagnosis of chronic adrenal insufficiency. Many use the cortisol response to exogenous ACTH as a "gold standard" test of adrenal steroidogenic ability. In the classic test, 250 μg of ACTH (1-24, cosyntropin) is given intravenously or intramuscularly at any time of day. This supraphysiologic dose of ACTH is a maximal stimulus to the adrenal gland, so that the serum cortisol level measured 30 to 60 minutes later is greater than 18 μg/dL. Lower values indicate adrenal insufficiency. Insulin-induced

hypoglycemia, metyrapone stimulation, and lower doses of ACTH stimulation have been proposed as better tests for patients with mild or recent secondary adrenal insufficiency, who may respond to pharmacologic doses of ACTH. None of these is an ideal test. Also, because there is no commercial formulation of ACTH for lower-dose tests, the product must be diluted and delivered on site, leading to concerns about the accuracy of the administered dose and the validity of results. Metyrapone has limited availability in the United States.

Cerebral adrenoleukodystrophy, presenting in childhood, is characterized by cognitive and gait disturbances; the adult form, adrenomyeloneuropathy, is characterized by spinal cord and peripheral nerve demyelination. In both forms, the accumulation of very long chain fatty acids in the adrenal cortex alters membrane function and inhibits signal transduction by ACTH. Because a substantial minority of patients in both groups present first with adrenal insufficiency, boys and young men with adrenal insufficiency should be screened for adrenoleukodystrophy.

Differential Diagnosis

Primary and secondary adrenal insufficiency can be distinguished by measuring plasma ACTH. In primary adrenal insufficiency, ACTH levels are generally above the normal range and may exceed the normal range before the cortisol response to exogenous ACTH stimulation is subnormal. In addition, hyperkalemia and elevated renin values are characteristic of primary but not of secondary adrenal insufficiency.

TREATMENT Rx

Acute Adrenal Insufficiency

In suspected acute adrenal insufficiency, hydrocortisone is the treatment of choice because it has both glucocorticoid and mineralocorticoid activity. Treatment with intravenous saline for volume expansion, glucose for hypoglycemia, and intravenous hydrocortisone (100 mg) is started immediately after placement of an intravenous line and withdrawal of blood for documentation of the cortisol value.

Chronic Adrenal Insufficiency

Therapy for chronic adrenal insufficiency aims to provide the physiologic replacement of steroids. Glucocorticoid replacement is achieved by administering 10 to 12 mg/m^2 of hydrocortisone daily in one or two oral doses, attempting to mimic the physiologic diurnal variation of cortisol concentrations. Hydrocortisone offers the advantage of multiple-dose tablets, which allows fine adjustment and splitting of the daily dose. Ideally, the morning dose is given as soon after waking as possible; for individuals who feel extremely fatigued in the morning before the agent is absorbed, a strategy of taking the medication 30 minutes before arising may be helpful. Although many patients do well with a single dose, others complain of pronounced fatigue in the afternoon and evening. For them, a split-dose regimen, in which about one third of the daily dose is given around 4:00 PM, may be useful.

Other glucocorticoids may be used for daily replacement therapy. Prednisone, 5 to 7.5 mg daily, has the advantage of a long half-life and may be particularly helpful in patients with afternoon or evening fatigue. Dexamethasone may be used, but because of variable interindividual metabolism, it is difficult to recommend a specific replacement dose; in addition, few options for fixed doses are available, so it is difficult to adjust the dose.

Patients with primary adrenal insufficiency should be encouraged to salt their food and not to limit salt intake. Nearly all patients also require a mineralocorticoid, such as fludrocortisone 50 to 300 µg/day. The dose is adjusted until plasma renin activity is normal. If a mineralocorticoid is not given, the dose of hydrocortisone or other steroid with mineralocorticoid activity is often mistakenly increased to reduce hyperkalemia or salt craving. The problem with this approach is that the amount of glucocorticoid increases beyond physiologic replacement, and the patient becomes cushingoid.

Patients with primary adrenal insufficiency also have decreased serum DHEA levels. Controversy exists regarding its replacement. A recent meta-analysis concluded that there is insufficient evidence to support its routine use in these patients.

Ensuring Proper Dosing

Education of the Patient

All patients receiving chronic glucocorticoid replacement therapy should be instructed that they must take the glucocorticoids as prescribed and that failure to take or absorb the medication will lead to adrenal crisis and possibly death. They should wear medical information bracelets or necklaces that identify this requirement. It is important to educate patients and their families about glucocorticoid adjustment during physiologic stress conditions, including the emergency administration of intramuscular glucocorticoid by means of a kit containing prefilled syringes with injectable steroid.

Dosing for Stress

The daily oral glucocorticoid dose is usually doubled for "stressful" physiologic conditions such as fever, nausea, and diarrhea, although there are few data to support this strategy. In addition, this practice may lead to chronic overmedication by the patient because of a liberal interpretation of what constitutes physical stress. Thus, education regarding when and how to change the dose of steroid should be reinforced periodically, preferably with written material, and the dangers of excessive steroid use should be emphasized. If the patient is vomiting, has severe diarrhea, or has collapsed, intramuscular glucocorticoids should be given before transport to a medical facility.

The glucocorticoid dose is increased in proportion to the amount of stress. Thus, during maximally stressful situations (e.g., adrenal crisis, major surgery, trauma, labor and delivery), the daily hydrocortisone dose is 100 to 300 mg (few data support the need for this pharmacologic rather than physiologic replacement dose, but the safety of not following this practice has not been established). The dose is usually tapered by 50% per day as long as the patient is clinically stable. For more moderate stress, such as that of cholecystectomy, 75 to 100 mg hydrocortisone is given on the day of surgery, and the dose is tapered more rapidly. Patients undergoing minimal stress, such as tooth extraction or short operative orthopedic procedures, may not require any additional supplementation.

Clinical Assessment to Ensure Proper Dosing

Clinical assessment is the best way to judge whether the glucocorticoid dose is correct. Symptoms of adrenal insufficiency improve with adequate therapy. The development of cushingoid features or osteopenia suggests frank or subtle overreplacement, respectively, and the presence of adrenal insufficiency symptoms (fatigue, anorexia, weight loss) suggests underreplacement. In women, DHEA replacement increases testosterone levels, so that hirsutism, acne, or other signs of androgen excess may suggest overreplacement. In primary adrenal insufficiency, adequate hormone replacement results in plasma ACTH levels that decrease but remain elevated, in the range of 100 to 200 pg/mL. Renin values, however, normalize completely and may be used to judge the adequacy of mineralocorticoid replacement. Although hydrocortisone is metabolized to cortisol, plasma cortisol values should not be used to monitor therapy because clearance from the blood stream is rapid, and circulating values are low for most of the day. UFC does not reflect adequate replacement; the increase in plasma cortisol levels after a single daily dose may exceed corticosteroid-binding globulin capacity, resulting in excessive urine levels and overestimation of integrated cortisol levels.

Mineralocorticoid Deficiency

DEFINITION

Hypoaldosteronism may be classified as a low-normal or a high renin state on the basis of plasma renin activity after 4 hours of upright posture. Renin deficiency is the most common cause of hypoaldosteronism, occurring most often in older patients with mild, nonoliguric renal disease who often have insulin-dependent diabetes and potentially diabetic nephropathy. Indomethacin and other prostaglandin synthesis inhibitors, as well as autonomic dysfunction associated with prolonged bedrest, can also result in hyporeninemic hypoaldosteronism.

CLINICAL MANIFESTATIONS

There are few clinical features associated with mineralocorticoid deficiency; as a result, it is usually suspected when laboratory results reveal hyperkalemia, hyponatremia, and a mild metabolic alkalosis. If glucocorticoid deficiency is excluded, isolated hypoaldosteronism is established if the circulating level of aldosterone is inappropriately low.

High renin states of hypoaldosteronism include congenital adrenal hyperplasias with mineralocorticoid deficiency and primary adrenal insufficiency when it is treated with pure glucocorticoid replacement.

Treatment of these conditions involves sodium replacement with at least 10 mEq/kg/day, roughly equivalent to the 4 g of sodium chloride found in a typical diet in the United States. For individuals who do not maintain such a diet (often the elderly or the young), fludrocortisone can be given at the same doses used in primary adrenal insufficiency.

235 ADRENAL MEDULLA, CATECHOLAMINES, AND PHEOCHROMOCYTOMA

WILLIAM F. YOUNG JR.

ADRENAL MEDULLA AND CATECHOLAMINES

The adrenal medulla occupies the central portion of the adrenal gland. Adrenomedullary cells are called chromaffin cells (they stain brown with chromium salts). Chromaffin cells differentiate in the center of the adrenal gland in response to cortisol; some chromaffin cells also migrate to form paraganglia. The largest cluster of chromaffin cells outside the adrenal medulla is near the level of the inferior mesenteric artery and is referred to as the organ of Zuckerkandl.

The term *catecholamine* refers to substances that contain catechol (*o*-dihydroxybenzene) and a side chain with an amino group—the catechol nucleus (Fig. 235-1). Epinephrine is synthesized and stored in the adrenal medulla and released into the systemic circulation. Norepinephrine is synthesized and stored not only in the adrenal medulla but also in the peripheral sympathetic nerves. Dopamine, the precursor of norepinephrine, is found in the adrenal medulla and peripheral sympathetic nerves.

Catecholamines affect many cardiovascular and metabolic processes, including increasing the heart rate, blood pressure, myocardial contractility, and cardiac conduction velocity. Specific receptors mediate the biologic actions. The three types of adrenergic receptors are α, β, and DA; their receptor subtypes are α_1, α_2, β_1, β_2, β_3, DA_1, and DA_2. The α_1 subtype is a postsynaptic receptor that mediates vascular and smooth muscle contraction; stimulation causes vasoconstriction and increased blood pressure. The α_2 receptors are located on presynaptic sympathetic nerve endings and, when activated, inhibit the release of norepinephrine; stimulation causes suppression in central sympathetic outflow and decreased blood pressure. Stimulation of the β_1 receptor causes positive inotropic and chronotropic effects on the heart, increased renin secretion in the kidney, and lipolysis in adipocytes as well as bronchodilation, vasodilation in skeletal muscle, glycogenolysis, and increased release of norepinephrine from sympathetic nerve terminals. The β_3 receptor regulates energy expenditure and lipolysis. DA_1 receptors are localized to the cerebral, renal, mesenteric, and coronary vasculature; stimulation causes vasodilation in these vascular beds. DA_2 receptors are presynaptic and localized to sympathetic nerve endings, sympathetic ganglia, and brain; stimulation inhibits the release of norepinephrine, inhibits ganglionic transmission, and inhibits prolactin release.

Catecholamines are synthesized from tyrosine by a process of hydroxylation and decarboxylation (see Fig. 235-1). Tyrosine is derived from ingested food or synthesized from phenylalanine in the liver, and it enters neurons and chromaffin cells by active transport. Tyrosine is converted to 3,4-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase, the rate-limiting step in catecholamine synthesis. α-Methyl-*p*-tyrosine (metyrosine) is a tyrosine hydroxylase inhibitor that may be used therapeutically in patients with catecholamine-secreting tumors. Aromatic L-amino acid decarboxylase catalyzes the decarboxylation of dopa to dopamine. Dopamine is actively transported into granulated vesicles to be hydroxylated to norepinephrine by the dopamine β-hydroxylase. These reactions occur in the synaptic vesicle of adrenergic neurons and the chromaffin cells of the adrenal medulla. In the adrenal medulla, norepinephrine is released from the granule into the cytoplasm, where phenylethanolamine *N*-methyltransferase converts it to epinephrine. Expression of phenylethanolamine *N*-methyltransferase is regulated by glucocorticoids. Thus, catecholamine-secreting tumors that secrete primarily epinephrine are localized to the adrenal medulla. In normal adrenal medullary tissue, approximately 80% of the catecholamine released is epinephrine.

The biologic half-life of circulating catecholamines is between 10 and 100 seconds. Thus, plasma concentrations of catecholamines fluctuate widely. Catecholamines are removed from the circulation by either reuptake by sympathetic nerve terminals or metabolism through two enzyme pathways (see Fig. 235-1), followed by sulfate conjugation and renal excretion. Almost 90% of catecholamines released at sympathetic synapses are taken up locally by the nerve endings (uptake 1). Uptake 1 can be blocked by cocaine, tricyclic antidepressants, and phenothiazine. Extraneuronal tissues also take up catecholamines (uptake 2). Most of these catecholamines are metabolized by catechol-*O*-methyltransferase. Metanephrine and normetanephrine are oxidized by monoamine oxidase to vanillylmandelic acid by oxidative deamination. Monoamine oxidase may also oxidize epinephrine and norepinephrine to 3,4-dihydroxymandelic acid, which is then converted by catechol-*O*-methyltransferase to vanillylmandelic acid. In the storage vesicle, norepinephrine is protected from metabolism by monoamine oxidase. Monoamine oxidase and catechol-*O*-methyltransferase metabolize dopamine to homovanillic acid (see Fig. 235-1).

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

DEFINITION

Catecholamine-secreting tumors that arise from chromaffin cells of the adrenal medulla and the sympathetic ganglia are referred to as pheochromocytomas and extra-adrenal catecholamine-secreting paragangliomas, respectively. Because the tumors have similar clinical presentations and are treated with similar approaches, many clinicians use the term *pheochromocytoma* to refer to both entities. However, the distinction between pheochromocytoma and paraganglioma is an important one because there are differences in the risk for associated neoplasms, risk for malignant transformation, and type of genetic testing that should be considered.

EPIDEMIOLOGY

Catecholamine-secreting tumors are rare; the annual incidence is 2 to 8 cases per million people. Nevertheless, it is important to suspect, confirm, localize, and resect these tumors. The associated hypertension is curable with surgical removal of the tumor, a risk of lethal paroxysm exists, and at least 10% of the tumors are malignant. Fifteen percent to 20% of cases are familial, so detection of this tumor in the proband may result in early diagnosis in other family members.

PATHOBIOLOGY

Genetics

Approximately 15 to 20% of patients with catecholamine-secreting tumors have germline mutations (inherited mutations present in all cells of the body) in genes associated with genetic disease. Hereditary catecholamine-secreting tumors typically present at a younger age than sporadic neoplasms do. Sporadic pheochromocytoma is typically diagnosed on the basis of symptoms or incidental discovery on computed imaging, whereas syndromic pheochromocytoma is frequently diagnosed earlier in the course of disease because of biochemical surveillance or genetic testing.

Multiple Endocrine Neoplasia

Multiple endocrine neoplasia (MEN) type 2a is an autosomal dominant disorder (Chapters 239 and 254). The phenotype includes adrenal pheochromocytoma in 50% (usually bilateral and may be asynchronous), medullary

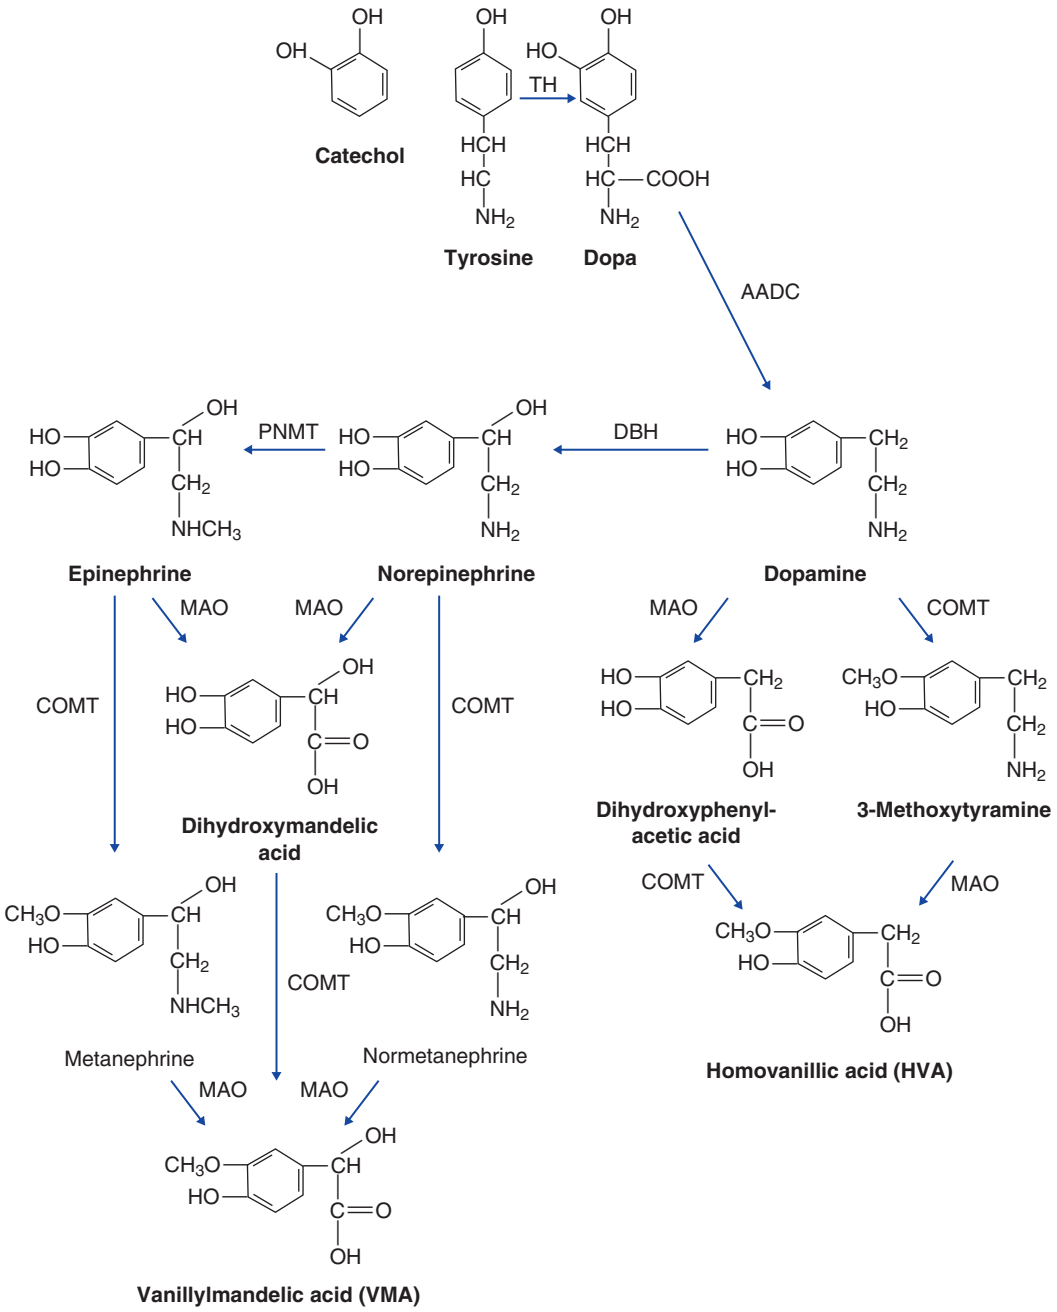

FIGURE 235-1. Biosynthetic and metabolic pathways for catecholamines. The term *catecholamine* comes from the catechol (*o*-dihydroxybenzene) structure and a side chain with an amino group—the catechol nucleus *(top left)*. Tyrosine is converted to 3,4-dihydroxyphenylalanine (dopa) in the rate-limiting step by tyrosine hydroxylase (TH). Aromatic L-amino acid decarboxylase (AADC) converts dopa to dopamine. Dopamine is hydroxylated to norepinephrine by dopamine β-hydroxylase (DBH). Norepinephrine is converted to epinephrine by phenylethanolamine *N*-methyltransferase (PNMT); cortisol serves as a cofactor for phenylethanolamine *N*-methyltransferase, and this is why epinephrine-secreting pheochromocytomas are almost exclusively localized to the adrenal medulla. Metabolism of catecholamines occurs through two enzymatic pathways. Catechol-*O*-methyltransferase (COMT) converts epinephrine to metanephrine and norepinephrine to normetanephrine by meta-*O*-methylation. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid by oxidative deamination. Monoamine oxidase also may oxidize epinephrine and norepinephrine to dihydroxymandelic acid, which is then converted by catechol-*O*-methyltransferase to vanillylmandelic acid. Dopamine is also metabolized by monoamine oxidase and catechol-*O*-methyltransferase, with the final metabolite homovanillic acid.

carcinoma of the thyroid in 100%, hyperparathyroidism in 20 to 30%, and cutaneous lichen amyloidosis in 5%. Medullary carcinoma of the thyroid is usually detected before pheochromocytoma. Numerous activating mutations in the *RET* proto-oncogene have been documented in persons with MEN type 2a (these are described in detail in Chapter 254).

MEN type 2b is also an autosomal dominant disorder, and it represents approximately 5% of all MEN type 2 cases. The phenotype includes pheochromocytoma in 50% (usually bilateral), medullary carcinoma of the thyroid in 100%, mucosal neuromas (typically involving the tongue, lips, and eyelids) in most patients, thickened corneal nerves, intestinal ganglioneuromatosis, and marfanoid body habitus. MEN 2b–associated tumors are caused by mutations in the RET protein's intracellular domain, as described in detail in Chapter 254.

Von Hippel-Lindau Disease

Von Hippel-Lindau (VHL) disease is an autosomal dominant disorder characterized by pheochromocytoma (frequently bilateral), paraganglioma (mediastinal, abdominal, pelvic), hemangioblastoma (involving the cerebellum, spinal cord, or brain stem), retinal angioma, clear cell renal cell carcinoma, pancreatic neuroendocrine tumor, endolymphatic sac tumor of the middle ear, serous cystadenoma of the pancreas, and papillary cystadenoma of the epididymis and broad ligament. Pheochromocytoma is reported to occur in about 10 to 20% of patients with VHL disease. Nearly 100% of patients have an identifiable gene mutation (VHL tumor suppressor gene). Certain missense mutations appear to be associated with a "pheochromocytoma only" presentation of VHL disease.

Neurofibromatosis

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder characterized by neurofibromas, multiple café au lait spots, axillary and inguinal freckling, iris hamartomas (Lisch nodules), bony abnormalities, central nervous system gliomas, pheochromocytoma and paraganglioma, macrocephaly, and cognitive deficits. The expression of these features is variable. Approximately 2% of patients with NF1 develop catecholamine-secreting tumors; in these patients, the tumor is usually a solitary benign adrenal pheochromocytoma, occasionally bilateral adrenal pheochromocytomas, and rarely an abdominal paraganglioma. Inactivating *NF1* mutations cause the disorder (NF1 tumor suppressor gene).

Familial Paraganglioma

Familial paraganglioma is an autosomal dominant disorder characterized by paragangliomas that are located in the head and neck, thorax, abdomen, and pelvis. Most cases of familial paraganglioma are caused by mutations in the succinate dehydrogenase (SDH; succinate:ubiquinone oxidoreductase) subunit genes (*SDHB, SDHC, SDHD, SDHAF2, SDHA*), which compose portions of mitochondrial complex II. Inactivating germline mutations in *SDHD* have been identified in multigenerational families with head and neck parasympathetic paragangliomas that are usually nonfunctional, and occasionally in those with adrenal pheochromocytoma. In patients with *SDHD* mutations, penetrance depends on the mutation's parent of origin. Hence, the disease does not manifest when the mutation is inherited from the mother but is highly penetrant when it is inherited from the father. This phenomenon is known as maternal imprinting. Missense mutations in *SDHC,* located on chromosome 1q21, have been reported in families with head and neck parasympathetic paragangliomas that are usually nonfunctional. Multiple cofactors are required for normal activity of the SDH complex, including flavin-adenine dinucleotide (FAD) in the SDH1subunit. FAD is covalently attached to Sdh1, and deletion of *SDHAF2* causes a complete loss of FAD cofactor attachment (flavination) of Sdh1. Germline loss-of-function mutations in the *SDHAF2* gene, located on chromosome 11q13.1, have been associated with disease in a family with hereditary paraganglioma. Like families with mutations in *SDHD*, those with mutations in *SDHAF2* also exhibit maternal imprinting and parasympathetic paragangliomas that typically occur in the head and neck. Inactivating mutations in the tumor suppressor gene *SDHB,* located on chromosome 1p35-36, are associated with paragangliomas in the abdomen, pelvis, and mediastinum. Adrenal pheochromocytomas may also be found in patients with *SDHB* mutations. Patients with *SDHB* mutations have an increased risk for malignant paraganglioma.

Genetic Testing

Genetic testing should be considered if a patient has one or more of the following: paraganglioma, bilateral adrenal pheochromocytomas, unilateral adrenal pheochromocytoma and a family history of pheochromocytoma or paraganglioma, onset of unilateral adrenal pheochromocytoma at a young age (before 30 years), or other clinical findings suggestive of one of the previously discussed syndromic disorders. Genetic testing can be complex; testing of one family member has implications for related individuals. Genetic counseling is recommended to help families understand the implications of genetic test results; to coordinate the testing of at-risk individuals; and to help families work through the psychosocial issues that may arise before, during, or after the testing process. A list of clinically approved molecular genetic diagnostic laboratories is available at *www.genetests.org*.

CLINICAL MANIFESTATIONS

Catecholamine-secreting tumors occur with equal frequency in men and women, primarily in the third, fourth, and fifth decades of life. These tumors are rare in children; when discovered, they may be multifocal and associated with a hereditary syndrome. When symptoms are present, they are due to the pharmacologic effects of excess concentrations of circulating catecholamines (Table 235-1). The resulting hypertension may be sustained (in approximately half of patients) or paroxysmal (in approximately a third of patients). The remaining patients have normal blood pressure. Episodic symptoms may occur in spells, or paroxysms, that can be extremely variable in presentation but typically include forceful heartbeat, pallor, tremor, headache, and diaphoresis. The spell may start with the sensation of a "rush" in the chest and a sense of shortness of breath, followed by a "pounding" heartbeat in the chest that typically progresses to a throbbing headache. Peripheral vasoconstriction with a spell results in cool or cold hands and feet and facial pallor. Increased sense of body heat and sweating are common symptoms that occur toward the end of the spell. Spells may be spontaneous or precipitated by postural change, anxiety, medications (e.g., metoclopramide, anesthetic agents), exercise, or maneuvers that increase intra-abdominal pressure (e.g., change in position, lifting, defecation, exercise, colonoscopy, pregnancy, trauma). Although the types of spells experienced by patients are highly variable, spells tend to be stereotypical for each patient. Spells may occur multiple times a day or as infrequently as once a month. The typical duration of a pheochromocytoma spell is 15 to 20 minutes, but it may be much shorter or last several hours. The clinician must recognize that most patients with spells do not have a pheochromocytoma.

Additional clinical signs of catecholamine-secreting tumors include hypertensive retinopathy, orthostatic hypotension, angina, nausea, constipation (megacolon may be the presenting symptom), hyperglycemia, diabetes mellitus, hypercalcemia, Raynaud's phenomenon, livedo reticularis, erythrocytosis, and mass effects from the tumor. Fasting hyperglycemia and diabetes mellitus are caused in part by the α-adrenergic inhibition of insulin release. Painless hematuria and paroxysmal attacks induced by micturition and defecation are associated with urinary bladder paragangliomas. Some of the co-secreted hormones that may dominate the clinical presentation include corticotropin (Cushing's syndrome), parathyroid hormone–related peptide (hypercalcemia), vasopressin (syndrome of inappropriate antidiuretic hormone secretion), vasoactive intestinal peptide (watery diarrhea), and growth hormone–releasing hormone (acromegaly) (see Table 235-1). Cardiomyopathy and congestive heart failure are the symptomatic presentations of pheochromocytoma that are most frequently unrecognized by clinicians. Cardiomyopathy, whether dilated or hypertrophic, may be totally reversible with tumor resection. Some patients with pheochromocytoma may be

TABLE 235-1 SIGNS AND SYMPTOMS ASSOCIATED WITH CATECHOLAMINE-SECRETING TUMORS

SPELL RELATED
Anxiety and fear of impending death
Diaphoresis
Dyspnea
Epigastric and chest pain
Headache
Hypertension
Nausea and vomiting
Pallor
Palpitation (forceful heartbeat)
Tremor
CHRONIC
Anxiety and fear of impending death
Cold hands and feet
Congestive heart failure—dilated or hypertrophic cardiomyopathy
Constipation
Diaphoresis
Dyspnea
Ectopic hormone secretion–dependent symptoms (e.g., CRH/ACTH, GHRH, PTH-RP, VIP)
Epigastric and chest pain
Fatigue
Fever
General increase in sweating
Grade II to IV retinopathy
Headache
Hyperglycemia
Hypertension
Nausea and vomiting
Orthostatic hypotension
Painless hematuria (associated with urinary bladder paraganglioma)
Pallor
Palpitation (forceful heartbeat)
Tremor
Weight loss
NOT TYPICAL OF PHEOCHROMOCYTOMA
Flushing

ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone; GHRH = growth hormone–releasing hormone; PTH-RP = parathyroid hormone–related peptide; VIP = vasoactive intestinal polypeptide.
Modified from Young WF Jr. Pheochromocytoma: 1926-1993. *Trends Endocrinol Metab.* 1993;4:122-127.

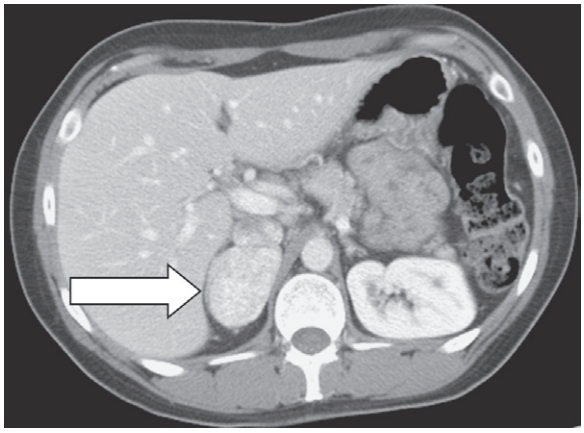

FIGURE 235-2. Contrast-enhanced computed tomography of the abdomen in a 32-year-old second-year medical student with the peripartum discovery of a pheochromocytoma. The plasma fractionated metanephrines were abnormal: metanephrine, 0.19 nmol/L (normal, <0.5 nmol/L); normetanephrine, 28.6 nmol/L (normal, <0.9 nmol/L). The 24-hour urine studies were abnormal: norepinephrine, 781 µg (normal, <170 µg); epinephrine, 2.4 µg (normal, <35 µg); dopamine, 197 µg (normal, <700 µg); metanephrine, 117 µg (normal, <400 µg); normetanephrine, 8760 µg (normal, <900 µg). The axial image shows a typical 5-cm heterogeneously enhancing right adrenal mass, consistent with pheochromocytoma *(arrow)*. After α- and β-adrenergic blockade, a 5.3- × 5.0- × 2.0-cm, 40-g pheochromocytoma was removed laparoscopically.

asymptomatic despite high circulating levels of catecholamines, probably reflecting adrenergic receptor desensitization related to chronic stimulation.

Pheochromocytomas are localized to the adrenal glands, with an average diameter of 4.5 cm (Fig. 235-2). Paragangliomas are found where there is chromaffin tissue: along the para-aortic sympathetic chain, within the organs of Zuckerkandl (at the origin of the inferior mesenteric artery), in the wall of the urinary bladder, and along the sympathetic chain in the neck or mediastinum. Paragangliomas in the head and neck region (e.g., carotid body tumors, glomus tumors, chemodectomas) usually arise from parasympathetic tissue and typically do not hypersecrete catecholamines and metanephrines, whereas paragangliomas in the mediastinum, abdomen, and pelvis usually arise from sympathetic chromaffin tissue and usually do hypersecrete catecholamines and metanephrines.

DIAGNOSIS

Differential Diagnosis

Numerous disorders can cause signs and symptoms that may lead the clinician to test for pheochromocytoma. These disorders span much of medicine and include endocrine disorders (e.g., primary hypogonadism), cardiovascular disorders (e.g., idiopathic orthostatic hypotension), psychological disorders (e.g., panic disorder), pharmacologic causes (e.g., withdrawal from an adrenergic inhibitor), neurologic disorders (e.g., postural orthostatic tachycardia syndrome), and miscellaneous disorders (e.g., mast cell disease). Indeed, most patients tested for pheochromocytoma do not have it. In addition, fractionated catecholamines and metanephrines may be elevated in several clinical scenarios: withdrawal from medications or drugs (e.g., clonidine, alcohol), any acute illness (e.g., subarachnoid hemorrhage, migraine headache, preeclampsia), and administration of many drugs and medications (e.g., tricyclic antidepressants, cocaine, phencyclidine, lysergic acid diethylamide, amphetamines, ephedrine, pseudoephedrine, phenylpropanolamine, isoproterenol) (Table 235-2).

Pheochromocytoma should be suspected in patients who have one or more of the following: hyperadrenergic spells (e.g., self-limited episodes of nonexertional palpitations, diaphoresis, headache, tremor, or pallor); resistant hypertension; a familial syndrome that predisposes to catecholamine-secreting tumors (e.g., MEN type 2, NF1, VHL disease); a family history of pheochromocytoma or a history of a resected pheochromocytoma and a present history of recurrent hypertension or spells; an incidentally discovered adrenal mass; hypertension and diabetes; pressor response during anesthesia, surgery, or angiography; onset of hypertension at a young age (before 20 years); and idiopathic dilated cardiomyopathy.

Laboratory Findings

The diagnosis must be confirmed biochemically by increased concentrations of fractionated catecholamines and fractionated metanephrines in the urine or plasma (Fig. 235-3). Most laboratories now measure fractionated catecholamines (dopamine, norepinephrine, and epinephrine) and metanephrines (metanephrine and normetanephrine) by high-performance liquid chromatography with electrochemical detection or tandem mass spectroscopy. These techniques have overcome the problems with fluorometric analysis (e.g., false-positive results caused by α-methyldopa, labetalol, sotalol, and imaging contrast agents). One of the most reliable methods of identifying catecholamine-secreting tumors is measurement of metanephrines and catecholamines in a 24-hour urine collection (sensitivity, 98%; specificity, 98%). If clinical suspicion is high, plasma fractionated metanephrines should also be measured. Some groups have advocated the measurement of plasma fractionated metanephrines as a first-line test for pheochromocytoma; the predictive value of a negative test result is extremely high, and the finding of normal plasma fractionated metanephrines excludes pheochromocytoma, except in patients with early preclinical disease and those with strictly dopamine-secreting neoplasms. A plasma test is also attractive because of its simplicity. Although measurement of plasma fractionated metanephrines has a sensitivity of 96 to 100%, the specificity is poor at only 85 to 89%; the specificity falls to 77% in patients older than 60 years. It has been estimated that 97% of patients with hypertension seen in a tertiary care clinic who have abnormal plasma fractionated metanephrine measurements do not have pheochromocytoma. This high false-positive rate results in excessive health care expenditures because of subsequent imaging and potentially inappropriate surgery. Thus, plasma fractionated metanephrines lack the necessary specificity to be recommended as a first-line test; this measurement is reserved for cases in which the index of suspicion is high. In addition, measurement of plasma fractionated metanephrines is a good first-line test for children because it is difficult to obtain a complete 24-hour urine collection.

The index of suspicion for pheochromocytoma should be high (see Fig. 235-3) in patients with the clinical scenarios described earlier and in those with an incidentally discovered adrenal mass that has imaging characteristics consistent with pheochromocytoma. These include marked enhancement with intravenous contrast medium on computed tomography (CT), high signal intensity on T2-weighted magnetic resonance imaging (MRI), cystic and hemorrhagic changes, bilaterality, and large size (>4 cm) (see later).

Although it is preferable for patients not to receive any medications during the diagnostic evaluation, treatment with most medications can be continued. Tricyclic antidepressants interfere most frequently with the interpretation of 24-hour urinary fractionated catecholamines and metanephrines. For the effective detection of catecholamine-secreting tumors, treatment with tricyclic antidepressants and other psychoactive agents listed in Table 235-2 should be tapered and discontinued at least 2 weeks before any hormonal assessments. Furthermore, catecholamine secretion may be appropriately increased in situations of physical stress or illness (e.g., stroke, myocardial infarction, congestive heart failure, obstructive sleep apnea). Therefore, the clinical circumstances under which catecholamines and metanephrines are measured must be assessed in each case.

TABLE 235-2 MEDICATIONS THAT MAY INCREASE MEASURED LEVELS OF CATECHOLAMINES AND METANEPHRINES

Tricyclic antidepressants (including cyclobenzaprine)
Levodopa
Drugs containing adrenergic receptor agonists (e.g., decongestants)
Amphetamines
Buspirone and antipsychotic agents
Prochlorperazine
Reserpine
Withdrawal from clonidine and other drugs
Ethanol
Acetaminophen (may increase measured levels of plasma fractionated metanephrines in some assays)

Imaging

Localization studies should not be initiated until biochemical studies have confirmed the diagnosis of a catecholamine-secreting tumor (see Fig. 235-3). Computer-assisted imaging of the adrenal glands and abdomen with CT or

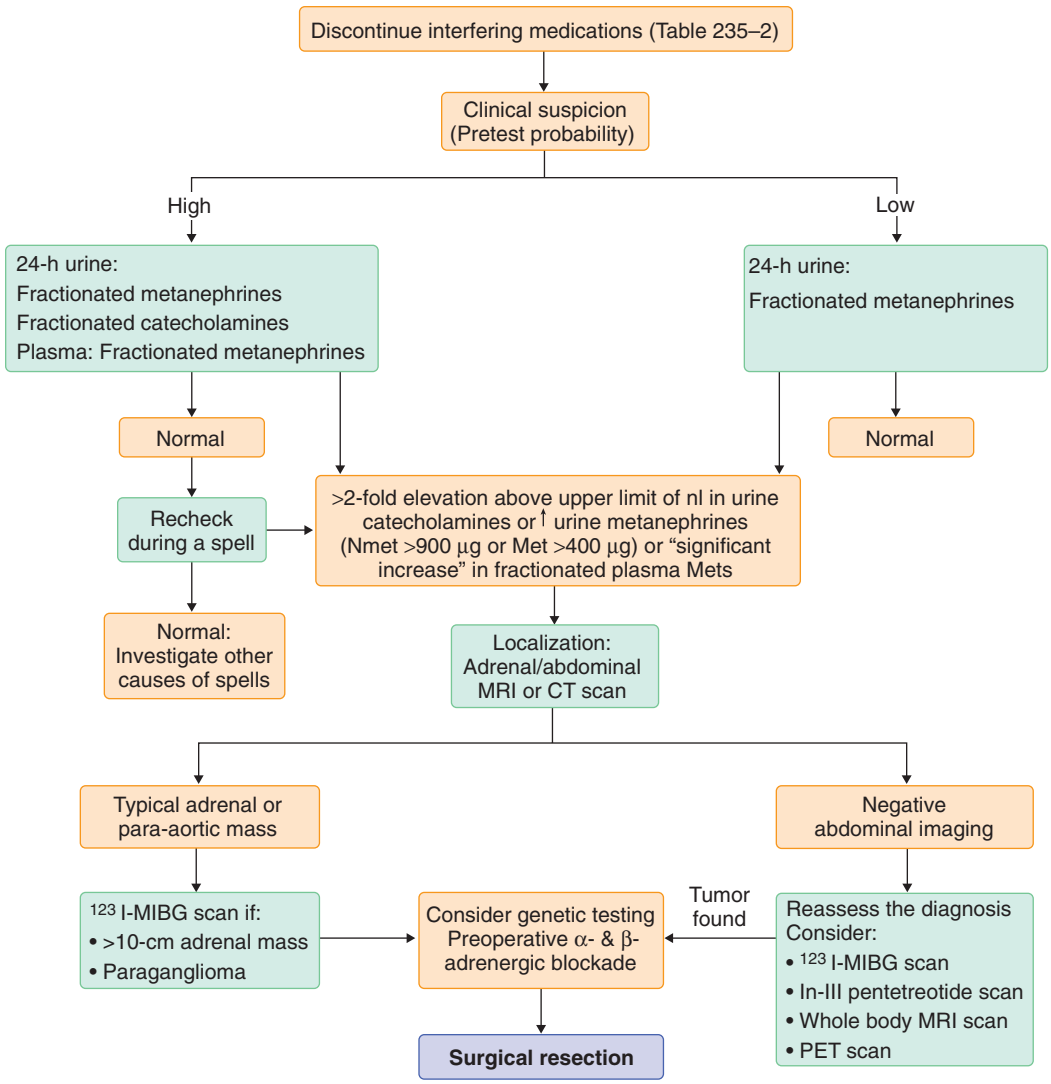

FIGURE 235-3. Evaluation and treatment of catecholamine-secreting tumors. Clinical suspicion is triggered by the following: paroxysmal symptoms (especially hypertension); hypertension that is intermittent, unusually labile, or resistant to treatment; family history of pheochromocytoma or associated conditions; or incidentally discovered adrenal mass. The details are discussed in the text. CT = computed tomography; ^{123}I-MIBG = ^{123}I-metaiodobenzylguanidine; Met = metanephrine; MRI = magnetic resonance imaging; nl = normal; Nmet = normetanephrine; PET = positron emission tomography. (Modified from Young WF Jr. Pheochromocytoma: 1926-1993. *Trends Endocrinol Metab.* 1993;4:122.)

MRI should be the first localization test (sensitivity, >95%; specificity, >65%). Approximately 85% of these tumors are found in the adrenal glands, and 95% are found in the abdomen. If the results of abdominal imaging are normal, scintigraphic localization with ^{123}I-labeled metaiodobenzylguanidine (^{123}I-MIBG) is indicated (see Fig. 235-3). This radiopharmaceutical agent accumulates preferentially in catecholamine-producing tumors (sensitivity, 88%; specificity, 84%). If a typical (<10 cm) unilateral adrenal pheochromocytoma is found on CT or MRI, ^{123}I-MIBG scintigraphy is superfluous, and the results may even cause confusion. If the adrenal pheochromocytoma is larger than 10 cm in diameter or if a paraganglioma is identified on CT or MRI, ^{123}I-MIBG scintigraphy is indicated because the patient has an increased risk of malignant disease and additional paragangliomas.

Other localizing procedures that can be used but are rarely required include computer-assisted imaging of the chest, neck, and head; somatostatin receptor imaging with [^{111}In]pentetreotide; and positron emission tomography scanning with [^{18}F]fluorodeoxyglucose, [^{11}C]hydroxyephedrine, or 6-[^{18}F]fluorodopamine (see Fig. 235-3). Because of marked gradients between the adrenal glands in non–pheochromocyotma patients, adrenal venous sampling for catecholamines is not helpful in the investigation of adrenal pheochromocytoma.

TREATMENT

Rx

Medical Therapy

Some form of preoperative pharmacologic preparation is indicated for all patients with catecholamine-secreting neoplasms. However, no randomized controlled trials have compared the different approaches. Combined α- and β-adrenergic blockade is one approach to control blood pressure and to prevent intraoperative hypertensive crises. α-Adrenergic blockade should be started 7 to 10 days preoperatively to normalize blood pressure and to expand the contracted blood volume. A longer duration of preoperative α-adrenergic blockade is indicated in patients with recent myocardial infarction, catecholamine cardiomyopathy, and catecholamine-induced vasculitis. Blood pressure should be monitored with the patient in the seated and standing positions twice daily. Target blood pressure is less than 120/80 mm Hg (seated), with systolic blood pressure greater than 90 mm Hg (standing); both targets should be modified on the basis of the patient's age and comorbid disease. On the second or third day of α-adrenergic blockade, patients are encouraged to start a diet high in sodium content (≥5000 mg daily) because of the catecholamine-induced volume contraction and the orthostasis associated with α-adrenergic blockade. This degree of volume expansion may be contraindicated in patients with congestive heart failure or renal insufficiency. After adequate α-adrenergic blockade has been achieved, β-adrenergic blockade is initiated, which typically occurs 2 or 3 days preoperatively.

Phenoxybenzamine is the preferred drug to control blood pressure and arrhythmia preoperatively. It is an irreversible, long-acting, nonspecific α-adrenergic blocking agent. The initial dosage is 10 mg once or twice daily, and the dose is increased by 10 to 20 mg in divided doses every 2 or 3 days as needed to control blood pressure and spells. The final dosage of phenoxybenzamine is typically between 20 and 100 mg daily.

The β-adrenergic antagonist should be administered only after α-adrenergic blockade is effective; with β-adrenergic blockade alone, hypertension may be more severe from the unopposed α-adrenergic stimulation. Preoperative β-adrenergic blockade is indicated to control the tachycardia associated with both the high concentrations of circulating catecholamines and the α-adrenergic blockade. The clinician should exercise caution if the patient is asthmatic or has congestive heart failure. Chronic catecholamine excess can produce a cardiomyopathy that may become evident with the initiation of β-adrenergic blockade, resulting in acute pulmonary edema. Therefore, the β-adrenergic blocker should be administered cautiously and at a low dose. Other agents that may be used to prepare the patient with pheochromocytoma for surgery include α-methyl-*p*-tyrosine (metyrosine) and calcium-channel blockers. Acute hypertensive crises may occur before or during an operation, and they should be treated with intravenous sodium nitroprusside, phentolamine, or nicardipine.

Surgical Therapy

The treatment of choice for pheochromocytoma is complete surgical resection. Surgical survival rates are 98 to 100% and are highly dependent on the skill of the endocrinologist–endocrine surgeon–anesthesiologist team. Careful preoperative pharmacologic preparation is crucial for successful treatment. Most catecholamine-secreting tumors are benign and can be totally excised. Tumor excision usually cures hypertension.

In the past, an anterior midline abdominal surgical approach was generally used to resect adrenal pheochromocytoma. However, the laparoscopic approach to the adrenal gland is currently the procedure of choice for a solitary intra-adrenal pheochromocytoma smaller than 8 cm in diameter. Laparoscopic adrenalectomy for pheochromocytoma should be converted to open adrenalectomy in cases of difficult dissection, invasion, adhesions, or an inexperienced surgeon. An anterior midline abdominal surgical approach is indicated for abdominal paragangliomas. The midline abdomen should be inspected carefully. Paragangliomas of the neck, chest, and urinary bladder require specialized approaches.

Management of Complications

Hypotension may occur during and after surgical resection of the pheochromocytoma, and it should be treated with fluids and colloids and then intravenous pressor agents if necessary. Postoperative hypotension is less frequent in patients who have had adequate preoperative α-adrenergic blockade and volume expansion. If both adrenal glands were manipulated during surgery, adrenocortical insufficiency should be considered a potential cause of postoperative hypotension. Because hypoglycemia can occur in the immediate postoperative period, blood glucose levels should be monitored, and intravenous fluids should contain 5% dextrose.

Approximately 1 to 2 weeks after surgery, fractionated catecholamines and metanephrines should be measured by collection of a 24-hour urine specimen. If the levels are normal, resection of the pheochromocytoma should be considered complete. Increased levels of fractionated catecholamines and metanephrines detected postoperatively are consistent with residual tumor due to either a second primary lesion or occult metastases. Common sites of metastasis include lymph nodes, liver, and bone.

Follow-up

The 24-hour urinary excretion of fractionated catecholamines and metanephrines or plasma fractionated metanephrines should be checked annually for life. Annual biochemical testing assesses for metastatic disease, tumor recurrence in the adrenal bed, or delayed appearance of multiple primary tumors. Follow-up CT or MRI is not needed unless the metanephrine or catecholamine levels become elevated or the original tumor was associated with minimal or no catecholamine or metanephrine excess.

MALIGNANT PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Distinguishing between benign and malignant catecholamine-secreting tumors is difficult on the basis of clinical, biochemical, or histopathologic characteristics. Malignant disease is rare in patients with an adrenal familial syndrome but common in those with familial paraganglioma caused by mutations in *SDHB*. Although the 5-year survival rate for patients with malignant pheochromocytoma is less than 50%, the prognosis is variable; approximately 50% of patients have an indolent form of the disease, with a life expectancy of more than 20 years, and the other 50% have rapidly progressive disease, with death occurring 1 to 5 years after diagnosis. The clinician should assess the pace of the malignant disease and base the level of therapy on the aggressiveness of the tumor's behavior. A multimodality, multidisciplinary individualized approach is indicated to control catecholamine-dependent symptoms, local mass effects, and overall tumor burden.

PHEOCHROMOCYTOMA IN PREGNANCY

Pheochromocytoma in pregnancy can cause the death of both the fetus and the mother. The approach to the biochemical diagnosis is the same as for nonpregnant patients. MRI without gadolinium enhancement is the preferred imaging modality, and ^{123}I-MIBG scintigraphy is contraindicated. The treatment of hypertensive crises is the same as for nonpregnant patients, except that nitroprusside should be avoided. Although the most appropriate management is debated, adrenal pheochromocytomas should be removed promptly after α- and β-adrenergic blockade if the diagnosis is made during the first two trimesters of pregnancy. The preoperative preparation is the same as for nonpregnant patients. If the pregnancy is in the third trimester, one operation is recommended for cesarean delivery and removal of the adrenal pheochromocytoma at the same time. Spontaneous labor and delivery should be avoided. The management of catecholamine-secreting paragangliomas in pregnancy may require modification of these guidelines, depending on tumor location.

236 TYPE 1 DIABETES MELLITUS

SILVIO E. INZUCCHI AND ROBERT S. SHERWIN

TYPE 1 DIABETES MELLITUS

DEFINITION

Diabetes mellitus is a chronic disorder characterized by hyperglycemia and the late development of vascular and neuropathic complications. Regardless of its cause, the disease is associated with a common hormonal defect—namely, insulin deficiency—that may be absolute or relative in the context of coexisting insulin resistance. The effect of insufficient insulin plays a primary role in the metabolic derangements linked to diabetes; hyperglycemia, in turn, plays an important role in disease-related complications.

CLASSIFICATION

The American Diabetes Association classification scheme for diabetes mellitus is summarized in Table 236-1. Clinical diabetes is divided into four general subclasses: type 1, primarily caused by autoimmune pancreatic β-cell destruction and characterized by absolute insulin deficiency; type 2, characterized by insulin resistance and relative insulin deficiency; other specific types of diabetes (associated with identifiable clinical conditions or syndromes); and gestational diabetes mellitus. In addition to these clinical categories, impaired glucose tolerance, impaired fasting glucose, and a high glycohemoglobin (hemoglobin A_{1c} [HbA_{1c}] 5.7 to 6.4%), sometimes referred to as *prediabetes*, describe intermediate metabolic states between normal glucose homeostasis and overt diabetes. Both impaired glucose tolerance and impaired fasting glucose significantly increase the risk for the future development of diabetes mellitus and in many cases are part of the disease's natural history. Patients with any form of diabetes may require insulin therapy; for this reason, the previously used terms *insulin-dependent diabetes* (type 1) and *non-insulin-dependent diabetes* (type 2) have been eliminated.

EPIDEMIOLOGY

In 2008 the Centers for Disease Control and Prevention estimated that nearly 24 million Americans (or nearly 8% of the U.S. population) fulfilled the diagnostic criteria for diabetes mellitus. Most (90 to 95%) have type 2 diabetes, and approximately one in four of these individuals is unaware of the diagnosis (Chapter 237). In those older than 60 years, the prevalence is now estimated at almost 25%. An additional 57 million Americans have prediabetes. Since 1980, the prevalence of diabetes in the United States has more than quadrupled. The number of affected patients continues to rise, with current estimates exceeding 1.6 million new cases per year in those older than 20 years. The most recent estimates of diabetes in youth reveal that approximately 15,000 are diagnosed with type 1 diabetes and nearly 4000 with type 2 diabetes each year. It is estimated that one of every three Americans born in the past decade will develop diabetes in their lifetime. Diabetes is the fourth most common reason for contact with a physician, accounting for approximately 14% of U.S. health care dollars and total annual costs exceeding $174 billion in 2007—$116 billion in direct medical costs, and another $58 billion in indirect costs due to losses in productivity. Worldwide, diabetes affects more than 220 million people; this figure is projected to double by the year 2030. The rate of increase in diabetes is greatest in developing nations as a result of urbanization and Westernization of lifestyle habits where barriers still exist to proper diagnosis and treatment.

Diabetes is a leading cause of both mortality and early disability; in the United States, it is the leading cause of blindness among working-age adults, end-stage renal disease, and nontraumatic limb amputation. Diabetes increases the risk of cardiac, cerebral, and peripheral vascular disease two- to seven-fold and is a major contributor to neonatal morbidity and mortality. A growing body of evidence, however, suggests that most if not all of the debilitating complications of diabetes can be prevented or delayed by the prospective treatment of hyperglycemia and other cardiovascular risk factors. In treating diabetes, the timing of therapy is crucial; clinical outcomes depend on early recognition and treatment of the disease.

Incidence and Prevalence

Prevalence rates for type 1 diabetes are relatively accurate because these patients invariably become symptomatic. In the United States, this is approximately 0.3%, with an annual incidence in youths of approximately 19 per 100,000. Type 1 diabetes is more prevalent in Finland, Scandinavia, and the United Kingdom; less prevalent in most of southern Europe and the Middle East; and relatively uncommon in Asian nations. The annual incidence appears to have risen in the last half century, which could imply the introduction of unidentified environmental factors. Prevalence rates are strikingly different among ethnic groups living in the same geographic region, probably because of genetic differences in susceptibility to the disease.

The recognition that type 1 diabetes has a protracted preclinical phase has shed new light on some epidemiologic characteristics of the disease. Type 1 diabetes has an increased incidence in the winter months and may be associated with specific viral epidemics. These observations may be explained in part by the superimposition of illness-provoked insulin resistance in patients with marginal β-cell function. Similarly, the common appearance of type 1 diabetes during puberty may be attributed to insulin resistance; even under normal circumstances, puberty is accompanied by impaired insulin-stimulated glucose metabolism. New methods for tracking islet-directed autoimmunity have led to a reappraisal of the age at which type 1 diabetes first appears. Although the age-specific incidence rises progressively from infancy to puberty and then declines, incidence rates persist at low levels for many decades; in fact, nearly 30% of patients are diagnosed after the age of 20 years. In patients with a later onset, the clinical syndrome tends to evolve more slowly; in addition, islet-directed antibody titers may be lower, and human leukocyte antigen (HLA) types may be different from those of younger patients. As a result, type 1 diabetes is initially misdiagnosed as type 2 in many of these patients.

PATHOBIOLOGY

Figure 236-1 summarizes the effects of insulin deficiency on body fuel metabolism.

Insulin Secretion and Action

The gene coding for human insulin is located on the short arm of chromosome 11. Insulin is initially synthesized in pancreatic β cells as proinsulin, a single-chain, 86–amino acid polypeptide. Subsequent cleavage of proinsulin removes a connecting strand (C-peptide) to form the smaller, double-chain insulin molecule, which contains 51 amino acid residues. Both insulin and the C-peptide remnant are packaged in membrane-bound storage granules; stimulation of insulin secretion results in the discharge of equimolar amounts of insulin and C-peptide (and a small amount of proinsulin) into the portal circulation. Whereas a large proportion of insulin is bound to its receptor and subsequently metabolized during its first pass through the liver, the C-peptide fragment largely escapes hepatic metabolism; as a result, peripheral C-peptide levels provide a more precise marker of endogenous insulin secretion.

Glucose Concentration

Glucose concentration is the key regulator of insulin secretion. For the activation of secretion, a glucose molecule must first be transported by a protein (GLUT 2) into the β cell, phosphorylated by the enzyme glucokinase, and metabolized. The precise triggering process is poorly understood but probably involves activation of signal transduction pathways and mitochondrial signals, closure of adenosine triphosphate–sensitive potassium channels, and calcium entry into the cytoplasm of the β cell. Normally, when the blood glucose concentration rises even slightly above fasting levels, β cells secrete insulin, initially from preformed (stored) insulin and later from de novo insulin synthesis as well. The magnitude of the insulin response is determined by the level of glucose as well as by the mode of glucose entry; compared with intravenous administration, higher insulin levels are produced when glucose is given orally because of the simultaneous release of gut peptides known as *incretins* (e.g., glucagon-like peptide-1 [GLP-1], glucose-dependent insulinotropic peptide [GIP, formerly, gastric inhibitory polypeptide]), which amplify the insulin response (see The Role of the Incretins later).

Other Secretagogues

Other insulin secretagogues include amino acids (e.g., leucine), vagal stimulation, sulfonylurea drugs, repaglinide, nateglinide, and agents that modulate the incretin system, such as GLP-1 agonists and dipeptidyl peptidase (DPP)-IV inhibitors. Once it is secreted into the portal vein, 50% or more of

TABLE 236-1 CLASSIFICATION OF DIABETES MELLITUS

ESTABLISHED DIABETES MELLITUS
Type 1 diabetes, formerly known as insulin-dependent diabetes mellitus or juvenile-onset diabetes (primarily due to β-cell destruction, usually leading to absolute insulin deficiency)
Immune mediated
Idiopathic
Type 2 diabetes, formerly known as non-insulin-dependent diabetes or adult-onset diabetes (may range from predominantly insulin resistance with relative insulin deficiency to predominantly secretory defect with insulin resistance)
Other specific types ("secondary diabetes")
Genetic defects of β-cell function (e.g., maturity-onset diabetes of the young, types 1 to 9; point mutations in mitochondrial DNA)
Genetic defects in insulin action (e.g., type A insulin resistance, leprechaunism, Rabson-Mendenhall syndrome, lipoatrophic diabetes)
Disease of the exocrine pancreas (e.g., pancreatitis, trauma, pancreatectomy, neoplasia, cystic fibrosis, hemochromatosis, fibrocalculous pancreatopathy)
Endocrinopathies (e.g., acromegaly, Cushing's syndrome, hyperthyroidism, pheochromocytoma, glucagonoma, somatostatinoma, aldosteronoma)
Drug or chemical induced (e.g., vacor, pentamidine, nicotinic acid, glucocorticoids, thyroid hormone, diazoxide, β-adrenergic agonists, thiazides, phenytoin, interferon-α)
Infections (e.g., congenital rubella, cytomegalovirus)
Uncommon forms of immune-mediated diabetes (e.g., stiff man syndrome, anti-insulin receptor antibodies)
Other genetic syndromes (e.g., Down syndrome, Klinefelter's syndrome, Turner's syndrome, Wolfram's syndrome, Friedreich's ataxia, Huntington's disease, Laurence-Moon-Biedl syndrome, myotonic dystrophy, porphyria, Prader-Willi syndrome)
Gestational diabetes mellitus
RISK CATEGORIES FOR DIABETES MELLITUS
Impaired fasting glucose
Impaired glucose tolerance
Increased glycohemoglobin

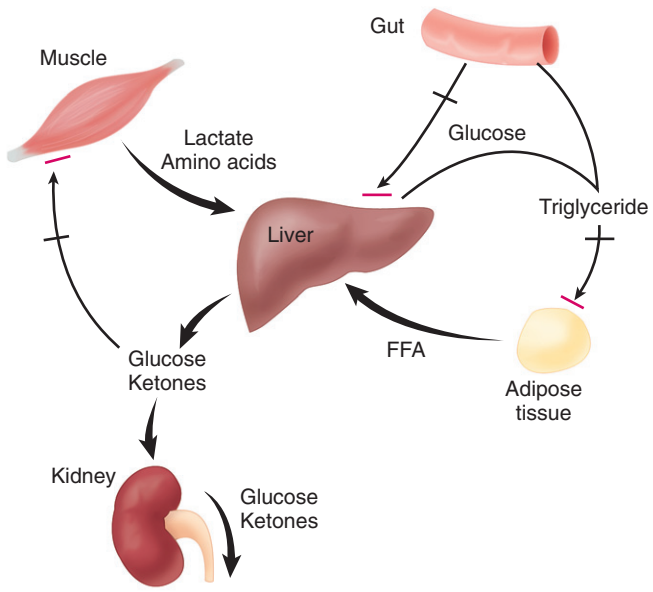

FIGURE 236-1. Effects of severe insulin deficiency on body fuel metabolism. Lack of insulin leads to mobilization of substrates for gluconeogenesis and ketogenesis from muscle and adipose tissue, accelerated production of glucose and ketones by the liver, and impaired removal of endogenous and exogenous fuels by insulin-responsive tissues. The net results are severe hyperglycemia and hyperketonemia that overwhelm renal removal mechanisms. FFA = free fatty acids.

insulin is removed by its first pass through the liver. The consequence of this hepatic metabolism is that portal vein insulin levels are at least two- to four-fold higher than levels in the peripheral circulation. This point has clinical relevance with regard to insulin therapy; whereas insulin secreted directly by pancreatic β cells enters the portal circulation, peripherally administered insulin cannot adequately raise portal insulin levels and therefore may be less efficient in inducing hepatic effects.

Insulin Action

Insulin acts on its target tissues (primarily liver, muscle, and fat) through a specific insulin receptor, which is a heterodimer containing two α chains and two β chains linked by disulfide bridges. The α subunits of the receptor reside on the extracellular surface and are the sites of insulin binding. The β subunits span the membrane and can be phosphorylated on serine, threonine, and tyrosine residues on the cytoplasmic face. The intrinsic protein tyrosine kinase activity of the β subunit is essential for the function of the insulin receptor. Rapid receptor autophosphorylation and tyrosine phosphorylation of insulin receptor substrates (IRS-1 and IRS-2) are important early steps in insulin action. Thereafter, a series of phosphorylation and dephosphorylation reactions are triggered, leading to insulin's ultimate cellular effects. A variety of postreceptor signal transduction pathways are activated by insulin, including phosphatidylinositol 3-kinase, an enzyme whose product appears to be critical for the eventual translocation of glucose transport proteins (GLUT 4) from inside the cell to the cell surface to facilitate glucose uptake, for example, in skeletal muscle.

A number of so-called counter-regulatory hormones oppose the metabolic actions of insulin, including glucagon, growth hormone, cortisol, and catecholamines. These hormones are released during illness and other stressful conditions and create a disproportionate increase in blood glucose in diabetic patients. Among these, glucagon plays an important role in the expression of the diabetic state. Glucagon is normally secreted by pancreatic α cells in response to hypoglycemia, amino acids, and activation of the autonomic nervous system. Its major effects are on the liver, where it stimulates glycogenolysis, gluconeogenesis, and ketogenesis through cyclic adenosine monophosphate–dependent mechanisms. Glucagon release is normally inhibited by hyperglycemia and insulin; however, in both types of diabetes, glucagon levels are absolutely or, more commonly, relatively elevated, despite the presence of hyperglycemia and elevated peripheral levels of insulin. Growth hormone secretion by the anterior pituitary gland is also inappropriately increased in type 1 diabetes, a result (at least in part) of the body's attempt to overcome a defect in insulin-like growth factor type 1 generation caused by insulin deficiency. The major metabolic actions of growth hormone are on peripheral tissues, where it acts to promote lipolysis and to inhibit glucose use. In type 1 diabetic patients with reduced portal insulin levels, growth hormone is also capable of stimulating hepatic glucose production.

Metabolic Effects of Insulin

Insulin deficiency—whether it is relative or absolute—plays a pivotal role in the pathophysiologic process of diabetes mellitus. The effects of insulin lack are best appreciated by first examining the normal role of insulin in fuel homeostasis.

Fasted State

After an overnight fast, low basal insulin levels result in diminished glucose uptake in peripheral insulin-sensitive tissues (e.g., muscle and fat). In the fasted state, most glucose uptake occurs in insulin-insensitive tissues, primarily the brain, which, because of its inability to effectively use long-chain free fatty acids, is critically dependent on a constant supply of glucose for oxidative metabolism. Maintenance of stable blood glucose levels is achieved through the release of glucose by the liver (and, to a small extent, by the kidney); production rates of 7 to 10 g/hour (approximately 2 mg/kg/minute) match those of the consuming tissues. The hepatic processes involved are glycogenolysis and gluconeogenesis; both play a significant role, and both depend critically on the ratio between insulin and glucagon in the portal circulation. Reduced portal insulin levels decrease glycogen synthesis, which allows glucagon's stimulatory effect on glycogenolysis to prevail. Glucagon predominance also stimulates gluconeogenesis, whereas concurrent low insulin levels promote the peripheral mobilization of gluconeogenic precursors (amino acids, lactate, pyruvate, glycerol) and alternative energy sources (free fatty acids and ketones).

Fed State

Ingestion of a large glucose load triggers multiple homeostatic mechanisms to minimize glucose excursions, including suppression of endogenous glucose production, stimulation of hepatic glucose uptake, and acceleration of glucose uptake by peripheral tissues, predominantly muscle. Each of these mechanisms depends principally on insulin. In the liver, meal-stimulated insulin levels rapidly suppress glucose production. At least 30% of ingested

glucose is deposited directly in the liver by glycogen synthesis and storage; concurrently, endogenous hepatic glucose production decreases and triglyceride synthesis increases. Peripherally, insulin-stimulated glucose transport across the cell membrane of both adipose and muscle tissue is attributable to the recruitment of glucose transport proteins (i.e., GLUT 4) from the cytosolic compartment to the plasma membrane. In muscle, glucose may then be metabolized or converted to glycogen for storage. In adipose tissue, glucose is used primarily for the formation of α-glycerophosphate, which is necessary for the esterification of free fatty acids to form triglycerides for storage in adipose tissue.

The scenario described—the ingestion of large quantities of pure glucose—is not representative of conditions during ordinary meals. If the quantity of carbohydrate consumed and the resulting insulin response are small, glucose homeostasis is maintained largely by reduced net hepatic glucose production rather than by increased glucose uptake; this is because glucose production is much more sensitive than glucose uptake to the effects of small changes in insulin secretion. The rise in insulin that accompanies the consumption of mixed meals also facilitates protein and fat storage. Because muscle is in negative nitrogen balance in the fasting state, repletion of muscle nitrogen depends on the net uptake of amino acids in response to protein feeding. In muscle, insulin acts to promote positive nitrogen balance by facilitating amino acid uptake, inhibiting the breakdown of protein, and (to a lesser extent) stimulating new protein synthesis. In adipose tissue, the action of insulin accelerates triglyceride incorporation by stimulating lipoprotein lipase while simultaneously inhibiting the hormone-sensitive lipase, which catalyzes the hydrolysis of stored triglycerides. In adipose tissue, the net effect of insulin is to inhibit lipolysis and to promote the synthesis and storage of triglycerides.

The Role of the Incretins

It has long been recognized that an equivalent amount of carbohydrate administered by mouth generates a more robust pancreatic insulin response than when it is administered by vein. This "incretin" effect is the result of the secretion of insulinotropic peptides by the gut, in response to meals that augment insulin output. The best studied of these hormones, GLP-1, has additional beneficial effects on glucose homeostasis, including the attenuation of glucagon secretion, a slowing of gastric emptying, and a central nervous system effect to enhance satiety.

Metabolic Defects in Diabetes

Fasting Hyperglycemia

In both type 1 and type 2 diabetes, fasting hyperglycemia results mainly from an inappropriate increase in hepatic glucose production; this effect is magnified in type 1 diabetes owing to absolute portal insulin deficiency. Increased hepatic glucose production in both types of diabetes is mostly due to accelerated gluconeogenesis; the loss of insulin's restraining effect on the α cell leads to a relative increase in portal glucagon levels, resulting in increased uptake and conversion of glycogenic substrates to glucose within the liver. Insulin deficiency in type 1 diabetes leads to the hypersecretion of growth hormone as well, which further accentuates glucose overproduction. In the extreme situation of total insulin lack, marked increases in counter-regulatory hormone release further stimulate gluconeogenesis while blocking compensatory increases in glucose disposal. The clinical correlate is profound hyperglycemia and glycosuria (see Fig. 236-1).

Postprandial Hyperglycemia

Diabetes is also characterized by marked postprandial hyperglycemia. In type 2 diabetes, delayed insulin secretion and hepatic insulin resistance join forces to impair both the suppression of hepatic glucose production and the liver's ability to store glucose as glycogen. Hyperglycemia ensues, even though insulin levels may eventually rise to exceed those seen in nondiabetic individuals (insulin secretion remains deficient relative to the prevailing glucose level), because insulin resistance also reduces the capacity of myocytes to extract and store the ingested carbohydrate calories and the excess glucose released from the liver.

Under normal circumstances, insulin increases the levels of glucose-6-phosphate in muscle; this rise is markedly attenuated in diabetes, which implies that the block in glycogen synthesis and glucose metabolism precedes glucose-6-phosphate formation and thus is mediated at the level of glucose transport (by GLUT 4). The conversion of glucose to glucose-6-phosphate (by hexokinase) might contribute as well. These defects are more pronounced in patients with severe hyperglycemia, in whom insulin secretion is further reduced.

Type 1 patients show the most marked and prolonged elevations in blood glucose after the ingestion of carbohydrates. These individuals have low portal vein insulin levels, which cannot be reversed by current subcutaneous insulin therapy. Consequently, during hyperglycemia, the liver fails to arrest glucose production and fails to appropriately take up glucose for storage as glycogen. In addition, glucose uptake by peripheral tissues is impaired by the lack of insulin and by the development of insulin resistance secondary to chronic insulin deprivation and the toxic effects of chronic hyperglycemia. The net result is a gross defect in glucose disposal that can be compensated only partially by renal glycosuria.

Free Fatty Acids

In addition to hyperglycemia, fasting free fatty acid levels are elevated in diabetes because of accelerated mobilization of fat stores. In type 2 diabetes, elevated free fatty acid levels occur in the presence of normal or even increased insulin levels, suggesting that adipocytes become resistant to insulin's inhibitory effect on lipolysis. This adipocyte resistance ultimately leads to the mobilization and inappropriate deposition of triglyceride into liver and muscle, which in turn is linked to insulin resistance in these organs. This is most likely caused by the combination of excessive fatty acid delivery and the defective capacity of mitochondria in liver and muscle to oxidize them. It has recently been suggested that this leads to the intracellular net accumulation of diacylglycerol, which induces cellular changes that impair insulin signaling.

Although free fatty acids are not directly converted to glucose, they do promote hyperglycemia by providing the liver with energy to support gluconeogenesis, as well as by impairing insulin signaling in muscle and liver. Endogenous insulin secretion in type 2 diabetes provides sufficient portal levels of insulin to suppress the conversion of free fatty acids to ketones in the liver. In type 1 diabetes, however, mobilized free fatty acids are more readily converted to ketone bodies. The combined effects of insulin deficiency and the presence of glucagon suppress fat synthesis in the liver. This suppression of fat synthesis reduces intrahepatic malonyl coenzyme A, which together with carnitine stimulates the activity of hepatic carnitine acyltransferase I and thereby facilitates the transfer of long-chain fatty acids into mitochondria, where they are broken down by β-oxidation and converted to ketone bodies. In addition, by decreasing ketone turnover, hypoinsulinemia enhances the magnitude of the ketosis for any given level of ketone production. During diabetic ketoacidosis, ketone levels are further increased because of the concurrent release of counter-regulatory hormones. Glucagon levels rise, accelerating hepatic ketogenesis, whereas elevations of catecholamines, growth hormone, and cortisol act in concert to increase lipolysis and the subsequent delivery of free fatty acids to the liver (see Fig. 236-1). The increase in substrate delivery may become so pronounced that it saturates the oxidative pathway, leading to hepatic steatosis and severe hypertriglyceridemia.

Hyperaminoacidemia

In addition to disordered glucose disposal, type 1 diabetic patients may exhibit defects in the disposal of ingested proteins and fats. In the absence of the normal rise in insulin, meal ingestion may produce hyperaminoacidemia, because of a failure to stimulate the net uptake of amino acids in muscle, and hypertriglyceridemia, through the reduced activity of lipoprotein lipase. Thus, diabetes should be viewed not only as a disorder of glucose tolerance but also as a disorder of protein and fat tolerance.

PATHOGENESIS

Type 1 diabetes produces profound β-cell failure with secondary insulin resistance, whereas type 2 diabetes is associated with less severe insulin deficiency but greater impairment of insulin action. Given their similarities overall, it is not surprising that the two major forms of diabetes share many pathophysiologic features. However, despite the apparent phenotypic similarity, the underlying pathogenetic mechanisms leading to type 1 and type 2 diabetes are strikingly different (see Chapter 237 for the pathogenesis of type 2 diabetes). Type 1 diabetes most likely results from an interplay of genetic, environmental, and autoimmune factors that selectively destroy insulin-producing β cells (Fig. 236-2).

Genetic Factors

The role of genetic factors in type 1 diabetes is underscored by data in identical twins showing concordance rates of 30 to 40%. It has been assumed that because concordance rates are not 100%, environmental factors must be important for disease expression. Although the presence of an environmental

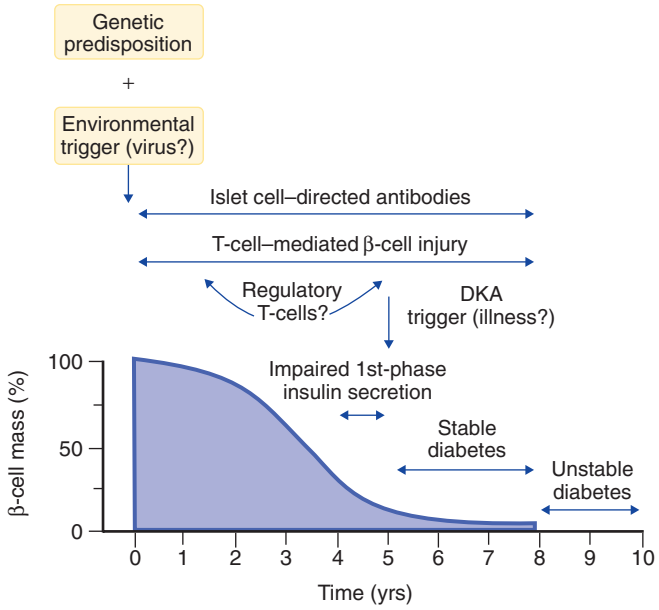

FIGURE 236-2. Summary of the sequence of events that lead to pancreatic β-cell loss and ultimately to the clinical evolution of type 1 diabetes. DKA = diabetic ketoacidosis.

trigger is highly likely, even identical twins do not express identical T-cell receptor and immunoglobulin genes; as a result, total concordance might not be expected.

Although many of the genes linked to type 1 diabetes have not been identified, some are known. HLA genes, located on the short arm of chromosome 6, clearly play a dominant role; in nonaffected siblings, the risk of developing diabetes is 15 to 20% if they are HLA identical, approximately 5% if they share one HLA gene, and less than 1% if no HLA genes are shared. Specific HLA haplotypes have been linked to type 1 diabetes; 90 to 95% of type 1 patients express DR3 or DR4 class II HLA molecules (compared with 50 to 60% of the general population), whereas 60% express both alleles—a rate more than 10-fold that of the general population. Another class II allele, DQB1*0602, has a negative association with the disease. Specific class II DQ haplotypes (e.g., DQ8 and DQ2) correlate even more strongly with disease susceptibility in white individuals; this susceptibility is associated with polymorphisms of the allele encoding the β chain of the DQ class II HLA molecule. The presence of aspartic acid at position 57 protects against disease, whereas substitution of a neutral amino acid at this position is associated with higher disease frequency. Other polymorphisms, such as the substitution of arginine at position 52 of the DQ α chain, may confer additional risk. Overall, it seems clear that significant genetic heterogeneity exists and that no single class II HLA gene accounts for all HLA-associated susceptibility to disease. Association of the disease with specific class II HLA genes implies the involvement of $CD4^+$ T cells in the autoimmune process because these molecules are critical for both the presentation of antigenic peptides to $CD4^+$ T cells and the selection of the $CD4^+$ T-cell repertoire in the thymus.

Other genes likely contribute to genetic susceptibility to type 1 diabetes. *IDDM2* (chromosome 11p), a noncoding promoter region of the insulin gene, may influence insulin gene expression in the thymus and may therefore affect thymic selection of insulin-reactive T cells. *CTLA4* (chromosome 2q) plays a role in T-cell action and regulation. Protein tyrosine phosphatase N22 *(PTPN22)* on chromosome 1 is also a regulator of T-cell activation. Many other genes have also been implicated, underscoring the polygenic nature of this disease.

Environmental Factors

Although environmental factors such as diet and toxins have been proposed as triggers of diabetes, most of the scientific attention has focused on putative viruses. Epidemics of mumps, congenital rubella, and coxsackievirus infection have been associated with an increased frequency of type 1 diabetes. Moreover, specific and convincing examples of virus-induced diabetes have been reported. However, it is likely that acute, lytic viral infections are responsible for only an occasional case of diabetes. Instead, if viruses are involved, it is far more likely that they trigger an autoimmune response. If a virus contains an epitope resembling a β-cell protein, viral infection could theoretically abrogate self-tolerance and trigger autoimmunity. It has recently been suggested based on rodent models of type 1 diabetes that disease expression may also be influenced by the microorganisms present in the gastrointestinal tract, the greatest surface area for interaction with the environment.

Autoimmune Factors

About 80% of patients with new-onset type 1 diabetes have islet cell antibodies. Antibodies to a variety of β-cell constituents have been identified, including insulin, isoforms of glutamic acid decarboxylase (GAD 65 and GAD 67), and the secretory granule protein islet cell antigen (ICA) 512 or IA-2, which contains a tyrosine phosphatase–like domain. The concept that type 1 diabetes is a chronic autoimmune disease with acute clinical manifestations is supported by the fact that islet antigen-directed antibodies may be present in asymptomatic first-degree relatives of patients. Such antibody-positive individuals are at risk for the development of type 1 diabetes, although clinical onset may be delayed by many years. The likelihood of developing type 1 diabetes is greater than 50% if autoantibodies are present to more than one β-cell antigen (i.e., insulin, GAD 65, ICA 512); diabetes rarely develops in antibody-negative relatives. If antibodies appear at a young age, the risk for clinical diabetes is particularly high.

The listed antibodies appear to be markers for rather than the cause of β-cell injury. β-cell destruction (by apoptotic and cytotoxic mechanisms) is mediated by a variety of cytokines or by direct T-lymphocyte activity. Supporting this notion, type 1 diabetes has been transferred through bone marrow cells from a diabetic patient to a nondiabetic recipient. In addition, autopsies performed on patients who died soon after disease onset have shown islet-restricted monocytic cellular infiltrates (termed *insulitis*) that are composed of $CD8^+$ and $CD4^+$ T cells, macrophages, and B cells. Usually, as the disease progresses, the islets become completely devoid of β cells and inflammatory infiltrates; α, δ, and pancreatic polypeptide cells are left intact, thus illustrating the exquisite specificity of the autoimmune attack. At the time of clinical diagnosis, about 10 to 20% of the original β-cell mass typically remains (see Fig. 236-2). In most patients there is gradual loss of these remaining β cells; some patients continue to exhibit residual insulin production for many years. These patients are generally easier to control with insulin and have fewer complications.

A critical role for T cells is supported by studies involving pancreatic transplantation in identical twins. Monozygotic twins with diabetes who received kidney and pancreas grafts from their nondiabetic, genetically identical siblings required little or no immunosuppression for graft acceptance. Nevertheless, the islets were soon selectively invaded by mononuclear cells, predominantly $CD8^+$ T cells, with the subsequent recurrence of diabetes. Thus, decades after the original onset of the disease, the immune system retains the ability to selectively destroy β cells. Evidence implicating T cells also derives from clinical trials using immunosuppressive drugs. Drugs such as cyclosporine or antibodies directed against a component of the T-cell receptor (anti-CD3) or that alter antigen presentation by B cells (anti-CD20) slow the progression of recent-onset diabetes, but this effect is not sustained if immunosuppression is withdrawn. Further supporting data for T cells' primary role derive from NOD mice, in which insulitis and islet autoantibodies develop at about 4 weeks of age and diabetes ultimately develops after 12 to 24 weeks; in these mice, a variety of treatments designed to deplete T cells can prevent diabetes. Most important, adoptive transfer of T cells isolated from diabetic mouse donors into immune-incompetent NOD mice rapidly produces diabetes. Both $CD4^+$ and $CD8^+$ T cells are generally required for disease transfer, which suggests that both are necessary for disease expression. These diabetogenic T cells target specific β-cell antigens, including insulin and GAD. A likely role for GAD or insulin is also suggested by data showing that if NOD mice are made tolerant to GAD or insulin (or to peptides derived from these molecules) early in life, insulitis and diabetes fail to develop. In keeping with the concept of immunomodulation, administration of a GAD vaccine reportedly slows the loss of β-cell function in patients with recent-onset diabetes. Finally, the chronic, smoldering nature of type 1 diabetes suggests the presence of regulatory or protective influences. In keeping with this observation, T cells that release immunoregulatory cytokines and, in turn, protect the islet from immune attack have been isolated from the islets of NOD mice. Such findings suggest that the rate of appearance and clinical expression of disease may be modulated by the balance between diabetogenic and protective populations of T cells. "Tipping the scales" in favor of protective T-cell proliferation is the goal of protective immunization.

CLINICAL MANIFESTATIONS

Patients with type 1 diabetes mellitus have little or no insulin secretory capacity and depend on exogenous insulin to prevent metabolic decompensation and death. Classically, symptoms appear relatively abruptly (i.e., over days or weeks) in previously healthy, nonobese children or young adults who may have close relatives with the disease but more commonly do not. Older patients often present more gradually. At the time of initial evaluation, most type 1 diabetic patients are ill and symptomatic, most commonly presenting with polyuria, polydipsia, polyphagia, blurred vision, fatigue, and weight loss; such patients may also present with ketoacidosis. Type 1 diabetes is believed to have a prolonged asymptomatic preclinical phase (often lasting years), during which pancreatic β cells are gradually destroyed by an autoimmune attack influenced by HLA and other genetic factors as well as by the environment (see Fig. 236-2). In some patients an acute illness and the development of secondary insulin resistance may speed the transition from the preclinical phase to clinical disease.

Initially, most type 1 patients require high-dose insulin therapy to restore a disordered metabolism. However, a so-called honeymoon period may follow (lasting weeks or months), during which smaller doses of insulin are needed because of partial recovery of β-cell function and reversal of the insulin resistance caused by acute illness. Thereafter, insulin secretory capacity is gradually lost; in some patients, particularly older individuals, this process commonly takes several years, sometimes referred to as *latent autoimmune diabetes of adulthood*. The rate of decline is slowed by intensive insulin therapy targeting near normoglycemia.

DIAGNOSIS

Because diagnosis and screening are more germane to the evaluation of patients with type 2 diabetes or other forms of diabetes, this topic is reviewed in Chapter 237.

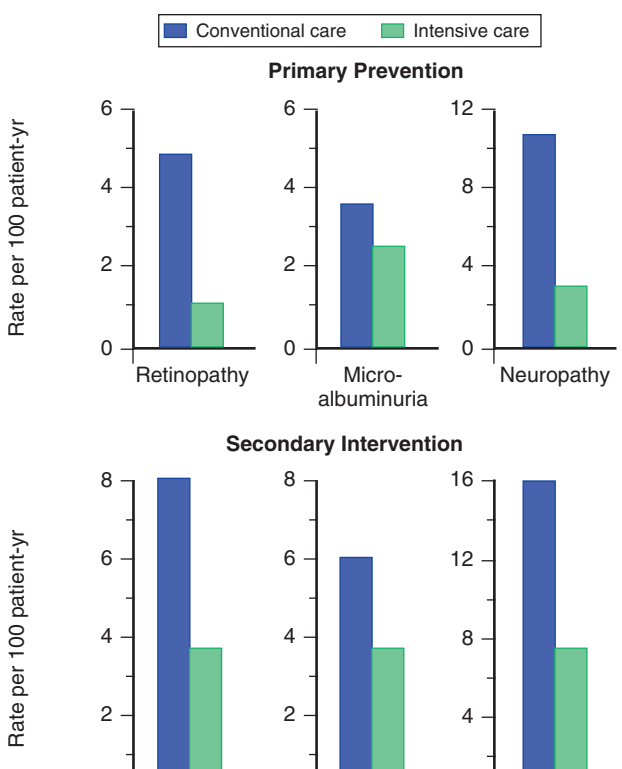

FIGURE 236-3. Summary of the results of the Diabetes Control and Complications Trial (DCCT).

TREATMENT

Rx

In type 1 diabetes, the primary focus of treatment is to replace the insulin secretion that has been lost. A healthy lifestyle is also required to facilitate insulin therapy and to optimize health. In the short term, the goals of diabetes treatment are to optimize metabolic control, improve the patient's sense of clinical well-being, and prevent long-term complications.

Management of Complications

Relation between Diabetes Control and Its Complications

Whether the vascular and neuropathic complications of diabetes mellitus can be prevented or delayed by improved glycemic control was debated for more than half a century. The definitive answer was provided by the Diabetes Control and Complications Trial (DCCT), a 9-year multicenter study involving 1441 type 1 patients aged 13 to 39 years who were randomly assigned to either intensive insulin therapy or conventional care.[1] The intensive therapy group used multiple insulin injections or an insulin pump to maintain preprandial blood glucose levels of 70 to 120 mg/dL, postprandial blood levels of less than 180 mg/dL, and glycohemoglobin (HbA_{1c}) values as close as possible to normal. In the conventional care group, the primary goal was simply to maintain clinical well-being, usually with two injections per day. The DCCT achieved a clear separation of glucose levels between the two groups during the study period. HbA_{1c} and mean glucose levels in the intensive therapy group were 1.5 to 2.0% and 60 to 80 mg/dL lower, respectively, than in those receiving conventional care. Intensive therapy reduced the development of retinopathy by 76% in the primary prevention group and the progression of retinopathy by 54% in the secondary intervention group (Fig. 236-3); the latter effect became apparent after only 4 years. In addition, intensive therapy reduced the risk of microalbuminuria by 39%, frank proteinuria by 54%, and clinical neuropathy by 60%. The incidence of major cardiovascular events also tended to be lower, but the number of events was insufficient for statistical proof; at the very least, intensive therapy did not pose a risk for macrovascular complications. An exponential relationship over time between the average blood glucose level (as reflected by HbA_{1c}) and the progression of retinopathy in the intensive care group suggests that there may be no threshold level at which complications occur. These findings imply that any degree of improvement in glycemic control has benefit and that normalization of glucose levels is not required to slow the progression of diabetic complications.

However, the benefits achieved by intensive control in the DCCT were not without risk. Weight gain was more common in the intensive care group. Most important, the frequency of severe hypoglycemia (including multiple episodes in some patients) was three-fold higher in the intensive care group. It is reasonable to conclude that in some patients, the risks of intensive therapy may outweigh the benefits; possibly included are patients with recurrent severe hypoglycemia and decreased perception of hypoglycemia, patients with advanced complications that are less likely to benefit from glucose lowering, young children, and patients who are unable or unwilling to participate in their management (e.g., self-monitoring of blood glucose level). Such individuals are likely to benefit from less aggressive therapy designed to lower glucose levels moderately without the risk of hypoglycemia. Despite the higher rate of hypoglycemia, intensive therapy in the DCCT had no detectable long-term effects on cognitive function.

Translating these results into clinical practice remains a challenge because patients require significant motivation to comply with the intensive monitoring and insulin administration regimens necessary. Significant expertise is also required on the part of practitioners to manage these individuals properly on an ongoing basis. An important lesson from these studies is that successful treatment of diabetes is largely accomplished through the efforts of the patients themselves as well as by nurse educators, dietitians, and diabetes counselors.

In an update involving the original DCCT cohort, the Epidemiology of Diabetes Interventions and Complications (EDIC) study, the beneficial effect of intensive glycemic control on microvascular complications persisted.[2] Even more important, the intensively treated group had long-lived cardiovascular benefits. Among the 1375 volunteers who agreed to participate in this observational extension of the DCCT, the intensively treated patients had less than half the number of cardiovascular events (myocardial infarction, coronary revascularization, stroke) of the conventionally treated group (46 vs. 98 events) during a total of 17 years of follow-up. These results were all the more impressive because the mean HbA_{1c} in the intensively treated group had actually risen to about 8% from about 7% during the EDIC study, whereas the conventionally treated group improved their mean HbA_{1c} from about 9% to about 8%. Therefore, despite nearly equal glycemic control during most of the EDIC study, a persistent benefit in terms of macrovascular end points was observed after intensive treatment. Some have referred to this process as *metabolic memory* or the *legacy effect* of tight glucose control.

Medical Therapy

Insulin Preparations and Pharmacokinetics

A variety of highly purified insulin preparations are commercially available (Table 236-2). Premixed insulin preparations are also available and offer added convenience for selected patients with residual endogenous insulin secretion. Nearly all insulin preparations contain 100 U/mL (U-100), although a more concentrated preparation of 500 U/mL (U-500) of regular insulin can be obtained for severely resistant patients.

TABLE 236-2 INSULIN PREPARATIONS: ONSET OF EFFECT, PEAK EFFECT, AND DURATION OF ACTION AFTER SUBCUTANEOUS ADMINISTRATION

CLASS	PREPARATION	ONSET OF EFFECT	PEAK EFFECT (HR)	DURATION OF ACTION (HR)
Rapid acting	Lispro, aspart, or glulisine	10-15 min	1-2	3-4
Short acting	Regular (R)	30 min	2-4	5-8
Intermediate acting	NPH (N)	2-4 hr	6-12	16-24
Long acting	Glargine Detemir	2-4 hr 1 hr	No peak No peak	>24 Up to 24

Short- and Rapid-Acting Insulin Preparations

After subcutaneous injection, regular (R) insulin begins to act in about 30 minutes and should therefore be administered 20 to 30 minutes before a meal. Because it acts relatively quickly and has a relatively short duration of action (5 to 8 hours), it is effective for blunting postprandial glucose excursions and for facilitating rapid dose adjustments based on measured blood glucose values. The properties of regular insulin are especially helpful in managing glucose elevations that occur during illness or after the consumption of large meals. Given by intravenous infusion, regular insulin is also effective in the perioperative period and in the management of severely ill hospitalized patients and acute hyperglycemic complications.

In regular insulin preparations, insulin molecules exist predominantly in hexameric form. Before being absorbed, insulin hexamers must first be diluted in subcutaneous interstitial fluid, then dissociate into single molecules; this property accounts for the slightly delayed absorption of regular insulin from subcutaneous injection sites. Advances in recombinant DNA technology led to the development of several insulin analogues intended to limit this property, allowing more rapid absorption in an effort to more closely mimic the normal brisk increase in endogenously secreted insulin in response to meals. Insulin lispro was the first analogue approved by the Food and Drug Administration (FDA), with amino acids in positions B28 (lysine) and B29 (proline) reversed. Lispro thereby has a reduced capacity for hexameric self-association and is more rapidly absorbed. Its effects begin within 10 to 15 minutes of administration and generally wane within 3 to 4 hours. In insulin aspart, a neutral proline residue at position B28 is replaced by negatively charged aspartic acid, resulting in a reduced capacity for self-association and faster absorption. The pharmacokinetic properties of insulin aspart are similar to those of insulin lispro; insulin aspart may have a slightly longer duration of effect. In a third rapid-acting insulin, insulin glulisine, lysine in position B29 is replaced by glutamic acid, and asparagine at position B3 is replaced by lysine, with changes in polarity similar to those seen with lispro and aspart. Because of their quick onset of action, these analogues can be administered a shorter time before eating (<30 minutes), which greatly simplifies the planning and consumption of meals; also, because the effects wane more rapidly, there is a reduced risk of "late" hypoglycemia if the next meal is delayed. With their use, postprandial glucose and HbA_{1c} reductions are equal to or better than those achieved with regular insulin, and there is a reduced incidence of delayed hypoglycemia. For these reasons, and because of their greater convenience and flexibility, rapid-acting analogues have become the standard in intensive treatment regimens. However, these differences in response are relatively modest, and these formulations are significantly more expensive than older insulins.

Intermediate- and Long-Acting Insulin Preparations

The longer acting insulin preparations have been modified to delay their absorption from injection sites, resulting in a longer duration of insulin activity. The addition of protamine and zinc yields intermediate-acting neutral protamine Hagedorn (NPH) insulin. Ideally, NPH is given twice per day, offering a compromise between some degree of meal coverage (coinciding with peak activity) and the provision of basal insulin levels. It is likely the most cost-effective insulin product.

Insulin glargine, the first long-acting, basal insulin analogue, differs from human insulin both at position A21, where asparagine is replaced by glycine, and at the carboxyl terminus of the B chain, where two arginine residues have been added. Insulin glargine is soluble at acidic pH and less so in physiologic conditions; injected at a pH of 4, it is neutralized in subcutaneous tissue and forms microprecipitates, delaying its absorption and prolonging its duration of activity. The primary advantages of glargine insulin are its longer than 24-hour activity (allowing once-daily dosing) and the near absence of peak concentrations; both characteristics are desirable for the provision of consistent basal insulin levels. Disadvantages include the higher cost, a higher incidence of mild injection site discomfort (compared with NPH, 6.0% vs. 0.3%), and the inability to mix glargine with other insulins. Insulin detemir is another basal insulin analogue. It has been engineered with a unique fatty acid side chain that facilitates self-association at the injection site and, once absorbed, binding to circulating serum albumin. Both these features allow a smooth basal profile when insulin determir is taken once or twice daily. Although it has a shorter duration of action compared with glargine, it appears to have less intraindividual variation in activity.

Insulin Regimens

Although it is a simple concept, the clinical use of insulin to treat diabetes mellitus, especially absolutely insulin-deficient type 1 diabetes, can be extraordinarily complex. There are many important interpatient (and intrapatient) variables, so a predictable algorithm cannot be uniformly applied to all patients or to a single patient at all times. In general, subcutaneous insulin regimens for type 1 diabetes can be classified as conservative or intensive. Continuous subcutaneous insulin infusion with insulin pumps is becoming increasingly popular, mainly in patients with type 1 diabetes, and this mode of therapy provides the most flexible and refined insulin replacement regimen to date.

Conservative Insulin Therapy

Through the early stages of type 1 diabetes, some degree of β-cell function is usually preserved, allowing many patients to achieve near-normal glycemic control with less intensive effort. Because intermediate-acting insulins are not generally sustained during a 24-hour period, and because insulin requirements tend to increase early in the morning, many of these patients can start with two daily injections, consisting of a mixture of intermediate-acting and short- or rapid-acting human insulins administered before breakfast and before dinner. Regardless of the initiation method used, insulin dose adjustments are inevitably required. Initially, doses of the intermediate-acting insulin should be adjusted to optimize predinner and fasting (morning) glucose levels. Once these goals are accomplished, short- or rapid-acting insulin doses should be adjusted to optimize postprandial, prelunch, and bedtime glucose values. Some patients may experience a brief "honeymoon" period, during which β-cell function partially recovers and insulin needs are temporarily reduced.

Premixed combinations of intermediate insulins and short- or rapid-acting insulins are also available (NPH/regular 70/30, neutral protamine lispro/lispro 75/25, and neutral protamine aspart/aspart 70/30). The fixed proportions in these insulin products make their titration more challenging.

Intensive Therapy: Multiple Subcutaneous Injections

Within several years after the onset of type 1 diabetes, residual insulin secretion typically ceases. When this occurs, twice-daily insulin injections are no longer acceptable, even if they continue to control marked hyperglycemia and diabetic symptoms. For optimal glycemic control, insulin delivery should more closely simulate the "normal" pattern of insulin secretion; continuous or "basal" insulin levels are required throughout the day, whereas brief increases in insulin levels ("boluses") should coincide with the ingestion of meals. Successful management of diabetes begins with fasting glucose control. Failure to control the morning glucose level often results in the stubborn perpetuation of hyperglycemia throughout the day. The key factors responsible for fasting hyperglycemia are inadequate overnight delivery of insulin and sleep-associated growth hormone release. The "dawn phenomenon" is most pronounced in patients with type 1 diabetes because of their inability to compensate by raising endogenous insulin secretion. The magnitude of the dawn phenomenon can be attenuated by designing insulin regimens to ensure that the effects of exogenous insulin do not peak in the middle of the night and dissipate by morning. Several approaches to insulin therapy can reduce this problem; some of the more common regimens are displayed in Figure 236-4. For patients seeking the tightest control, multidose insulin regimens have gained in popularity. These incorporate rapid-acting insulin analogue injections before each meal, with one or two daily doses of a long-acting basal insulin. Ideally, the rapid insulin dose is calculated based on carbohydrate intake, typically using a fixed ratio, such as 1 U for every 15 g consumed. Many intensive programs also adjust this calculated dose based on the preprandial blood glucose reading and/or any anticipated exercise after the meal. Such regimens require a motivated patient and intensive education and monitoring. Pen-style insulin injectors are also available; these may make multidose regimens more convenient for patients.

Pramlintide

Amylin is a natural peptide that is normally secreted by the pancreatic β cell with insulin in response to meals. It has several beneficial effects on glucose homeostasis, including the suppression of glucagon secretion, the retardation of gastric emptying, and the promotion of satiety. Pramlintide, a synthetic amylin analogue, is currently approved for use in patients with type 1 diabetes (as well as those with insulin-requiring type 2 diabetes) who are inadequately controlled with their current regimens. It is given before meals, usually in conjunction with prandial insulin, but in a separate subcutaneous injection. Its major role is to decrease postprandial glucose excursions, stabilizing glycemic control. In clinical trials, the absolute reduction in HbA_{1c} is modest (–0.3 to 0.5%), although it is associated with mild weight loss, which distinguishes it from insulin therapy. Side effects include nausea and vomiting, especially at higher doses. At this time, its niche appears to be for poorly controlled type 1

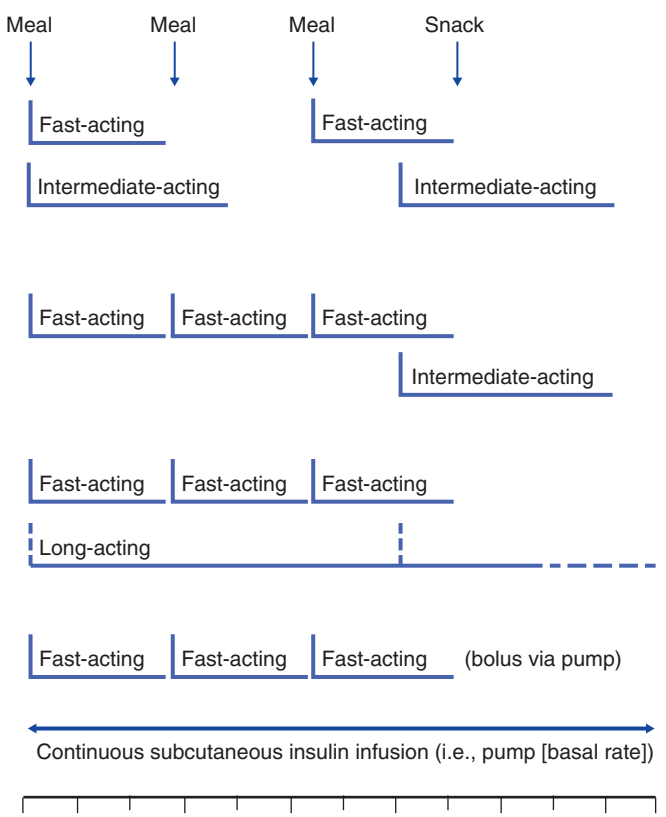

FIGURE 236-4. Several intensive insulin regimens commonly used in the treatment of type 1 diabetes. Each is designed to provide a continuous supply of insulin around the clock and to make extra insulin available at the time of meals, thereby simulating more closely the normal physiologic pattern of insulin secretion. The dashed lines for long-acting insulin indicate that it can be given either in the morning or at bedtime.

TABLE 236-3 LIFESTYLE MODIFICATIONS FOR PATIENTS WITH DIABETES

DIETARY PRESCRIPTION
Weight loss to achieve or maintain ideal body weight
Restriction of saturated fat to <10% of total calories, to be replaced in the diet by carbohydrates and monounsaturated fats; if low-density lipoprotein cholesterol (LDL-C) reduction is also desired, saturated fats should be further restricted to <7% of daily calorie intake
Decreased cholesterol intake to <300 mg/day; if LDL-C reduction is also desired, cholesterol intake should be further restricted to <200 mg/day
Sodium restriction (< 2.4 g/day) in patients with hypertension; with overt nephropathy, sodium intake should be further restricted to <2.0 g/day
Protein restriction to <20% of total calories; with nephropathy, protein intake should be further restricted to <0.8 mg/kg/day or to about 10% of daily calorie intake
EXERCISE PRESCRIPTION*
A combination of aerobic exercise and resistance training is preferred; avoid extreme heavy lifting, straining, and Valsalva maneuvers, which can raise blood pressure and may aggravate proliferative diabetic retinopathy
Intensity: increase heart rate "moderately" to at least 55% of "maximal" heart rate (220 minus age in years), with adjustments based on the patient's cardiovascular fitness; patients with improved cardiovascular fitness can proceed to "harder" activities, achieving heart rates >70% of maximum
Duration: 30 min, preceded and followed by stretching and flexibility exercises for a minimum of 5-10 min
Frequency: at least 3 days/wk; results are best if exercise occurs nearly every day and, to have a consistent effect on blood glucose, at the same time each day
Avoid strenuous exercise if fasting glucose levels are ≥250 mg/dL; avoid any exercise if glucose levels are ≥300 mg/dL or ketosis is present
Monitor blood glucose level before, during, and after exercise to learn responses to different exercise conditions and to identify when changes in insulin or food intake might be necessary
Consume additional foods as needed to avoid hypoglycemia; a rapidly absorbed carbohydrate source should be readily available during exercise and for up to 8 hr after exercise is completed

*Exercise limitations are imposed by preexisting coronary or peripheral vascular disease, proliferative retinopathy, peripheral or autonomic neuropathy, and poor glycemic control.

(and type 2) diabetes in patients already on intensive insulin regimens but whose glucose profile shows postprandial hyperglycemia not adequately addressed by increasing the dose of pre-meal rapid-acting insulin.

Continuous Subcutaneous Insulin Infusion

In continuous subcutaneous insulin infusion, rapid-acting insulin is administered around the clock by an externally worn, battery-powered, computer-controlled infusion pump (see Fig. 236-4).[3] The pump delivers a continuous basal rate and can be programmed to vary the flow rate automatically for set periods, such as reducing the rate after bedtime and increasing the flow to compensate for increased insulin requirements in the predawn hours. Boluses, determined by self-monitoring of blood glucose concentration and expected mealtime carbohydrate intake, are given by manual or remote electronic pump activation. Most insulin pumps contain an insulin reservoir (typically containing up to 300U) attached to a subcutaneous catheter (the catheter is inserted subcutaneously by an introducer needle, which is then removed). Catheters are generally best placed in the abdomen to standardize absorption and maximize visibility. Overall, continuous subcutaneous insulin infusion provides diabetic patients with the highest degrees of lifestyle flexibility and glucose control. Certain units now communicate by radio frequency to separate capillary blood glucose–monitoring meters, even offering supplemental insulin dosing suggestions. Subcutaneous interstitial sensors that provide continuous glucose monitoring are now electronically linked to modern pumps. At present, the glucose data are displayed by the pump, but there is no automatic feedback control of insulin delivery. There is an active research program aimed at developing an "artificial pancreas," whereby the infusion pump will be largely regulated by the glucose sensor data. Several obvious hurdles in terms of precision, accuracy, and safe, reliable interfaces need to be passed before such closed-loop devices will be ready for commercial use.

The continuous subcutaneous insulin infusion approach has several limitations. One obvious disadvantage of pump therapy is the need to wear the pump itself; the device can be removed only for very brief periods, during such activities as intense exercise, contact sports, submersion in water, or personal intimacy. Furthermore, because continuous subcutaneous insulin infusion uses only rapid-acting insulin, any interruption in flow (most commonly because of occlusions within or at the terminus of the catheter) can lead to the rapid deterioration of metabolic control. Local infections at the catheter site occasionally occur, necessitating a site change every 2 or 3 days.

The intensive treatment regimens described are not for everyone. In appropriate patients, however, intensive insulin therapy should be strongly encouraged to reduce the risk of late diabetic complications. Pregnancy is an absolute indication for intensive therapy, and reduction of the excess neonatal morbidity and mortality associated with diabetic pregnancies requires tight glycemic control. Ideally, intensive insulin therapy should be instituted in type 1 patients before conception to minimize the risk of fetal anomalies. After conception, blood glucose targets are more stringently applied than at other times, with the specific aim of maintaining glucose levels in the normal range.

General Measures

Lifestyle Changes

Diet and exercise contribute importantly to the care of patients with type 1 diabetes. Patients should be educated about balancing calorie intake (diet) with energy expenditure (exercise), and they should understand the basic concepts of insulin therapy as it relates to stress and physical activity. If they are properly managed and sufficiently motivated, diabetic patients should be able to consume the foods they enjoy and participate fully in exercise and sports.

Diet

The introduction of intensive insulin regimens has increased meal flexibility by allowing more latitude in varying the size, content, and timing of meals. New approaches offer the opportunity for a more normal lifestyle, thus reducing compliance problems and optimizing acceptance by and satisfaction of patients. Meals should be nutritionally sound, carbohydrate controlled, and designed to reduce cardiovascular risk, and they should provide sufficient calories to meet the energy needs of growing children, active young adults, and pregnant women; the 1800-kcal diet classically prescribed for overweight type 2 diabetic patients is grossly insufficient in these and other individuals. Furthermore, diabetic diets should specifically aim to minimize long-term cardiovascular risk by minimizing the ingestion of sodium, cholesterol, and saturated fats (Table 236-3).

Because type 1 patients depend on exogenous insulin, proper management is facilitated by a meal plan designed to match the time course of the selected insulin regimen. Patients should learn to compensate for departures from the meal plan by adjusting their insulin doses and for periods of

altered activity by adjusting their consumption of food. Even in patients on basal-bolus regimens or those receiving continuous subcutaneous insulin infusion, an effort should be made to avoid long delays between meals, and small snacks may be helpful at times of peak insulin action to avoid hypoglycemia. The potential for insulin-induced weight gain requires special emphasis on portion control; to control hypoglycemia, patients should master the determination of appropriate carbohydrate intake and avoid overcompensation.

Exercise

Regular exercise is important to promote overall health and to reduce cardiovascular complications. Through accelerated insulin absorption (due to increased local blood flow at the injection site) and increased muscle glucose consumption, exercise can rapidly reduce blood glucose levels, particularly when it coincides with the peak action of an insulin injection. In nondiabetic individuals, blood glucose levels remain stable during exercise, as decreased endogenous insulin secretion promotes increased hepatic glucose production to match the increased rate of glucose consumption. In diabetic patients receiving exogenous insulin, however, this finely tuned homeostatic mechanism is perturbed. The continued presence of exogenous insulin during exercise further accelerates glucose uptake and, more important, blocks the compensatory increase in glucose production; as a result, circulating glucose levels can fall precipitously during exercise. Because the magnitude of this fall is not easily titrated, hypoglycemia may occur if the patient is unable to adjust diet and insulin appropriately before, during, and after physical activity. Some general guidelines useful in regulating the glycemic response to exercise are summarized in Table 236-3.

Monitoring

Self-Monitoring of Blood Glucose Concentration

Self-monitoring of blood glucose concentration has revolutionized the management of diabetes. It actively involves patients in the treatment process, allows more rapid treatment adjustments, and reinforces dietary changes. Self-monitoring provides patients with the tools necessary to assist in management of the disease; it is especially useful during periods of stress and for patients who are susceptible to hypoglycemia. Urine glucose testing provides only a gross approximation of recent glucose status and should be used only in patients who cannot or refuse to test their blood.

Newer glucose meters are small, portable, and reliable; they provide a digital readout and have a computerized memory to facilitate recordkeeping. Blood sampling is facilitated (and made less painful) by automated, spring-operated lancet devices and the option of testing at sites other than the finger (e.g., the arm), which are less painful. Self-monitoring of blood glucose concentration is of maximal value if patients perform tests on a regular basis, can accurately measure glucose levels, and can make use of the results. Patients must become familiar with what a normal glucose value is, what the glucose targets are, and how levels can vary with changes in diet or activity and insulin absorption. At a minimum, patients should be able to adjust to repetitive patterns of hypoglycemia or hyperglycemia, as well as to periods of stress and illness ("sick days").

Continuous Glucose Monitoring

Traditional self-monitoring of blood glucose concentration is often inadequate to optimize metabolic control. Continuous glucose monitoring of interstitial fluid has revealed that tight glycemic control is often achieved at the expense of unacceptably high rates of nocturnal hypoglycemia, and postprandial glucose excursions are often larger than expected. To minimize these highs and lows, continuous glucose monitoring systems have been approved for clinical use, despite some limitations in accuracy. Data from the first generation of "real-time" glucose sensors were evaluated post hoc, similar to a cardiac Holter monitor, to alert clinicians to previously undetected nocturnal hypoglycemia and postprandial glucose elevations. Current models are needle-like percutaneous glucose sensors inserted under the skin by the patient; the sensors use an enzyme (glucose oxidase) coupled to electrochemical detectors to measure glucose levels for several days to 1 week before they must be replaced. Mechanical continuous glucose sensors give patients (and parents of young children) the ability to view real-time glucose levels (every 5 minutes), review trends and fluctuations in recent blood glucose levels, and receive alerts when blood glucose levels become too high or too low. Recent clinical trials suggest that continuous glucose monitoring, if used daily, helps patients improve glycemic control without increasing the near-term risk of hypoglycemia.[4]

Glycohemoglobin

Glycohemoglobin (glycosylated hemoglobin) assays have emerged as the "gold standard" for long-term glycemic control. The test does not rely on a patient's ability to self-monitor blood glucose levels and is not influenced by acute glycemic changes or by recent meals. Glycohemoglobin is formed when glucose reacts nonenzymatically with the hemoglobin A molecule; it is composed of several fractions, the largest being HbA_{1c}. HbA_{1c} (expressed as the percentage of total hemoglobin) varies in proportion to the average level of glucose during the lifespan of the red blood cell, thereby providing an index of glycemic control during the preceding 8 to 12 weeks. Several assay methods have been developed, but all are now standardized to the DCCT assay, as approved by the National Glycohemoglobin Standardization Program.

Although ambient glucose levels are the dominant influence on glycohemoglobin levels, other factors can confound the interpretation of the test result. For example, any condition that increases red blood cell turnover (e.g., pregnancy, hemolytic anemia) spuriously lowers glycohemoglobin levels, regardless of the assay used. Some assays yield spuriously low values in patients with hemoglobinopathies (e.g., sickle cell disease or trait, hemoglobin C or D) or high values when either hemoglobin F is increased (e.g., thalassemia, myeloproliferative disorders) or large doses of aspirin are consumed. HbA_{1c} can also be affected in uremia and iron deficiency anemia. In addition, poorly understood genetic factors may affect the results of this test, although while estimated average glucose ranges have been proposed for each percentage HbA_{1c}, there remains a fair degree of variability from patient to patient (the so-called glycation gap).

Treatment Planning

A management plan should take into consideration the life patterns, age, work and school schedules, psychosocial needs, educational level, and motivation of each individual patient. The plan should include lifestyle changes, a meal plan, medications, monitoring instructions (including sick-day management), and education about the prevention and treatment of hypoglycemia. Importantly, all components of the plan must be both understood and accepted by the patient. The patient's active participation in problem solving, as well as ongoing support from the health care team, is critical for the successful management of diabetes.

At each visit, the management plan should be reviewed, and the patient's progress in achieving glucose targets should be assessed. If goals are not being met, causes need to be identified, and the plan should be modified accordingly. Regular clinical evaluation should focus on early signs and symptoms of retinal, cardiovascular, neurologic, and podiatric complications and on reinforcement of the diet and exercise prescription. A complete ophthalmologic examination, assessment of cardiovascular risk factors, and measurement of urinary albumin excretion (through either a timed collection or the more convenient spot urine albumin-to-creatinine ratio) should be performed annually. Specialized podiatric care is also recommended for all patients with evidence of peripheral neuropathy, foot deformities, history of ulcerations, or evidence of peripheral vascular disease. Table 236-4 presents target glycemic guidelines for nonpregnant diabetic patients as well as targets for other clinical factors (e.g., blood pressure, lipids) related to the development of diabetic complications.

Surgical Therapy

Pancreas or Islet Transplantation

Intensive insulin therapy rarely if ever restores glucose homeostasis to levels achieved in nondiabetic individuals. As a result, a more effective method of treatment remains a crucial long-term goal of diabetes research. Pancreas transplantation is conceptually promising in this regard; with growing experience in recent years, there have been substantial improvements in the outcome of pancreas transplantation surgery. Unfortunately, because of the need for long-term immunosuppression, pancreas transplantation is currently an option for only a select group of patients, mainly type 1 diabetic patients who already require immunosuppression for a renal allograft. In such individuals, successful pancreas transplantation may also be effective in preventing nephropathy in the grafted kidney. In the absence of indications for kidney transplantation, pancreas transplantation alone should generally be considered only in rare diabetic patients with a history of frequent, severe metabolic complications (e.g., life-threatening hypoglycemia with or without recurrent ketoacidosis) in whom insulin therapy consistently fails to achieve metabolic control.

Pancreatic islet cell transplantation holds many potential advantages over whole gland transplantation because it is simpler to perform and less costly. Initially, this still largely experimental procedure involves the intraportal injection of isolated islets from cadaveric sources. Although initial reports appeared encouraging, subsequent follow-up of patients beyond 1 to 2 years reveals that most must resume insulin therapy, and many have little or no β-cell function. The critical issue of an adequate source of islets remains a major challenge, and extensive research efforts are being directed at the bioengineering of islets from noncadaveric sources ("islet farming").

ACUTE METABOLIC COMPLICATIONS

Hyperglycemic States

Metabolic decompensation in diabetes is generally classified into one of two broad clinical syndromes: diabetic ketoacidosis (DKA) or hyperosmolar hyperglycemic syndrome (HHS). Although DKA is generally seen in type 1 patients, whereas HHS affects patients with type 2 diabetes (Chapter 237), lines of classification are commonly blurred. For example, HHS can present with variable degrees of ketosis and acidosis, and DKA is seen with increasing

TABLE 236-4 THERAPEUTIC TARGETS FOR NONPREGNANT DIABETIC PATIENTS

PARAMETER	NORMAL	TARGET*
Preprandial plasma glucose (mg/dL)	<100	90-130
2-hr postprandial glucose (mg/dL)	<140	<160-180
Bedtime plasma glucose (mg/dL)	<120	110-150
Hemoglobin A_{1c} (%)†	<6	<7
LDL cholesterol (mg/dL)	<130	<100‡
HDL cholesterol (mg/dL)	>40 (m), >50 (w)	>45 (m), >55 (w)
Fasting triglycerides (mg/dL)	<150	<150
Blood pressure (mm Hg)	<140/90	<130/80§

HDL = high-density lipoprotein; LDL = low-density lipoprotein; m = men; w = women.
*Clinical targets vary for individual patients, depending on an assessment of overall health and the risk-benefit ratio.
†Whereas the hemoglobin A_{1c} goal in general is <7%, a goal as close as possible to normal (<6%) without significant hypoglycemia is advisable. Also, less stringent goals may be appropriate for some patients (those with a history of severe hypoglycemia, limited life expectancy, or significant comorbidities, and very young children or older adults).
‡<70 mg/dL an optional target in very high risk patients, such as those with overt cardiovascular disease.
§<125/75 is the target in patients with overt nephropathy or proteinuria.

TABLE 236-5 PRECIPITANTS OF DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC SYNDROME

MOST COMMON PRECIPITANTS
Infections (30-50%): pneumonia, urinary tract infections, sepsis, gastroenteritis
Inadequate insulin treatment (20-40%): includes noncompliance, insulin pump failure
Myocardial ischemia or infarction (3-6%): often clinically "silent" in diabetic patients
OTHER PRECIPITANTS
Cerebrovascular accident
Intracranial bleeding (e.g., subdural hematoma)
Acute pulmonary embolism
Intestinal or mesenteric thrombosis
Intestinal obstruction
Acute pancreatitis
Alcohol intoxication or abuse
Severe burns; hyperthermia or hypothermia
Endocrine disorders: Cushing's syndrome, thyrotoxicosis, acromegaly
Total parenteral nutrition
Drugs: corticosteroids, pentamidine, sympathomimetics, thiazides

frequency in obese type 2 patients. Criteria for both conditions can be met by some patients who experience an overlap syndrome. Despite aggressive treatment, mortality rates remain high for both conditions, approaching 5% for DKA and 15% for HHS. Mortality is associated with advanced age and comorbidity and is usually due to an associated catastrophic illness (e.g., myocardial infarction, cerebrovascular accident, sepsis) or acute complications, including aspiration, cardiac arrhythmias, and cerebral edema. Treatment of hyperglycemic states therefore involves far more than the administration of insulin to reverse hyperglycemia; it also depends on prompt attention to the accompanying fluid and electrolyte disturbances, as well as the detection and treatment of any precipitating illness.

DIABETIC KETOACIDOSIS

PATHOBIOLOGY

DKA may herald the onset of type 1 diabetes, but it most often occurs in established diabetic patients as a result of intercurrent illness (e.g., infection), inappropriate reduction in insulin dosage, or missed insulin injections (especially in adolescents). A common scenario is a patient who fails to adjust insulin therapy or to maintain adequate volume status during an illness, typically a viral gastroenteritis or an influenza-like syndrome. A list of common precipitants appears in Table 236-5.

The three cardinal biochemical features of DKA—hyperglycemia, ketosis, and acidosis—result from the combined effects of deficient circulating insulin activity and the excessive secretion of counter-regulatory hormones. These hormonal imbalances mobilize the delivery of substrates from muscle (amino acids, lactate, pyruvate) and adipose tissue (free fatty acids, glycerol) to the liver, where they are actively converted to glucose or to ketone bodies (β-hydroxybutyrate, acetoacetate, acetone). Both are ultimately released into the circulation at rates that greatly exceed the capacity of tissues to use them. The end results are hyperglycemia (>250 mg/dL), ketoacidosis (arterial pH <7.30), and an osmotic diuresis that promotes dehydration and electrolyte loss.

CLINICAL MANIFESTATIONS

The clinical history of DKA typically involves deterioration over several days, with advancing polyuria, polydipsia, and other symptoms of progressive hyperglycemia. Other common clinical features are weakness, lethargy, nausea, and anorexia. Abdominal pain in the setting of DKA is classically periumbilical and can mimic an acute abdomen. Reduced motility of the gastrointestinal tract or, in severe cases, paralytic ileus may further contribute to diagnostic confusion. Nausea and vomiting are ominous symptoms because they preclude oral replacement of fluid losses; severe volume depletion may follow quickly. Physical findings in DKA are mainly secondary to dehydration and acidosis; these include dry skin and mucous membranes, reduced jugular venous pressure, tachycardia, orthostatic hypotension, depressed mental function, and Kussmaul (deep, rapid) respirations. Ketosis may be recognizable by a sweet, sickly smell on the patient's breath.

DIAGNOSIS

The diagnosis of DKA is usually straightforward and needs to be made promptly. The clinical picture and the presence of hyperglycemia should alert the clinician to test for ketones, assess the acid-base status, and measure arterial pH. Initial laboratory tests to be performed include routine serum chemistries (including divalent cations), complete blood count with differential, and urinalysis. Cardiac enzymes and liver and pancreatic function tests should also be checked. An electrocardiogram and a chest x-ray are routinely obtained, and culture specimens should be taken from blood, urine, and other potential sources as clinically indicated. In DKA, glucose levels may vary from 250 to more than 1000 mg/dL, serum bicarbonate concentration drops below 18 mEq/L, and there is an excess anion gap that is generally proportional to the decrease in serum bicarbonate. Hyperchloremia may be superimposed if the patient maintains an adequate glomerular filtration rate and is able to exchange ketoacid anions for chloride in the kidney. The degree of depression of arterial pH depends largely on respiratory compensation. In mild cases the pH may range from 7.20 to 7.30; in severe cases it can fall below 7.00. In general, the clinical severity of DKA depends more on the magnitude of acidosis than on hyperglycemia; as a result, arterial pH is widely used as a reference indicator of DKA severity (Table 236-6). On occasion, a degree of superimposed metabolic alkalosis (e.g., caused by vomiting or diuretic use) may obscure the true severity of the ketoacidosis. An anion gap out of proportion to the fall of bicarbonate should suggest this possibility. Other laboratory abnormalities commonly seen in DKA include a reduced measured serum sodium concentration (due to hyperosmolarity and the resulting osmotic shift of intracellular water into the intravascular space), prerenal azotemia, and hyperamylasemia. The last is usually of nonpancreatic origin and can lead to an erroneous diagnosis of pancreatitis. Normal, elevated, or reduced concentrations of potassium, phosphate, and magnesium may exist when DKA is diagnosed; however, large deficits of these electrolytes invariably accompany the osmotic diuresis and become readily apparent during the course of treatment. The serum triglyceride concentration is frequently elevated, a reflection of deranged lipid metabolism in the setting of insulin deficiency. The white blood cell count is typically elevated; the hemoglobin and hematocrit may be elevated, reflecting volume contraction.

Special care should be taken in interpreting serum or urine ketone results. Because quantitative measurements of β-hydroxybutyrate and acetoacetate are not readily available, rapid diagnosis usually requires qualitative assessment of serum ketones by the use of serum dilutions and reagent strips (e.g., Ketostix) or tablets (e.g., Acetest), which depend on a nitroprusside reaction with acetoacetate. However, acetone reacts weakly with nitroprusside, and β-hydroxybutyrate does not react at all; thus, the results of qualitative testing for ketones can be misleadingly low. Furthermore, because of the presence of

TABLE 236-6 DIAGNOSTIC CRITERIA FOR DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC SYNDROME

CRITERION	MILD DKA	MODERATE DKA	SEVERE DKA	HHS
Plasma glucose (mg/dL)	>250	>250	>250	>600
Effective serum osmolality (mOsm/kg)*	Variable	Variable	Variable	>320
Urine or serum ketones (NP reaction)	Positive	Positive	Positive	Negative to small
Arterial pH	7.25-7.30	7.00-7.24	<7.00	>7.30
Serum bicarbonate (mEq/L)	15-18	10-15	<10	>15
Anion gap (mEq/L)	>10	>12	>12	Variable, usually <12
Typical mental status	Alert	Drowsy	Stupor or coma	Stupor or coma

*Effective serum osmolality (mOsm/kg) = 2 [measured serum sodium (mEq/L)] + [serum glucose (mg/dL)/18]. Normal range = 285 ± 5 mOsm/kg. Urea nitrogen is an "ineffective osmole" (i.e., it diffuses freely across compartments) and is therefore purposely excluded from this equation.
DKA = diabetic ketoacidosis; HHS = hyperosmolar hyperglycemic syndrome; NP = nitroprusside.
Modified from Kitabchi AE, Umpierrez G, Miles JM, et al. Management of hyperglycemic crises in patients with diabetes. *Diabetes Care.* 2009;32:1335-1343.

intracellular acidosis, β-hydroxybutyrate levels are often much higher than acetoacetate levels, which may further conceal the true degree of ketoacidosis. Conversely, after insulin therapy begins, the nitroprusside reaction may give the "false" impression of sustained ketoacidosis for hours or even days. This results because nonacidic acetone is slowly cleared from the circulation and also because, as acidosis improves, β-hydroxybutyrate is converted to acetoacetate, giving the illusion of worsening ketonemia.

HHS is discussed in Chapter 237.

TREATMENT

The initial goals of therapy for both hyperglycemic states are to replace fluid and electrolyte deficits and to slowly correct hyperglycemia. Unless it is severe, ketoacidosis is generally corrected with these measures and requires no specific therapy. Current management guidelines of the American Diabetes Association are presented in Figure 236-5 and summarized here. In the treatment of hyperglycemic states, special attention must be paid to both the precipitating illness and potential complications that may arise during (or as a result of) medical therapy.

Conventional Medical Therapy

In the early hours of treatment, the primary considerations are to restore intravascular volume, correct tissue hypoperfusion, and restore insulin sensitivity. With DKA, large total body deficits of water (5 to 10 L), sodium (5 to 10 mEq/kg), and other electrolytes (see later) may exist (these losses are even more profound in HHS, which typically develops over a longer time). Although water loss usually exceeds the loss of sodium, it is almost always preferable to begin fluid replacement with isotonic normal saline (0.9% NaCl solution) for efficient intravascular volume restoration. Fluid replacement regimens vary, but it is common to administer 1 L of normal saline within the first hour, followed by a continuous infusion with either 0.45% NaCl or 0.9% NaCl, depending on the corrected serum sodium concentration, the patient's hemodynamic status, and the clinical assessment of tissue perfusion. Likewise, the rate of infusion (commonly 250 to 500 mL/hour) should be adjusted according to both biochemical responses and the age and clinical status of the patient (e.g., oliguria or underlying cardiovascular disease). In pediatric patients with DKA, isotonic solutions are generally preferred because they are less likely than hypotonic solutions to accelerate water shifts into the intracellular space and contribute to cerebral edema. During the course of treatment, once the blood glucose concentration falls below 250 mg/dL, dextrose should be added to intravenous fluids to avoid eventual hypoglycemia because continued insulin delivery will be required to correct the often persistent acidosis.

Although insulin resistance is present in both DKA and HHS, supraphysiologic doses of insulin are unnecessary and are more likely to provoke hypokalemia, hypophosphatemia, and delayed hypoglycemia. A typical insulin replacement regimen uses an intravenous bolus of 0.15 U/kg of rapid-acting (e.g., regular) insulin, followed by 0.1 U/kg/hour thereafter. Intravenous administration is the most predictable way to deliver insulin to target tissues, particularly in severely hypovolemic patients with reduced peripheral blood flow. If intravenous administration is not possible, intramuscular or subcutaneous routes of administration can be used. It is ideal if blood glucose levels fall at a steady and predictable rate (50 to 75 mg/dL/hour), so it is important to monitor blood glucose levels hourly during insulin therapy to ensure an appropriate rate of decline. Blood glucose levels should not fall too rapidly, especially in young children, in whom accelerated correction of plasma glucose concentrations has been associated with cerebral edema.

After a stable blood glucose level below 250 mg/dL is achieved, with resolution of the anion gap acidosis, subcutaneous administration of insulin can be started, and the intravenous insulin infusion may be discontinued. With DKA, it is important to overlap the intravenous and subcutaneous routes by 1 to 2 hours to avoid the return of ketoacidosis. After the return of normoglycemia, long-term medical management should be initiated (or resumed), with both long-acting and short-acting insulins, to approximate the discharge regimen. A temporary "regular insulin sliding scale" is not advisable because such therapy will likely allow the glucose levels to rise into the hyperglycemic range before insulin is administered. More proactive insulin replacement regimens are preferred. The eventual dosage and frequency of insulin depend on multiple factors, including body habitus, comorbidity, insulin sensitivity, and effectiveness of prior therapeutic regimens.

Potassium replacement in DKA (and HHS) is vital. Hypokalemia can result in muscle weakness, cramps, and nausea; both hyperkalemia and hypokalemia are associated with cardiac arrhythmias. At the time of initial evaluation, patients have a severe total body potassium deficit (about 3 to 7 mEq/kg), yet measured serum potassium levels may be normal or high, especially if acidosis or renal failure is present. Once intravenous fluids and insulin are started, serum potassium levels fall quickly because of an insulin-mediated shift of potassium into the intracellular space. In addition, fluid replacement causes extracellular dilution of potassium, leading to improved renal perfusion and increased urinary potassium excretion. This rapid decline can be countered by potassium replacement based on measured serum levels. A low potassium level (<3.5 mEq/kg) requires prompt treatment with up to 40 mEq/hour, whereas "normal" serum levels (3.5 to 5.0 mEq/kg) call for less aggressive repletion (10 to 30 mEq/hour), assuming adequate urine output. In patients who may have lost potassium for additional reasons, such as diuretic use or gastrointestinal loss, one should anticipate the need for greater potassium supplementation.

In the majority of patients with mild to moderate DKA, ketoacids clear spontaneously with standard therapeutic measures, and artificial correction with alkali (bicarbonate) is unnecessary. Suppression of lipolysis by insulin reduces free fatty acid flux to the liver and blocks ketogenesis. The remaining ketoacids are then cleared or oxidized, with subsequent regeneration of bicarbonate and restoration of arterial pH. In cases of severe acidosis (pH <6.9 to 7.0), however, bicarbonate administration may be indicated; the hyperventilatory drive of severe acidosis is uncomfortable, and severe acidosis also impairs cardiac function and peripheral vasodilation. Bicarbonate therapy should be used with caution, however, and only at the minimal doses required to stabilize the patient, because it can further provoke hypokalemia. In addition, by causing a sudden left shift of the dissociation curve for oxyhemoglobin, bicarbonate may impair oxygen delivery to the tissues. Therefore, if alkali therapy is given, small amounts should be administered slowly: 50 mEq (one ampoule) of $NaHCO_3$ over 1 hour for arterial pH 6.9 to 7.0, and 100 mEq (two ampoules) over 2 hours for pH below 6.9. After bicarbonate administration, arterial pH (and serum potassium levels) should be rechecked every 2 hours, and alkaline therapy should be discontinued when the pH rises above 7.0.

In the setting of DKA, phosphate losses average 3 to 7 mmol/kg; magnesium losses reach 1 to 2 mEq/kg. (Magnitudes of depletion for both ions may be greater for HHS because of a more prolonged osmotic diuresis.) Phosphate is shifted extracellularly during hyperosmolar states, so initial serum levels may be falsely elevated and may drop rapidly during therapy. Complications of hypophosphatemia generally occur at serum levels below 1.0 mg/dL and include respiratory and skeletal muscle weakness, impaired cardiac systolic performance, and hemolytic anemia. Phosphate repletion should be used in patients with serum phosphate levels below 1.0 mg/dL and in patients with evidence of cardiac or respiratory compromise, hypoxia, or hemolytic anemia. An effective means of replacing phosphate is to replace one third to one half of the potassium losses (discussed previously) as potassium phosphate. In severe hypophosphatemia, cautious IV administration of additional small amounts of potassium phosphate may be necessary. Because of calcium binding, hypocalcemic tetany may complicate phosphate therapy unless magnesium supplements are also provided; for this reason, serum calcium, phosphate, and magnesium levels should be monitored during any phosphate infusion.

Management of Complications

The most common complications of therapy for hyperglycemic states are hypoglycemia, hypokalemia, hypophosphatemia, and fluid overload; precautions to avoid these complications are described earlier. Cerebral edema, which occurs primarily in pediatric patients, is associated with overaggressive correction of hyperglycemia and with hypotonic fluid replacement. It is likely

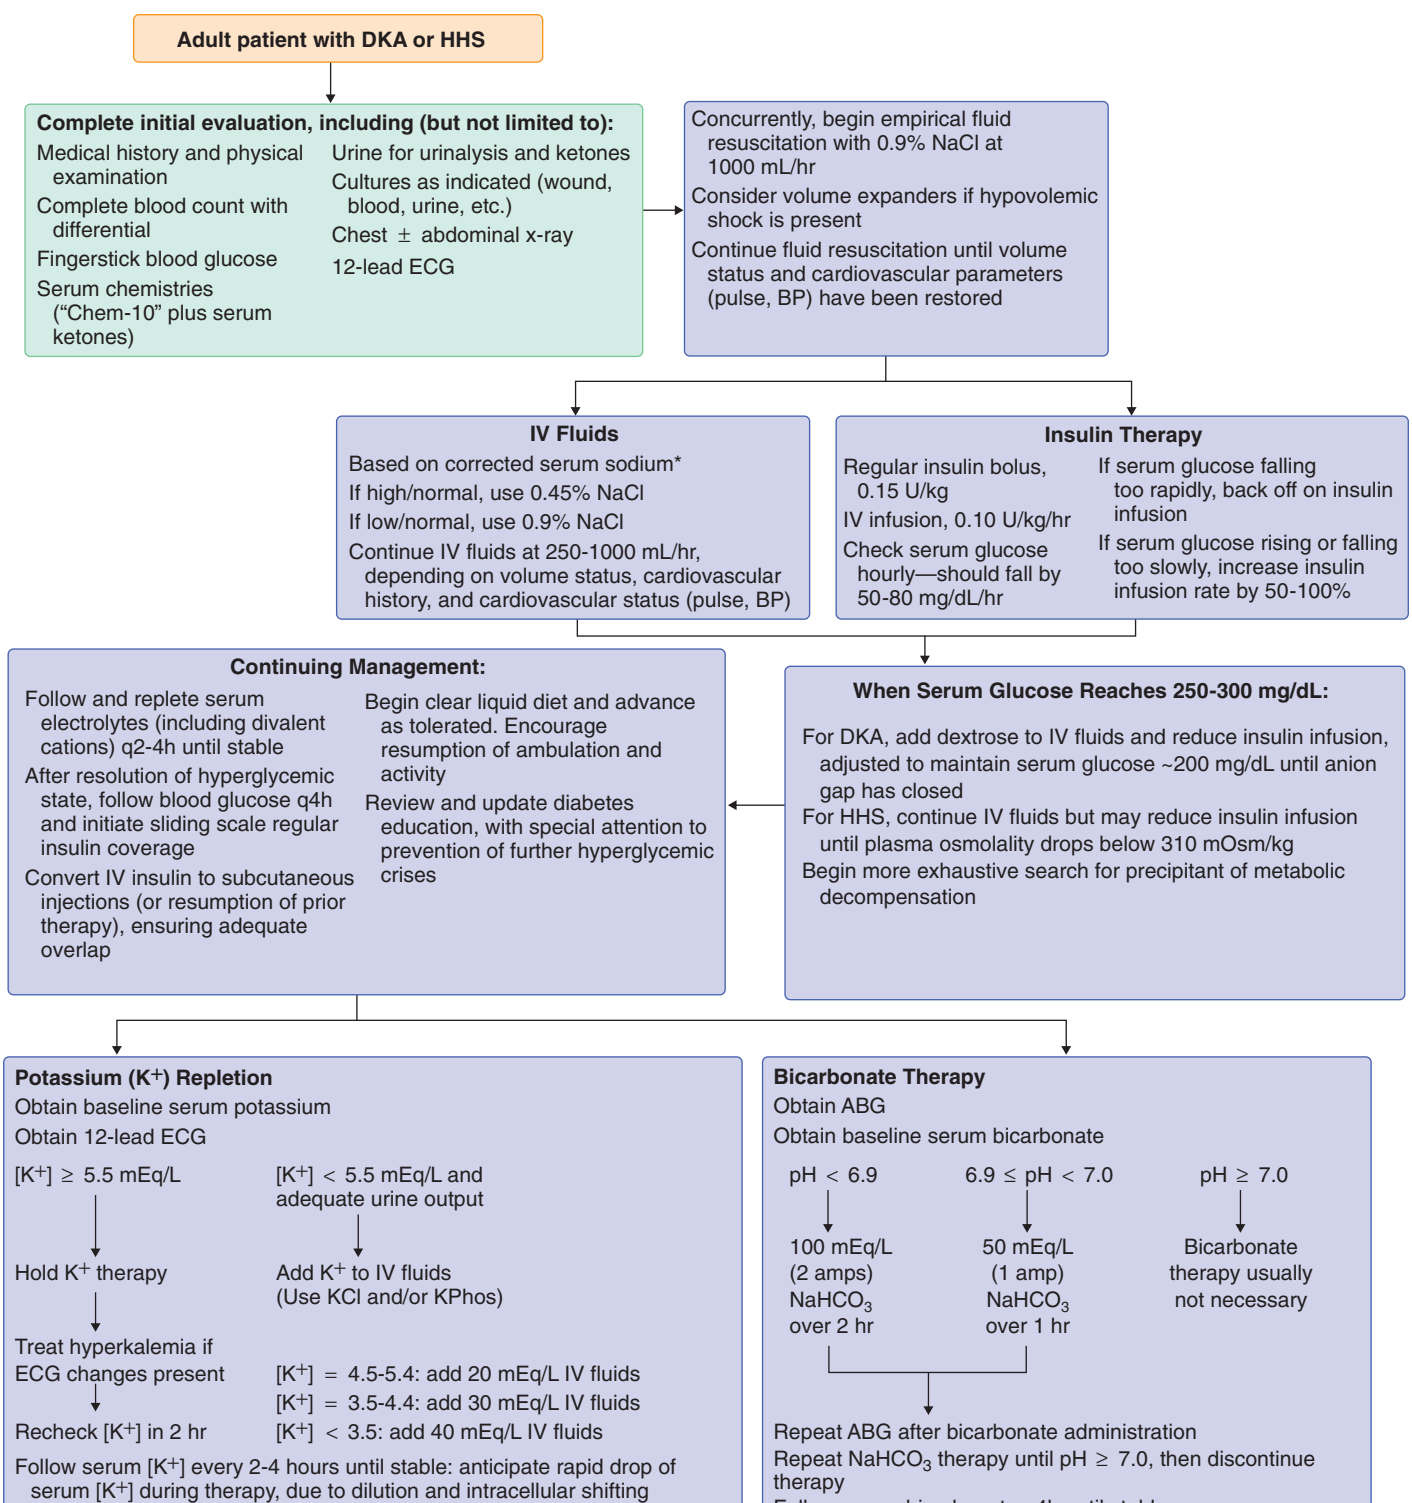

FIGURE 236-5. Management of diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic syndrome (HHS). ABG = arterial blood gases; BP = blood pressure; ECG = electrocardiogram; IV = intravenous.

the result of the osmotically driven movement of water into the central nervous system when plasma osmolarity declines too rapidly. Clinically, cerebral edema is characterized by lethargy and headache, with progressive decline in mental status and neurologic deterioration. The acute respiratory distress syndrome is also attributed to rapid reductions in colloid osmotic pressure, causing increased lung water content, decreased lung compliance, and noncardiogenic pulmonary edema.

PREVENTION

Prevention of DKA requires extensive education in sick-day insulin and fluid management, as well as home-based assessment of urine ketones whenever severe hyperglycemia or physical illness is noted.

Hypoglycemia

DEFINITION

Hypoglycemia is the most frequent complication of insulin therapy for type 1 diabetes. Nearly all patients are symptomatically affected at least once per year, and a significant percentage have severe hypoglycemia requiring medical assistance. Studies using continuous glucose monitoring of type 1 diabetics have shown alarmingly high rates of hypoglycemia, especially at night, when sleeping patients are unaware of its existence.

PATHOBIOLOGY

Symptoms of low blood glucose concentration result from changes in autonomic activity and brain function. Autonomic symptoms, including sweating, tremor, and palpitations, are often the earliest subjective warning signs of hypoglycemia. Central nervous system symptoms and signs of glucose deficiency, termed *neuroglycopenia*, may be nonspecific (e.g., fatigue, weakness) or more clearly neurologic (e.g., double vision, oral paresthesias, slurring of speech, apraxia, personality change, behavioral disturbances). Hypoglycemia affects type 2 patients as well; most cases occur during treatment with insulin or insulin secretagogues, especially the longer acting sulfonylureas. Because of the long-acting nature of some oral insulin secretagogues, low blood glucose concentration can recur up to 24 to 48 hours after drug withdrawal, and a more extended course of therapy is often required.

It is well known that prolonged, severe hypoglycemia can cause irreversible brain damage. What is less clear, however, is whether significant neurologic damage results from shorter, milder episodes of low blood glucose concentration over time. Nevertheless, hypoglycemia may provoke seizures, accidental injury, and a catecholamine response that can induce cardiac ischemia or arrhythmias in patients with underlying cardiac disease. Overall, hypoglycemia is thought to account for 3 to 4% of deaths in insulin-treated diabetic patients. Hypoglycemia also has far-reaching social implications. On a personal level, it can induce great fear, preclude comfortable engagement in routine activities (e.g., driving), and lead both patient and clinician to aim deliberately for less than optimal glycemic control.

In nondiabetic persons, hypoglycemia provokes a rapid, multitiered metabolic response intended to restore normal blood glucose levels. The brain cannot store more than a few minutes' supply of energy; in the short term, its function is exclusively dependent on a constant supply of glucose for fuel. To preserve central nervous system function, spontaneous recovery from hypoglycemia involves both the activation of endogenous glucose production and reduced peripheral glucose use. Three fundamental mechanisms are responsible for this process: dissipation of endogenous insulin; counter-regulatory hormone activity; and subjective awareness of hypoglycemia, resulting in hunger and subsequent carbohydrate ingestion. Early hormonal changes are triggered when the plasma glucose concentration approaches the hypoglycemic range (65 to 70 mg/dL). A rise in glucose production, attributable mainly to stimulation of hepatic glycogenolysis, is initiated by the release of glucagon from pancreatic α cells in conjunction with falling levels of endogenous insulin. Catecholamines are also released, producing "alarm" symptoms of hypoglycemia (e.g., hunger, tremor, palpitations) and further promoting the synthesis of glucose through the stimulation of hepatic glycogenolysis, mobilization of substrates for gluconeogenesis, and further suppression of insulin production. When hypoglycemia is sustained, additional counter-regulatory hormones such as growth hormone and corticosteroids are released; through a variety of complementary mechanisms, these hormones also help promote continued glucose availability. For a more in-depth discussion of metabolic responses to hypoglycemia, refer to Chapter 238.

Patients with type 1 diabetes are more likely to have hypoglycemia, for several reasons. First, injected insulin enters the circulation from a nonphysiologic source (e.g., a subcutaneous depot) and therefore cannot be curtailed by any counter-regulatory response to falling glucose levels, as may occur in type 2 patients who have residual endogenous insulin secretion. In addition, patients with type 1 diabetes, as a rule, are insulin sensitive, as opposed to their type 2 counterparts. Type 1 patients also lose their glucagon response to hypoglycemia; this appears to be a stimulus-specific phenomenon because their glucagon response to other stimuli may be unaffected. Defective glucagon responses develop in most type 1 patients 2 to 5 years after diagnosis, at about the same time they become completely insulin deficient, implying that the loss of endogenous insulin regulation is a contributory factor. Once this occurs, glucose counter-regulation must rely predominantly on epinephrine release. Unfortunately, half of patients with long-standing type 1 diabetes exhibit diminished epinephrine responses to hypoglycemia as well, further predisposing them to severe episodes. In addition, patients may lose the ability to recognize hypoglycemia and take corrective action. In some cases the irritability and confusion that occur during hypoglycemia may prevent the patient's awareness of its cause. In other cases, patients may lose the autonomic warning symptoms of hypoglycemia and may recognize the condition (or even fail to recognize it) only when somatic neurologic function becomes impaired. This so-called hypoglycemic unawareness syndrome has been associated with a number of factors, including duration of diabetes and autonomic neuropathy.

Hypoglycemia unawareness may also occur when patients are switched to intensive insulin regimens. The introduction of intensified treatment regimens can lower the glucose level that triggers epinephrine release and adrenergic symptoms, which at least partly explains the increased frequency of severe hypoglycemia reported in the DCCT. This leads to an increased incidence of iatrogenic hypoglycemia during intensified insulin therapy. It has been shown that even brief periods of antecedent hypoglycemia can suppress counter-regulatory responses during subsequent hypoglycemic episodes.

CHRONIC DIABETIC COMPLICATIONS

The pathogenesis of the microvascular and neuropathic complications of diabetes is complex and poorly understood. However, these complications are undoubtedly mediated in large part by the metabolic derangements associated with diabetes, especially hyperglycemia. It has been suggested that glucose-induced cell injury is particularly pronounced in those cell types that are unable to regulate their intracellular glucose concentration (e.g., endothelial cells and neurons) and that this leads to the increased production of reactive oxygen species (superoxide) as well as advanced glycation end products (AGEs), accelerated polyol and hexosamine pathways, and protein kinase C activation.

Studies suggest that hyperglycemia-mediated intracellular overproduction of reactive oxygen species may be the common mechanism triggering a variety of pathways thought to contribute to cell injury in diabetes. In addition, a variety of proteins are nonenzymatically glycosylated in vivo (including hemoglobin, collagen, laminin, low-density lipoprotein particles, and peripheral nerve proteins) in direct proportion to prevailing levels of glucose. AGE cross-linking capabilities render them resistant to natural degradation. The consequent AGEs accumulate in a variety of tissues (including the kidneys and blood vessels), where they bind to a receptor for AGE (RAGE). Of particular interest, the binding of AGEs to RAGE is thought to contribute to cell injury through a variety of mechanisms, including stimulation of oxidative reactions as well as pro-inflammatory cytokines, complement, and growth factors. In the polyol pathway, increased activity of intracellular aldose reductase leads to accumulation of sorbitol and fructose, resulting in decreased glutathione antioxidant activity (through decreased NAD^+) and enhanced formation of diacylglycerol. Diacylglycerol formation, in turn, can activate specific isoforms of protein kinase C, which stimulate transforming growth factor-β release and play an important role in cell proliferation and vascular permeability. In experimental diabetic animals, prevention of superoxide accumulation, inhibition of AGE formation, and specific protein kinase C inhibitors reduce diabetic complications.

Hemodynamic changes in the microcirculation may also contribute to microangiopathy. In the diabetic kidney, glomerular filtration rate is increased out of proportion to renal plasma flow owing to an elevation in the transglomerular pressure gradient. It is assumed that raised glomerular pressures promote the passage of proteins and AGEs; with time, their accumulation in the mesangium is likely to trigger the proliferation of mesangial cells and matrix production, eventually leading to glomerulosclerosis. Compensatory hyperfiltration and a decreasing number of functional glomeruli would

exacerbate matters, increasing intraglomerular pressure and resulting in progressive glomerular damage.

Although microvascular complications can affect patients with either type 1 or type 2 diabetes, they are discussed in this chapter. The macrovascular complications, which are particularly common in type 2 diabetes, are discussed in Chapter 237.

Diabetic Retinopathy

DEFINITION

Diabetic retinopathy refers to progressive pathologic alterations in the retinal microvasculature, leading to areas of retinal nonperfusion, increased vascular permeability, and the pathologic proliferation of retinal vessels.

CLINICAL MANIFESTATIONS

Nonproliferative Diabetic Retinopathy

E-Table 236-1 details the revised international classification (disease severity scales) for this complication. The earliest pathologic changes associated with retinopathy are termed *mild nonproliferative diabetic retinopathy*. In type 1 patients, these changes generally begin no sooner than 5 years after diagnosis. The first signs of mild nonproliferative diabetic retinopathy are microaneurysms, which arise most often in areas of capillary occlusion. Subsequently, increasing vascular permeability leads to retinal blot hemorrhages (round, with blurred edges) and "hard" exudates (sharply defined and yellow). Infarctions of the nerve fiber layer, known as *soft exudates* or *cotton-wool spots*, appear as white or gray, rounded swellings. At this early stage of retinopathy, visual acuity is generally unaffected, and the risk of progression to high-risk proliferative diabetic retinopathy (see later) is about 15% at 5 years.

Moderate nonproliferative diabetic retinopathy is characterized by intraretinal microvascular abnormalities, including venous caliber changes, beading, and increased capillary dilation and permeability. Later changes, termed severe or very severe nonproliferative diabetic retinopathy, include progressive retinal capillary loss and ischemia, with further development of extensive hemorrhages, exudates, and microaneurysms. After 5 years, moderate and severe nonproliferative diabetic retinopathy are associated with a 30% and 60% risk of progression to high-risk proliferative diabetic retinopathy, respectively.

Proliferative Diabetic Retinopathy

Proliferative diabetic retinopathy involves neovascularization—the growth of fine tufts of new blood vessels and fibrous tissue from the inner retinal surface or the optic head. Early proliferative changes are confined to the retina, but later invasion of the vitreous body constitutes high-risk proliferative diabetic retinopathy; during this end stage, fibrosis and contracture of the neovasculature result in retinal detachment and hemorrhage, the most important determinants of blindness. On occasion, new vessels can invade the iris and anterior chamber, leading to sight-threatening closed-angle glaucoma.

Clinically Significant Macular Edema

Clinically significant macular edema results from vascular leakage at the macula and can occur either with or without the stages of retinopathy described earlier. Clinically significant macular edema is suggested by hard macular exudates on funduscopic examination and can be confirmed with slit lamp biomicroscopy. In general, maculopathy is more common in type 2 patients, in whom it is an important contributor to the loss of visual acuity. As discussed later, the treatment of clinically significant macular edema runs parallel to the treatment of other forms of diabetic retinopathy.

E-TABLE 236-1 INTERNATIONAL CLINICAL DIABETIC RETINOPATHY AND MACULAR EDEMA DISEASE SEVERITY SCALES

PROPOSED DISEASE SEVERITY LEVEL	FINDINGS OBSERVABLE ON DILATED OPHTHALMOSCOPY
A. RETINOPATHY	
No apparent retinopathy	No abnormalities
Mild NPDR	Microaneurysms only
Moderate NPDR	More than just microaneurysms but less than severe NPDR
Severe NPDR	Any of the following: >20 intraretinal hemorrhages in each of 4 quadrants Definite venous beading in 2+ quadrants Prominent intraretinal microvascular abnormalities in 1+ quadrant And no signs of proliferative retinopathy
PDR	One or more of the following: Neovascularization Vitreous or preretinal hemorrhage
B. MACULAR EDEMA	
DME apparently absent	No apparent retinal thickening or hard exudates in posterior pole
DME apparently present	Some apparent retinal thickening or hard exudates in posterior pole
DME present	Mild DME (some retinal thickening or hard exudates in posterior pole, but distant from the center of the macula) Moderate DME (retinal thickening or hard exudates approaching the center of the macula but not involving the center) Severe DME (retinal thickening or hard exudates involving the center of the macula)

DME = diabetic macular edema; NPDR = nonproliferative diabetic retinopathy; PDR = proliferative diabetic retinopathy.

From Fong DS, Aiello LP, Ferris FL, Klein R. Diabetic retinopathy. *Diabetes Care*. 2004;27: 2540-2553.

TREATMENT

Medical Therapy

At present, medical management of diabetic retinopathy is aimed at controlling risk factors for progression. The value of tight glycemic control was proved by the DCCT,[1] whose primary prevention arm demonstrated an impressive 76% risk reduction for the onset of retinopathy with intensive therapy. In the secondary prevention arm, patients with early nonproliferative diabetic retinopathy undergoing intensive therapy demonstrated a 47% risk reduction in the development of severe nonproliferative diabetic retinopathy or proliferative diabetic retinopathy, a 51% risk reduction in the need for laser treatment, and a 26% risk reduction in the development of clinically significant macular edema. Other targets for medical management, all associated with accelerated retinal damage, include the control of hypertension and hyperlipidemia, treatment of nephropathy, and careful follow-up during pregnancy, when accelerated retinal disease has been linked to preexisting diabetes (but not gestational disease). Fenofibrate can reduce the progression of retinopathy and the need for laser treatment by about one third, with the benefit not clearly related to its reduction of lipid levels.[5] In the Diabetic Retinopathy Candesartan Trials (DIRECT) involving 3326 adults with type 1 diabetes, the angiotensin II receptor blocker candesartan modestly reduced the incidence of diabetic retinopathy, a finding of borderline significance, but it could not prevent its progression in those with established disease.[6]

Surgical Therapy

Surgical management of retinopathy is aimed at slowing disease progression because baseline visual acuity is difficult to recover. In the 1980s large-scale prospective clinical trials such as the Diabetic Retinopathy Study and the Early Treatment Diabetic Retinopathy Study established photocoagulation as the treatment of choice when retinopathy threatens vision. Most patients with proliferative diabetic retinopathy, and selected patients with severe nonproliferative diabetic retinopathy, are now treated primarily with scatter (panretinal) photocoagulation; cryotherapy or vitrectomy may be required if laser treatment is unfeasible for technical reasons or because of extensive disease. Clinically significant macular edema is treated with focal photocoagulation, with the possible exception of patients exhibiting no or minimal nonproliferative diabetic retinopathy. In such patients, close follow-up at 2- to 4-month intervals is an acceptable option. The decision to treat depends not only on stage of retinopathy and extent of clinically significant macular edema but also on the type of diabetes, the patient's general medical status, compliance with follow-up, and the status of the contralateral eye.

These considerations make it imperative for physicians to prospectively identify diabetic patients at risk for retinopathy and visual loss. Nonspecialists may have difficulty diagnosing the stages of retinopathy. Accordingly, patients should be referred to an experienced eye specialist for a complete examination, including a dilated funduscopic examination, tonometry, and slit lamp biomicroscopy. The most recent guidelines of the American Diabetes Association recommend an initial eye examination within 5 years of diagnosis of type 1 diabetes and at the time of diagnosis in type 2 patients.

Follow-up

Follow-up of all patients should occur at least annually, with the possible exception of those with retinopathy-free type 2 diabetes. Even in the latter cases, the American Diabetes Association recommends yearly examinations to avoid lost follow-up and to identify patients with more aggressive ocular disease. Of special note, because retinopathy rarely develops in children before puberty, patients with early-onset type 1 diabetes generally do not require screening before 10 years of age. Also, the acceleration of retinopathy during pregnancy demands that all patients with preexisting diabetes be examined during the first trimester. Recently, the availability of high-quality retinal photography with remote interpretation by specialists has become available. This is now thought to be a reasonable substitute when an in-person evaluation is not possible (e.g., in remote areas).

Diabetic Nephropathy

RISK FACTORS

There are several known risk factors for the development of diabetic nephropathy: duration of disease; elevated glycohemoglobin levels; and concurrent hypertension, hyperlipidemia, and tobacco use. Race is known to play a major role as well, as demonstrated by a higher prevalence of nephropathy in African American, Hispanic, and Native American patients. There is also a high concordance rate in families; studies in both type 1 and type 2 diabetic families revealed a three- to four-fold increase in the prevalence of nephropathy among those with affected siblings. Strong associations have been noted with several other factors as well, including a deletion polymorphism of the angiotensin-converting enzyme (ACE) gene, increased sodium-lithium countertransport, and degree of insulin resistance.

CLINICAL MANIFESTATIONS

Natural History

Details are less clear in type 2 diabetes, but the natural history of diabetic nephropathy in type 1 diabetes is well described (Fig. 236-6). The period immediately after diagnosis is best characterized by glomerular hyperfiltration. During this time there is renal hypertrophy, increased renal blood flow, increased glomerular volume, and increased transglomerular pressure gradient, all contributing to a rise in glomerular filtration rate. Importantly, these changes depend at least in part on hyperglycemia, as they are diminished by intensive diabetes treatment. Three to 5 years after diagnosis, early glomerular lesions appear, characterized by thickening of glomerular basement membranes, mesangial matrix expansion, and arteriolosclerosis. Albumin excretion remains low during early glomerular changes; however, as pathologic changes mount, the glomeruli lose their functional integrity, resulting in glomerular filtration defects and increased glomerular permeability. Although the results of routine tests of renal function (creatinine concentration and urinalysis) remain normal, microalbuminuria (30 to 300 mg/day) appears. Systemic hypertension is also present at this time in more than 50% of cases.

Without intervention, approximately 80% of patients with type 1 diabetes who develop sustained microalbuminuria experience an increase in albuminuria on the order of 10 to 20% per year, with overt nephropathy (≥300 mg/24 hours) appearing over 10 to 15 years. Once overt nephropathy occurs, glomerular filtration rate begins a relentless decline (10 mL/minute/year or more), which is eventually reflected by an increase in serum creatinine concentration. The appearance of massive proteinuria and the nephrotic syndrome is common in this context and often heralds progression to end-stage renal disease (ESRD). Once the serum creatinine concentration rises (reflecting an approximately 50% decline in glomerular filtration rate), ESRD develops in most patients within 10 years. This course is highly variable, however, particularly in type 2 diabetics, who may exhibit moderate proteinuria for several years without a substantial deterioration of renal function. A simple but useful method of monitoring progression to renal failure is to plot the reciprocal of the serum creatinine concentration as a function of time. This technique allows better assessment of both therapeutic interventions and the time at which renal replacement therapy will become necessary. Notably, in patients with diabetes who have no sustained microalbuminuria after 20 years of disease, the development of significant nephropathy is rare.

Most diabetic patients with nephropathy exhibit diffuse glomerulosclerosis; only a minority have pathognomonic Kimmelstiel-Wilson nodular lesions. Although pathologic changes continue to mount throughout the disease, glomerulosclerosis extensive enough to cause ESRD develops in a minority of patients.

TREATMENT Rx

Early-Stage Treatment

Treatment of nephropathy has become an important focus of recent research and depends heavily on the stage of disease. Early in the course of diabetes (before the onset of microalbuminuria), strict glycemic control is of the utmost importance. The DCCT demonstrated that intensive therapy reduced microalbuminuria by 39% and overt albuminuria by 54% in type 1 diabetics, with a mean follow-up of 6.5 years. A similar result was demonstrated in the United Kingdom Prospective Diabetes Study (UKPDS) of patients with type 2 diabetes (Chapter 237), in which a less dramatic improvement in glycemic control reduced microalbuminuria and overt albuminuria by 24% and 33%, respectively, with a mean follow-up of 9 years. In normotensive, normoalbuminuric type 2 diabetics, treatment with ACE inhibitors retards microalbumin production, but studies achieving similar results with β-blockers and calcium-channel blockers suggest that blood pressure lowering may be responsible for this effect. Studies using ACE inhibitors and angiotensin II receptor blockers have consistently shown that both drug classes can delay the progression of both proteinuria and declining glomerular filtration rate.[7] These drugs are therefore widely favored in diabetic patients, whose blood pressure should be maintained at 130/80 mm Hg or less if possible. Lower targets (<125/75) are endorsed for those with overt nephropathy.

Later Stage Treatment

Once clinical nephropathy becomes evident, aggressive efforts at strict glycemic control have marginal value in slowing the progression of nephropathy. As noted before, efforts aimed at reducing hypertension and glomerular pressure have become the mainstay of therapy. Dietary protein restriction (i.e., 0.8 g/kg body weight) may add limited benefit, and adherence is difficult. Aggressive lipid management is useful in preventing both renal and extrarenal vascular complications. As ESRD approaches, long-term treatment plans should proceed much as they would in nondiabetic uremic patients, but therapy should usually be initiated sooner. It is well known that diabetic patients have a poorer tolerance for uremia than their nondiabetic counterparts do. Protein wasting is accelerated, hypertension becomes more difficult to control, and there is an acceleration of generalized atherosclerosis with

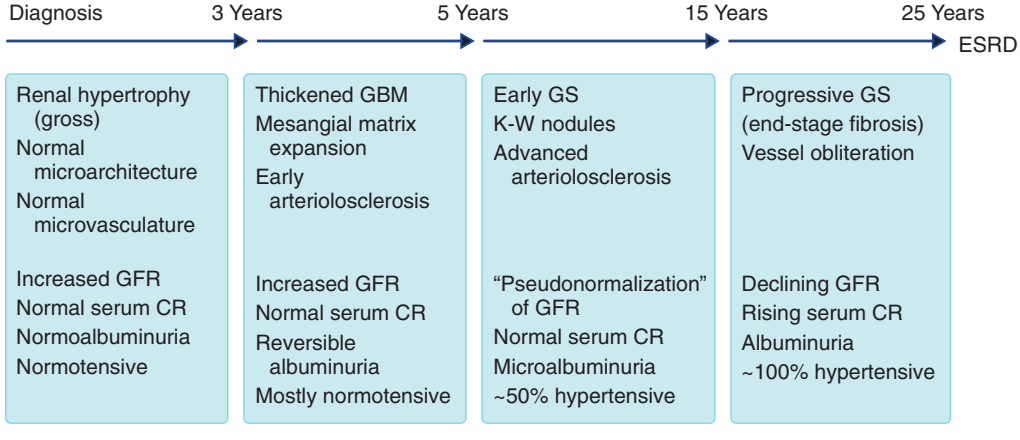

FIGURE 236-6. Pathogenesis of diabetic nephropathy. CR = creatinine; ESRD = end-stage renal disease; GBM = glomerular basement membrane; GFR = glomerular filtration rate; GS = glomerulosclerosis; K-W = Kimmelstiel-Wilson.

extensive cardiovascular morbidity. Current options for ESRD patients include hemodialysis, peritoneal dialysis, kidney transplantation, and combined kidney-pancreas transplantation (Chapter 133). Choosing among these options is complex, and decisions must be made on an individual basis. Careful attention to and treatment of coexisting anemia (due to erythropoietin deficiency; Chapter 161) and optimization of calcium–vitamin D homeostasis are also very important in any patient with advancing renal disease, but especially in those with diabetes. Finally, mortality associated with both dialysis and organ transplantation is higher in diabetic than in nondiabetic patients, usually because of cardiovascular comorbidity and the more rapid development of complications such as vascular insufficiency.

Management of Complications

Glomerular nephropathy is not the only entity that commonly affects the genitourinary system in diabetic patients. Asymptomatic bacteriuria and pyelonephritis are twice as common in diabetic women because of several factors, including autonomic bladder dysfunction, impaired organ perfusion, and glycosuria. Papillary necrosis is also associated with diabetes, and renal artery stenosis is more common as well. Hyperkalemia, another frequent complication of diabetes, is due to a variety of factors, including insulin deficiency, metabolic acidosis, reduced glomerular filtration rate, use of pharmacologic modulators of the renin-angiotensin axis, and the syndrome of hyporeninemic hypoaldosteronism commonly seen in elderly patients with impaired renal function. Finally, diabetic patients are at notable risk for azotemic complications after the injection of contrast dye for radiologic studies. For this reason, aggressive hydration with intravenous fluids, especially those containing sodium bicarbonate, before and after the study or the prophylactic use of *N*-acetylcysteine is critical in these cases.

Diabetic Neuropathy

PATHOBIOLOGY

The term *diabetic neuropathy* describes a wide variety of clinical syndromes representing a complex interplay of pathogenic factors. Chronic, more insidious neuropathies may be mediated by metabolic factors, whereas the more acute, self-limited neuropathies most likely have a vascular cause. Also, nerve growth factor is diminished in the neurons of patients with neuropathy, perhaps limiting regenerative capacity. Autoimmune mechanisms may also be involved; in affected type 1 diabetics, autonomic nerve bundles may show monocytic infiltration, and the sera may contain complement-fixing antibodies to sympathetic ganglia. Because of the multifactorial nature of diabetic neuropathy, current classification schemes are based largely on clinical presentation. Current taxonomy includes focal, diffuse, and autonomic neuropathies. Our suboptimal understanding of the underlying causes of diabetic neuropathy has slowed the development of appropriate medical therapies.

CLINICAL MANIFESTATIONS

Focal Diabetic Neuropathies

Focal diabetic neuropathies (mononeuropathies) typically present with pain, but motor losses and abnormal deep tendon reflexes can be present. They usually begin suddenly, suggesting a vascular cause. Although any cranial or peripheral nerve can be involved, the most common sites include the oculomotor, median, radial, and lateral popliteal nerves. Painful radiculopathy may also occur in the distribution of one or more spinal roots and can easily be confused clinically with internal organ disease or postherpetic neuralgia. Because of the self-limited nature of focal neuropathy, treatment is generally aimed at pain control, with physical therapy as needed to maintain function of the affected muscle groups. Focal neuropathies are generally self-limited, with an average duration of 6 to 8 weeks; chronicity can occur but is less common.

Distal Symmetrical Polyneuropathy

Distal symmetrical (sensorimotor) polyneuropathy (Chapter 428) is the most common neurologic syndrome seen in diabetes. This process involves all somatic nerves but has a strong predilection for distal sensorimotor nerves of the feet and, to a lesser extent, the hands. Sensory fibers are generally preferentially affected; disease affects both small, unmyelinated C fibers (transmitting pain and temperature) and larger, myelinated Aδ/Aβ fibers, which carry touch, vibration, and proprioception. Early on, most patients with distal neuropathy are asymptomatic, with subtle abnormalities on examination, including the loss of vibration sense, light touch, two-point discrimination, and thermal sensitivity. Once they become symptomatic, patients typically report numbness and tingling of the distal extremities, often in the classic "stocking-glove" distribution. Pain is also common, involving either C fibers (burning, dysesthesia, and allodynia) or the large fibers, usually described as gnawing or like a toothache. Severe, spontaneous, short-lived lancinating pains may also occur. Left unchecked, all types of pain may gradually gain in intensity, with a tendency to worsen at night, and there may be progressive loss of sensorimotor function as well. Later stages of disease can involve severe sensory loss, small muscle wasting of the hands and feet, sensory ataxia, and neuropathic arthropathy (Charcot joints).

Proximal Motor Neuropathy

Proximal motor neuropathy (diabetic amyotrophy), although classified as a polyneuropathy, is a unique condition that deserves special mention. This syndrome primarily affects elderly type 2 patients and is more common in men. It classically begins with pain in the bilateral thighs, hips, and buttocks, followed by weakness and atrophy of the proximal pelvic muscle groups. Iliopsoas, obturator, and adductor muscles of the pelvis are preferentially affected, with relative preservation of the hamstrings and gluteal muscles. Weight loss may also occur.

Autonomic Neuropathy

Symptomatic autonomic diabetic neuropathy (Chapter 427) carries a poor prognosis and is thankfully now less common than it once was. Autonomic neuropathy typically accompanies other chronic complications of diabetes and may play a pathogenetic role through disturbed regulation of local blood flow.

Cardiac

Common cardiovascular abnormalities seen with autonomic neuropathy include resting tachycardia (due to preferential dysfunction of parasympathetic fibers), diminished heart rate variability, prolonged QTc, and silent myocardial ischemia. Diabetic patients often have defective heart rate and blood pressure responses to exercise, and their lack of autonomic regulation places them at high risk for myocardial infarction, congestive heart failure, and sudden cardiac death.

Vascular

Postural hypotension is probably caused by an impaired sympathetic vasoconstrictor response and impaired cardiac reflexes. Non-neurogenic causes of orthostasis, such as volume depletion, impaired cardiac function, and infectious causes, should be ruled out before the diagnosis is made. Tilt-table testing can be useful to confirm the diagnosis (Chapter 62). Nonpharmacologic measures, such as a raised head position at night, reduction of rapid positional changes, and supportive elastic stockings, can be useful in mild cases. Disabling disease may require pharmacologic intervention; first-line agents include mineralocorticoids (9-α-fluorohydrocortisone) and α-agonists (midodrine).

Gastrointestinal

Altered gastrointestinal function is commonly seen in diabetes. Constipation is the most common clinical syndrome. Diarrhea is another frequent complaint and can be caused by a variety of conditions, including hypermotility (impaired sympathetic inhibition), hypomotility with bacterial overgrowth, pancreatic insufficiency, and bile salt irritation. Treatment is generally aimed at the underlying condition and may include antidiarrheals, intermittent use of broad-spectrum antibiotics, pancreatic enzymes, and bile acid sequestrants (cholestyramine).

Gastroparesis is a particularly disabling condition, often presenting with bloating, early satiety, nausea, and vomiting. Labile glycemic control can result from delayed delivery of nutrients to the small bowel. Treatment of gastroparesis begins with small, frequent meals and the use of metoclopramide, a central dopaminergic agonist with gastric cholinergic activity. Early treatment is useful, but the drug's effect may diminish over time. In selected cases, erythromycin, which acts on the motilin receptor to promote gastric motility, may also be considered. Recently, gastric pacemakers have been used as experimental therapy in selected cases.

Genitourinary

Impaired parasympathetic innervation leads to bladder hypotonia, incomplete bladder emptying, dribbling, and overflow incontinence. Bethanechol, a parasympathomimetic agent, can be helpful to reverse these symptoms, but its use is often limited by side effects, including salivation, lacrimation,

diarrhea, and bronchoconstriction. α-Blockers help by relaxing the urinary sphincter, but these agents potentiate postural hypotension, which is already prevalent in diabetic patients. Advanced cases of bladder dysfunction often require intermittent straight catheterization or, if absolutely necessary, the placement of an indwelling catheter. Chronic bacterial colonization and actual infections may result, however.

Erectile dysfunction is commonly seen in male diabetic patients. Selective oral inhibitors of phosphodiesterase type 5 (sildenafil, tadalafil, vardenafil) inhibit the local breakdown of cyclic guanosine monophosphate, which, in the presence of nitric oxide, leads to selective engorgement of the corpus callosum. Caution should be used in patients with suspected coronary disease, and such drugs are contraindicated in combination with nitrate therapy. In men who do not respond to these drugs, intrapenile injections of locally acting vasomotor agents, such as alprostadil and papaverine, have been used with moderate success but carry the risk of priapism, infection, and local fibrosis with repeated use. In refractory cases, urologic referral for a penile prosthetic implant should be considered.

TREATMENT

Rx

Early treatment of diabetic sensory neuropathy should include tight glycemic control. In the DCCT, intensive therapy slowed the onset of neuropathy by 70% and the progression of early neuropathy by 57%; in the UKPDS, glucose control in type 2 diabetes was associated with improved vibratory sensation.

The use of several therapies for neuropathic pain (Chapters 29 and 428) has been supported by randomized controlled trials. Tricyclic antidepressants, including amitriptyline, desipramine, and nortriptyline, are moderately effective and well tolerated at low doses, but dose escalation can result in drowsiness, anticholinergic effects, potentiation of cardiac arrhythmias, and worsening of glaucoma. Anticonvulsants, such as carbamazepine and gabapentin, are also effective, but carbamazepine can cause hematologic abnormalities, and patients taking gabapentin may report dizziness, fatigue, headaches, or diarrhea. Two drugs have been specifically approved by the FDA for use in diabetic neuropathy. The first, duloxetine, is a selective serotonin and norepinephrine reuptake inhibitor (related to venlafaxine) that is also approved as an antidepressant. The second, pregabalin, an analogue of γ-aminobutyric acid (GABA; related to gabapentin), modulates calcium channels and GABAergic neurotransmission. Both are modestly effective in decreasing neuropathic pain. Topical therapies, such as capsaicin cream (which depletes stores of axonal substance P) and lidocaine gels, can be moderately effective.

The Diabetic Foot

DEFINITION

The diabetic foot is characterized by slowly healing plantar ulcers that result from apparently insignificant trauma. Left untreated, superficial ulcers may penetrate to underlying tissues, leading to complications including cellulitis, abscess formation, joint sepsis, and osteomyelitis. Gangrene may occur, and amputation may be required.

CLINICAL MANIFESTATIONS

To varying degrees, the diabetic foot is characterized by the combination of chronic sensorimotor neuropathy, vascular disease, autonomic neuropathy, and impaired immune function. Sensory neuropathy prevents the detection of minor traumatic events, so that ill-fitting shoes (or sharp objects in the shoe) may erode the skin surface without signaling pain. Pedal neuropathy also produces abnormalities in both proprioception and intrinsic muscle motor function, pathologically altering weight distribution on the metatarsal heads and leading to "clawing" of the metatarsophalangeal joints. In advanced cases, abnormal loading of the foot can result in repeated painless fractures and the displacement of normal joint surfaces, producing the so-called Charcot foot or Charcot joint. Aortic and peripheral vascular disease often coexist. Diminished cardiac output or disturbed autoregulatory mechanisms of the microcirculation may further contribute to impaired blood flow and delay ulcer healing. Finally, abnormal immune function (secondary to hyperglycemia) can predispose to prolonged inflammation and infection, further slowing wound closure and increasing the likelihood of ulcer complications.

PREVENTION

Prevention of the diabetic foot parallels general diabetes care, with an emphasis on proper nutrition, tight glycemic control, and medical risk factor modification, including smoking cessation. A general foot care prescription (Table 236-7) is valuable, and office visits should routinely include careful examination of the feet. In affected patients, examination by a specialist is recommended at least once per year. In cases of deformed feet, pressure relief (offloading) is essential and may include the use of orthotics, specialty shoes, assistive devices, or a total-contact cast to direct pressure away from a high-risk area.

TABLE 236-7 FOOT CARE PRESCRIPTION FOR DIABETIC PATIENTS WITH LOWER EXTREMITY SENSORY NEUROPATHY

Avoid walking barefoot
Do not apply very hot water or heating pads to the feet
Inspect the feet daily, using a mirror for plantar surfaces
Wash the feet daily, drying thoroughly between the toes
Lubricate dry skin to avoid cracking
Wear clean, soft, cotton socks
Wear properly fitting, well-cushioned shoes (insoles)
Break in new shoes slowly
Consider a second pair of shoes for evenings (larger size to account for any dependent edema)
Cut toenails straight across
Schedule regular visits to a diabetic foot care specialist, especially if there are any signs or symptoms of neuropathy, vascular disease, or bony deformity

TABLE 236-8 KEY ELEMENTS OF A COMPREHENSIVE MANAGEMENT PLAN FOR PATIENTS WITH DIABETES MELLITUS

LIFESTYLE CHANGES
Healthy diet
Aerobic exercise
Weight control
Smoking cessation
Stress reduction
CONTROL OF MODIFIABLE METABOLIC FACTORS
Glucose
Lipids
Blood pressure
Aspirin prophylaxis in higher risk patients
PREVENTIVE CARE
Regular medical screening examinations
Regular screening for albuminuria
Regular ophthalmologic examinations
Regular podiatric examinations (and self-examinations)
Regular dental check-ups
Yearly influenza vaccinations
Pneumococcus vaccination

TREATMENT

Rx

Once an ulcer has formed, it should be treated aggressively with antibiotics, appropriate local wound care, and débridement of necrotic tissue. In selected cases, local application of recombinant human platelet-derived growth factor can moderately accelerate wound healing. Bioengineered tissue therapies, containing human dermal-epidermal components, are also effective in refractory cases. These products act as biologic dressings and contain live human fibroblasts that deliver growth factors and extracellular matrix components directly to damaged skin. For extensive cases of gangrene or deep tissue infections, surgical amputation may be required. A compromised peripheral circulation makes such an outcome more likely. If poor circulation is a dominant clinical feature, a vascular surgeon should be consulted for consideration of revascularization.

Key elements of a comprehensive management plan for the care of diabetic patients are summarized in Table 236-8.

TYPE 2 DIABETES MELLITUS

SILVIO E. INZUCCHI AND ROBERT S. SHERWIN

DEFINITION

In this chapter, we discuss the pathogenesis and treatment of type 2 diabetes and other forms of the disease. See Chapter 236 for a general overview of normal carbohydrate metabolism and the complex physiology of insulin secretion and action. Although type 2 diabetes has many similarities to type 1 diabetes, there are many important differences from the vantage point of both biology and therapeutics.

Type 2 diabetes accounts for most cases of diabetes encountered in clinical practice. Patients retain some endogenous insulin secretory capacity; however, their insulin levels are low relative to their ambient glucose concentrations and magnitude of insulin resistance. Type 2 patients are not dependent on insulin for immediate survival, and ketosis rarely develops, except under conditions of great physical stress. Nevertheless, many of these patients will require insulin therapy for optimal glycemic control over time. Although type 2 diabetes has recently been found with increasing frequency in children, adolescents, and young adults, it is usually associated with advancing age; most cases are diagnosed after the age of 45 years. Type 2 diabetes has a high rate of genetic penetrance unrelated to HLA genes and is associated with obesity and a lack of physical activity. The clinical features of type 2 diabetes can be insidious; classic symptoms may be quite mild. Fatigue, weakness, dizziness, blurred vision, and other nonspecific complaints often dominate the clinical picture, but these may be tolerated for many years before the patient seeks medical attention. Moreover, if the degree of hyperglycemia is insufficient to produce any symptoms at all, the diagnosis can be made only after the development of vascular or neuropathic complications.

The general classification scheme for diabetes mellitus is summarized in Table 237-1.

Other Specific Types of Diabetes

This category encompasses a wide variety of diabetic syndromes attributed to a specific disease, drug, or condition. Categories include genetic defects of β-cell function or insulin action, diseases of the exocrine pancreas (e.g., chronic pancreatitis), other endocrinopathies (e.g., Cushing's syndrome, acromegaly), drug- or chemical-induced diabetes (e.g., due to glucocorticoids), infections, and other immune-mediated and genetic syndromes associated with diabetes mellitus.

Maturity-onset diabetes of the young (MODY), formerly classified as a subtype of type 2 diabetes, has now been more accurately described as a consequence of genetic research. Clinically, patients with MODY generally present in adolescence or young adulthood; unlike patients with classic type 2 diabetes, they are usually nonobese, normotensive, and normolipidemic at the time of diagnosis. MODY is a heterogeneous disorder encompassing several monogenic defects of β-cell function; it has an autosomal dominant inheritance and a penetrance exceeding 80%. Mutations of at least nine genetic loci have been identified. The most common form, MODY type 3, is associated with a mutation of *HNF1α* (hepatocyte nuclear factor-1α), a gene transcription factor encoded on chromosome 12. A subgroup of MODY type 2 patients has a mutation in the gene encoding glucokinase, the key enzyme responsible for the phosphorylation of glucose within the β cell and the liver. A variety of glucokinase mutations, each capable of interfering with the transduction of the glucose signal in the β cell, have been identified in different families. These forms of diabetes may respond to insulin secretagogues, such as sulfonylureas or, if needed, to insulin injections.

Severe illness (e.g., burns, trauma, sepsis) can provoke stress hyperglycemia as a result of the hypersecretion of insulin antagonistic hormones (e.g., catecholamines, cortisol). Although this may represent the unmasking of underlying diabetes, the metabolic disturbance may be self-limited and should therefore not be formally classified as diabetes until the precipitating illness has resolved (unless there is evidence of more chronic hyperglycemia, as reflected by a hemoglobin A_{1c} [HbA_{1c}] of 6.5% or greater). Whereas most patients can be readily classified on clinical grounds, a small subgroup of patients is difficult to categorize because they display features common to both type 1 and type 2 diabetes. Such patients are classically nonobese, with reduced insulin secretory capacity but little tendency for ketosis. Many of these patients initially respond to oral agents; however, nearly all of them will eventually require insulin therapy. Many of these patients appear to have a slowly evolving form of type 1 diabetes, with measurable titers of autoimmune markers, referred to as *latent autoimmune diabetes of adulthood* (LADA).

Gestational Diabetes Mellitus

The term *gestational diabetes mellitus* (Chapter 236) describes women with abnormal glucose tolerance that appears or is first detected during pregnancy. Women with known diabetes before conception are not classified as having gestational diabetes. Gestational diabetes mellitus usually appears in the second or third trimester, when pregnancy-associated insulin antagonistic factors (many placentally derived) reach their peak. After delivery, glucose tolerance generally (but not always) reverts to normal. However, within 10 years, type 2 diabetes develops in most women with prior gestational diabetes; on occasion, pregnancy can precipitate type 1 diabetes as well. As a whole, gestational diabetes occurs in approximately 7% of U.S. pregnancies, accounting for approximately 200,000 cases per year; local prevalence rates may rise as high as 14% in high-risk populations. Although patients with gestational diabetes generally present with mild, asymptomatic hyperglycemia, rigorous treatment is indicated to protect against hyperglycemia-associated fetal morbidity. Most respond to diet, but pharmacotherapy is often required, with insulin remaining the standard treatment approach in these individuals.

EPIDEMIOLOGY

Systematic screening for asymptomatic type 2 diabetes mellitus is generally limited to high-risk populations, rendering broader prevalence estimates imprecise. Total U.S. prevalence is now estimated at 8%, but probably exceeds 25% in persons older than 65 years. Type 2 diabetes is more common in Native Americans, Hispanic Americans, and African Americans, in whom the prevalence exceeds 12 to 13%, than in whites,; these patients also typically present at an earlier age. Prevalence rates vary worldwide; type 2 diabetes has a propensity for Asiatic Indians, Polynesians-Micronesians, and Latin Americans. Interestingly, African blacks, Australian Aborigines, Asians, and Pacific Islanders all have an increased risk for diabetes after emigration to the United States; this may be attributable to a genetically determined inability to adapt metabolically to "Western" behavior patterns (i.e., reduced physical activity and a high-fat, high-calorie diet).

Although relatively little is known about the specific genetic abnormalities associated with type 2 diabetes, the personal factors promoting disease expression are well established. Increased age, reduced physical activity, and obesity are risk factors for the disease, especially in genetically susceptible persons. The severity and duration of obesity contribute significantly to diabetes risk; patients with high waist-to-hip ratios (i.e., central or upper body obesity) are also more prone to the disease. Family history is also important because type 2 diabetes occurs more frequently in persons with diabetic parents or siblings. Identical twin concordance rates approach 100%; in these cases, affected twins will even often develop diabetes at a similar age.

Impaired Fasting Glucose and Impaired Glucose Tolerance

In 2008, the Centers for Disease Control and Prevention estimated that 57 million adults had prediabetes in the United States. There is only partial overlap between the impaired fasting glucose (IFG) and impaired glucose tolerance (IGT) groups, as demonstrated by the fact that approximately 37% of patients with IFG also have IGT, whereas approximately 24% of patients with IGT also have IFG. Because of the insidious nature of both conditions, precise rates of progression to overt diabetes are difficult to establish; current estimates approach 5 to 10% per year for each condition, with even higher rates if both conditions are present. In general, IGT appears to have a greater sensitivity for predicting the future development of diabetes; it is also an independent risk factor for cardiovascular complications. Recently, high HbA_{1c} levels (5.7 to 6.4%) have been added to the laboratory criteria that define prediabetes. As with IFG and IGT, there is imperfect concordance between individuals with HbA_{1c} levels in this range and those with the glucose-based abnormalities that define prediabetes. Nonetheless, each identifies a group of patients at increased risk for developing diabetes and for which preventive strategies should be considered.

PATHOBIOLOGY

Whereas the pathogenesis of hyperglycemia in patients with type 1 diabetes is reasonably straightforward (lack of insulin due to β-cell destruction), the

TABLE 237-1 DIAGNOSTIC CATEGORIES*: DIABETES MELLITUS AND AT-RISK STATES

FASTING PLASMA GLUCOSE LEVEL	2-Hour (75-g) OGTT Result		
	<140 mg/dL	**140-199 mg/dL**	**≥200 mg/dL**
<100 mg/dL	Normal	IGT†	DM
100-125 mg/dL	IFG†	IGT† *and* IFG†	DM
≥126 mg/dL	DM	DM	DM
HbA_{1c} LEVEL	**<5.7%**	**5.7-6.4%**	**≥6.5%**
	Normal	High risk†	DM

*These diagnostic categories are based on the combined fasting plasma glucose level and a 2-hour, 75-g oral glucose tolerance test (OGTT) result. Note that a confirmed random plasma glucose level of 200 mg/dL or higher in the appropriate clinical setting is diagnostic of diabetes and precludes the need for further testing.
†May be referred to as prediabetes.
DM = diabetes mellitus; IFG = impaired fasting glucose; IGT = impaired glucose tolerance.

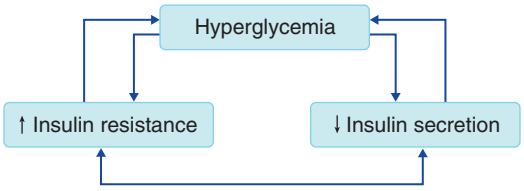

FIGURE 237-1. Elevations of circulating glucose initiate a vicious circle in which hyperglycemia begets more severe hyperglycemia.

metabolic underpinnings of type 2 diabetes are comparatively more varied, and to a large degree enigmatic, involving defects in both insulin action and secretion. Hyperglycemia in type 2 diabetes probably results from complex genetic interactions, the expression of which is modified by environmental factors such as body weight and exercise. With type 2 diabetes, identical twin concordance rates approach 100%, although disease onset and course can vary greatly on the basis of environmental factors. Hyperglycemia itself is known to impair insulin secretion and action; elevated free fatty acid levels also play an important pathogenic role. By the time that hyperglycemia is detected, nearly all type 2 patients exhibit both defective insulin secretion and insulin sensitivity; this makes it somewhat of a challenge to determine which of the two factors is primarily responsible for the vicious cycle leading to disease (Fig. 237-1). Nonetheless, it is difficult to develop diabetes if β-cell function remains adequate for the peripheral demands for insulin action.

Genetics

Although monogenic forms of diabetes have been identified (e.g., MODY types), most cases are likely to be polygenic in nature. Type 2 diabetes shows clear familial aggregation but does not segregate in classic mendelian fashion; this implies that the disease results either from a combination of genetic defects or from the simultaneous presence of multiple susceptibility genes and predisposing environmental factors. Candidate gene mutations for polygenic forms of type 2 diabetes include mutations of the transcription factor-7–like 2 *(TCF7L2)*, the coding region of the insulin gene, peroxisome proliferator-activated receptor-γ (PPAR-γ), β-cell adenosine triphosphate-sensitive potassium channel, intestinal fatty acid–binding protein 2, calpain 10, and β_3-adrenergic receptor. These and other mutations have been associated with isolated clusters of patients with type 2 diabetes. *TCF7L2* has received substantial attention recently because single nucleotide polymorphisms in this gene have been strongly associated with type 2 diabetes risk and impaired insulin secretion.

Pathogenesis

Insulin Secretion

It is now quite apparent that the driving force in the progression from normal glucose tolerance to IGT to frank type 2 diabetes is the progressive loss of insulin secretory capacity. Once type 2 diabetes becomes manifested, fasting insulin levels in type 2 diabetes generally appear normal or elevated, yet they are *relatively* low given the degree of coexisting hyperglycemia. As the disease progresses and hyperglycemia becomes more severe, basal insulin levels eventually fail to keep up and may even decline. Indeed, autopsy studies demonstrate that β-cell mass is reduced by 50% in such patients. The insulin secretory defect usually correlates with the severity of fasting hyperglycemia and is more evident after carbohydrate ingestion. In its mildest form, the β-cell defect is subtle, involving the loss of the "first-phase" insulin response and the normal oscillatory pattern of insulin secretion. Although the overall insulin response may appear to be fairly intact, this "normal" response is actually totally inadequate to maintain glucose tolerance when it is viewed in the context of simultaneous insulin resistance. During this early stage, the β-cell defect is usually specific for glucose; other secretagogues (e.g., amino acids) maintain their potency, and insulin deficiency is thus less pronounced during the ingestion of mixed meals. Patients with more severe fasting hyperglycemia lose this capacity to respond to the other insulin secretagogues; thus, their secretory defect worsens as their disease progresses. The underlying cause of the secretory defect remains uncertain and is probably multifactorial, involving both functional and anatomic defects, and to large degree genetically determined.

Studies in rodents suggest that the loss of glucose-stimulated insulin secretion is associated with a decreased expression of GLUT 2, the primary glucose transport protein of the pancreatic β cell. Pathologic studies of islets from patients with long-standing type 2 diabetes have demonstrated amyloid-like deposits composed of islet amyloid polypeptide, or amylin, a peptide synthesized in the β cell and co-secreted with insulin. Chronic hypersecretion of amylin may lead to intra-islet precipitation of the peptide, which over time might also contribute to impaired β-cell function. Experiments in gene knockout mice suggest a potential role for impaired insulin receptor signaling in the development of impaired β-cell function. A link between insulin resistance and secretion is also suggested by the accumulation of fat within the β cell, which may interfere with normal insulin secretion. Finally, studies in patients with type 2 diabetes demonstrate reduced circulating glucagon-like peptide 1 (GLP-1) concentrations, particularly in response to meals. Whether this phenomenon is a causative factor or occurs secondarily in patients with preexisting hyperglycemia is uncertain.

Insulin Resistance

With few exceptions (e.g., a subgroup of African American patients), type 2 diabetes is characterized by impaired insulin action. The insulin dose-response curve for augmenting glucose uptake in peripheral tissues is shifted to the right, representing decreased insulin sensitivity, and maximal response is reduced, particularly in the setting of severe hyperglycemia. Other insulin-dependent processes, such as inhibition of hepatic glucose production and lipolysis, also show reduced sensitivity to insulin. The mechanisms responsible for insulin resistance remain poorly understood. Studies suggest that an important contributory factor is impaired mitochondrial function and the resulting accumulation of free fatty acids and their metabolites in insulin-responsive tissues ("ectopic fat theory").

Early studies of insulin resistance focused on defects of the insulin receptor. Mutation of the insulin receptor gene can produce leprechaunism (Chapter 212), characterized by severe growth retardation, extreme insulin resistance, and early infant death. Other syndromes related to mutated insulin receptors include the Rabson-Mendenhall syndrome, also associated with tooth and nail abnormalities and pineal gland hyperplasia, and "type A insulin resistance," most often affecting young females with acanthosis nigricans, polycystic ovaries, and hirsutism. Another example of extreme insulin resistance involves the presence of anti-insulin receptor antibodies; it is associated clinically with acanthosis nigricans and a number of autoimmune phenomena. These disorders are not involved in most patients with or at risk for type 2 diabetes.

Although insulin receptors may be abnormal in a few type 2 patients, defects in more distal "postreceptor" pathways play a far greater role in insulin resistance. One important aspect of insulin resistance is a reduced capacity for translocation of GLUT 4 to the cell surface in muscle cells. A separate defect in glycogen synthesis also is likely to be present. Whether the defects uncovered are primary or secondary to the disturbance in glucose metabolism is not entirely known, but the bulk of the experimental data would suggest that insulin resistance is a primary defect in this disease. Potentially, a variety of genetic abnormalities in cellular transduction of the insulin signal may individually or in concert produce an identical clinical phenotype. It is uncertain whether mechanisms of insulin resistance in nonobese patients are identical to those of their obese counterparts; however, the coexistence of obesity clearly accentuates the severity of the resistant state. In particular, upper body or abdominal (compared with lower body or peripheral) obesity is associated with insulin resistance and diabetes. Intra-abdominal visceral fat

deposits, detected by computed tomography or magnetic resonance imaging, have a higher lipolytic rate than peripheral fat and are more resistant to insulin. The resulting increase in circulating free fatty acid levels promotes fat deposits within the liver and muscle, worsening insulin resistance. Intracellular free fatty acid metabolites appear to promote insulin resistance through complex mechanisms involving serine (rather than tyrosine) phosphorylation of insulin signaling molecules. Disordered cortisol secretion or enhanced local cortisol generation from relatively inactive cortisone in the adipocyte or hereditary factors may also influence the distribution of body fat, the latter contributing an additional genetic influence on the expression of disease.

Adipocyte-Derived Hormones and Cytokines

Adipocytes, once thought of as inert fat storage cells, are now known to produce a number of metabolically active hormones that may affect insulin sensitivity (Chapter 227). Leptin, for example, acts on the hypothalamus to promote satiety and energy expenditure and may accelerate glucose metabolism. Adiponectin, another fat-derived hormone, circulates at levels that correlate inversely with both adiposity and degree of insulin resistance. The administration of adiponectin to obese mice causes a transient, dose-dependent, insulin-independent decrease in circulating glucose levels; adiponectin also improves insulin sensitivity by decreasing triglycerides in the liver and muscle, probably by increasing the expression of molecules (e.g., adenosine monophosphate kinase) involved in fatty acid combustion and energy dissipation. Weight loss paradoxically increases adiponectin, as does pharmacologic therapy that improves insulin sensitivity. Interestingly, adiponectin may have some beneficial effects on atherosclerosis, which may explain at least to some degree the increased prevalence of cardiovascular disease in obesity and type 2 diabetes. Finally, adipose tissue is an abundant source of the cytokine tumor necrosis factor-α, which is known to inhibit muscle glucose metabolism by inducing serine phosphorylation of insulin-signaling molecules. The precise impact that these and other adipocyte-derived factors (resistin, angiotensinogen, interleukin-6, transforming growth factor-β, and plasminogen activator inhibitor 1) exert on insulin resistance and on diabetes and its vascular complications is an active area of scientific research but has yet to be firmly established.

Glucotoxicity and Lipotoxicity

Hyperglycemia per se impairs the β-cell response to glucose and promotes insulin resistance. Reversal of this "glucotoxicity" can disrupt the vicious circle that perpetuates hyperglycemia (see Fig. 237-1). Similarly, circulating lipids can also adversely affect glucose metabolism; increased free fatty acid levels accelerate hepatic gluconeogenesis, inhibit muscle glucose metabolism, and impair pancreatic β-cell function. As is the case with glucotoxicity, the reversal of lipotoxicity can rapidly improve metabolic control and facilitate favorable therapeutic outcomes.

What Is the Primary Defect?

It remains uncertain whether insulin resistance or defective insulin secretion is the primary defect in type 2 diabetes (Fig. 237-2). This issue is difficult to resolve once diabetes has developed; therefore, research attention has focused primarily on high-risk nondiabetic subjects. Studies in high-risk populations (e.g., Pima Indians, Mexican Americans) have suggested that insulin resistance is the initial defect; similar findings have been reported in first-degree relatives of type 2 diabetic patients and in healthy prediabetic offspring of two diabetic parents. Interestingly, hyperinsulinemia has been detected in prediabetic subjects as early as one to two decades before clinical onset, suggesting that the development of diabetes can be exceedingly slow. Although these studies support the view that insulin resistance generally antedates insulin deficiency, the presence of insulin resistance alone is generally insufficient to generate hyperglycemia; this implies that for diabetes to occur, impaired insulin secretion is required (see Fig. 237-2). It is possible that the appearance of a secretory defect is a secondary phenomenon resulting from "β-cell exhaustion," excess fatty acid delivery, amylin accumulation, or factors associated with β-cell growth. Perhaps more likely, diminished insulin secretion may result from an independent defect that becomes evident only on chronic β-cell stimulation, such as a subtle genetic defect in insulin signaling or β-cell replication.

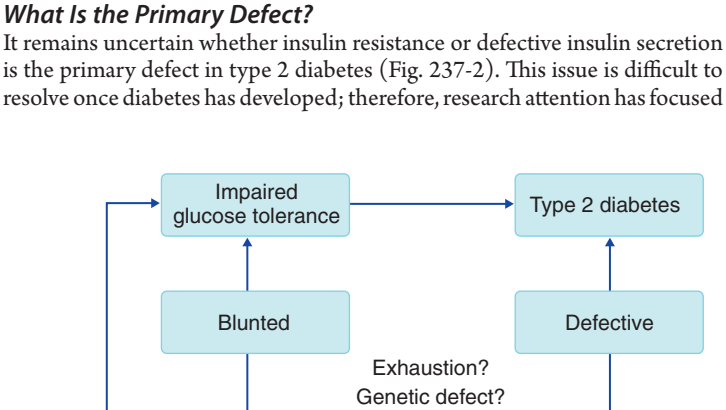

FIGURE 237-2. A proposed sequence of events leading to the development of type 2 diabetes. Insulin resistance resulting from genetic influences, central obesity, inactivity, or a combination of these factors leads over time to a progressive loss of the β cell's capacity to compensate for this defect.

The sequence of events described—underlying insulin resistance followed by a secretory defect—is common but clearly does not describe all type 2 diabetic patients. For example, a subgroup of African American patients exhibits little or no insulin resistance. (An insulin deficiency–predominant phenotype is also encountered not infrequently in clinical practice in other racial groups, although, admittedly, many of these individuals may potentially have a slowly progressive form of type 1 diabetes.) In addition, diminished glucose-stimulated insulin secretion is seen in women with gestational diabetes in whom type 2 diabetes later develops. Finally, the demonstration of functional β-cell-associated gene mutations in patients with MODY indicates that primary β-cell defects are capable of producing a similar phenotype. Taken together, these lines of evidence strongly suggest that type 2 diabetes cannot be explained by insulin resistance alone or indeed by any single pathogenic mechanism.

DIAGNOSIS

The diagnosis of diabetes mellitus is straightforward when classic symptoms of polyuria, polydipsia, and unexplained weight loss are present. In these cases, a random (or "casual") plasma glucose measurement of 200 mg/dL or more is sufficient to confirm the diagnosis. Although glycosuria is strongly suggestive of diabetes, urine test results should never be used exclusively to diagnose diabetes because an altered renal threshold for glucose excretion can produce similar findings. If suspected diabetes is not confirmed through random glucose determination, additional diagnostic testing should be performed.

An 8-hour (overnight) fasting plasma glucose measurement is most convenient; diabetes is established if fasting glucose levels are 126 mg/dL or higher on two separate occasions. Alternatively, a 75-g oral glucose tolerance test may be employed. The oral glucose tolerance test should be performed after an overnight fast, with use of a glucose load containing 75 g of anhydrous glucose dissolved in water; 2-hour postload glucose levels of 200 mg/dL or higher confirm the presence of diabetes. An important note about the oral glucose tolerance test: although it is able to detect diabetes in its earliest stage, this test should be performed under controlled conditions to ensure its accuracy. Common factors that can nonspecifically interfere with the oral glucose tolerance test result include antecedent dietary carbohydrate restriction, bedrest or severe inactivity, medical or surgical stress, drugs (e.g., thiazides, β-blockers, glucocorticoids, phenytoin), smoking, and anxiety from repeated phlebotomies. As a result, the oral glucose tolerance test should not be performed in acutely ill patients, and patients undergoing the oral glucose tolerance test should ideally stop smoking and consume a liberal carbohydrate diet for at least 3 days before testing. More recently, with global standardization of HbA_{1c} assays, this test is now widely endorsed as an acceptable, and more convenient, screening test for diabetes, with the diagnostic cutoff point set at 6.5%. This threshold was chosen because it correlates with the presence of retinopathy, similar to the diagnostic thresholds for fasting and 2-hour plasma glucose.

The current (2010) American Diabetes Association (ADA) criteria (see Table 237-1) for the diagnosis of diabetes mellitus are as follows. In the absence of unequivocal hyperglycemia with acute metabolic decompensation, each criterion should be confirmed by repeated testing on a separate occasion:

1. Classic symptoms of diabetes (polyuria, polydipsia, and unexplained weight loss) *plus* random plasma glucose concentration ≥ 200 mg/dL (≥11.1 mmol/L); *or*

2. Fasting (≥8-hour) plasma glucose concentration ≥126 mg/dL (≥7.0 mmol/L); *or*
3. A 2-hour postload plasma glucose concentration ≥200 mg/dL (≥11.1 mmol/L) during a 75-g oral glucose tolerance test; *or*
4. An HbA_{1c} ≥6.5% (nonfasting).

In certain scenarios, clinicians may have available to them results from easily obtained tests, namely, fasting plasma glucose and HbA_{1c}. Not uncommonly, the results of these tests may be discordant. That is, a patient may have an HbA_{1c} of 6.5% or greater but a "subdiabetic" fasting plasma glucose, or vice versa. In this circumstance, it is recommended that the diagnosis default to the most abnormal test because both measures correlate with retinopathy risk.

The two traditional risk categories for diabetes, IFG and IGT, are associated with an increased risk for development of diabetes as well as subsequent cardiovascular events, with IGT being a much stronger predictor for both sequelae. Diabetes mellitus is established if fasting glucose levels are 126 mg/dL or higher; however, a fasting glucose concentration of 99 mg/dL is now designated the upper limit of normal. Patients with fasting glucose levels between 100 and 125 mg/dL are classified as having IFG (see Table 237-1). Because individuals with IFG may exhibit significant postprandial hyperglycemia, a 75-g oral glucose tolerance test may be considered to rule out diabetes, although the need for this will be less, now that HbA_{1c}, which captures both fasting and postprandial hyperglycemia, is recommended as a diagnostic test. During the 75-g oral glucose tolerance test, 2-hour postload glucose concentrations of 200 mg/dL or higher are diagnostic of diabetes; patients with levels between 140 and 199 mg/dL are defined as having IGT. Patients displaying IFG and IGT simultaneously have a greater risk for development of diabetes. It should be noted that the thresholds that define these "states" are somewhat arbitrary because the risk for diabetes actually runs along a continuum. In fact, the World Health Organization, which is in accord with the other diagnostic thresholds, has kept the lower bound of the IFG range at 110 mg/dL because individuals with levels above this range appear to be at increased cardiovascular risk, similar to those with IGT. As noted previously, the ADA has also recently endorsed the use of the HbA_{1c} for diabetes screening, based on the recommendations of the International Expert Committee, with a diagnostic threshold of 6.5% or higher. In so doing, it considered elevated but not frankly diabetic levels to represent high risk, defining this range as 5.7 to 6.4%. Table 237-1 summarizes the diagnosis of IFG, IGT, and overt diabetes mellitus. Patients with IFG or IGT or increased glycohemoglobin, each of which may be referred to as *prediabetes*, should be advised about healthy lifestyle changes, including diet and exercise, and should be screened annually for progression to diabetes. In very high-risk individuals, such as those with both IFG and IGT, a Consensus Statement from the ADA and the European Association for the Study of Diabetes (EASD) has proposed that, in addition to lifestyle change, metformin be considered as adjunctive therapy (see Prevention).

The clinical utility and cost-effectiveness of screening for diabetes mellitus have never been directly demonstrated. However, because patients with diabetes may harbor the disease for many years before symptoms are appreciated, the ADA has endorsed the screening at 3-year intervals beginning at 45 years of age (Table 237-2). More frequent screening is advised for high-risk individuals, such as those with a personal history of IFG, IGT, gestational diabetes mellitus, obesity, hypertension, or dyslipidemia, patients in high-risk ethnic groups, and patients with first-degree relatives with diabetes. In most cases, a fasting plasma glucose level has been the screening test of choice; however, the oral glucose tolerance test has the advantage of detecting patients with IGT and early diabetes. The more convenient HbA_{1c} test will likely be used more often now that it is endorsed as a screening test by the ADA, but there is little information about its predictive value across various groups of patients.

Gestational Diabetes Mellitus

Because even mild glucose elevations can have serious adverse effects on a developing fetus, an aggressive screening approach is recommended during pregnancy (Chapter 247). Women with a high clinical risk of gestational diabetes (personal history of gestational diabetes mellitus, obesity, glycosuria, or a strong family history of diabetes) should undergo screening as soon as possible after conception; in these patients, screening *before* pregnancy is preferred if possible. At 24 to 28 weeks of gestation, screening is recommended for *all* pregnant women, except those in the lowest risk category who meet *all* of the following clinical characteristics:

TABLE 237-2 CRITERIA FOR DIABETES SCREENING IN ASYMPTOMATIC INDIVIDUALS

1. Testing should be considered in all adults who are overweight (BMI > 25 kg/m^{2*}) and have additional risk factors:
   - Physical inactivity
   - A first-degree relative with diabetes
   - High-risk ethnic population (e.g., African American, Hispanic American, Native American, Asian American, Pacific Islander)
   - Delivered a baby weighing more than 9 pounds or diagnosed with gestational diabetes mellitus
   - Systemic hypertension (blood pressure > 140/90 mm Hg or on antihypertensive therapy)
   - High-density lipoprotein cholesterol level < 35 mg/dL or triglyceride level > 250 mg/dL
   - Polycystic ovary syndrome
   - Hemoglobin A_{1c} ≥ 5.7%, impaired glucose tolerance or impaired fasting glucose on prior testing
   - Other clinical conditions associated with insulin resistance (e.g., severe obesity, acanthosis nigricans)
   - History of cardiovascular disease
2. If none of the above criteria are present, screening for diabetes should begin at age 45 years.
3. If the results are normal, screening should be repeated at least every 3 years. Depending on initial results and risk status, more frequent testing may need to be considered.

*In some ethnic groups, such as Asians, at-risk body mass index (BMI) may be lower.
Modified from American Diabetes Association. Diagnosis and classification of diabetes mellitus. *Diabetes Care.* 2010;33(Suppl. 1):S14.

- Age younger than 25 years
- Weight normal before pregnancy
- Member of an ethnic group with a low risk for gestational diabetes (e.g., whites)
- No known diabetes in first-degree relatives
- No history of abnormal glucose tolerance
- No history of poor obstetric outcome

In pregnant women, a casual plasma glucose level of 200 mg/dL or higher or a confirmed fasting plasma glucose level of 126 mg/dL or higher establishes the diagnosis of gestational diabetes mellitus and precludes the need for a glucose challenge. In the absence of overt hyperglycemia, a screening 1-hour 50-g glucose challenge test should be performed between 24 and 28 weeks of gestation. If the fasting glucose level is 105 mg/dL or higher or the 1-hour postload value is 140 mg/dL or higher, a diagnostic 3-hour 100-g oral glucose tolerance test is indicated. Gestational diabetes is then diagnosed if two or more values equal or exceed the upper limits of normal: fasting, 95 mg/dL; 1 hour, 180 mg/dL; 2 hour, 155 mg/dL; and 3 hour, 140 mg/dL. To save time and effort, proceeding directly to the 100-g diagnostic oral glucose tolerance test is an acceptable alternative, particularly in those deemed at higher risk. The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study included more than 25,000 pregnancies, examining adverse clinical outcomes associated with mild elevations in plasma glucose during oral glucose tolerance testing. The investigators found that increases in plasma glucose above 75 mg/dL fasting, 105 mg/dL at 1 hour, and 90 mg/dL at 2 hours were associated with a higher risk for several adverse fetal and maternal outcomes (e.g., increased birthweight, primary cesarean delivery, and neonatal hypoglycemia). Importantly, no specific glucose thresholds could be identified, suggesting that adverse outcomes occur over a continuum of blood glucose elevations during pregnancy. These data will likely lead to a reevaluation of the current screening guidelines and diagnostic categories for gestational diabetes.

TREATMENT Rx

Complications

As discussed in Chapter 236, the Diabetes Control and Complications Trial (DCCT), involving solely patients with type 1 diabetes, conclusively determined that improved glucose control reduces the risk for microvascular complications. It was assumed but not entirely known if the same relationship would apply to patients with type 2 diabetes. Ultimate evidence for such a benefit came from the United Kingdom Prospective Diabetes Study (UKPDS).[1] The UKPDS initially recruited 5102 patients with newly diagnosed type 2 diabetes; after 3 months of diet therapy, the 3867 patients with fasting

glucose levels between 6.1 and 15.0 mmol/L (110 and 270 mg/dL) were randomized to a more intensive regimen, consisting of sulfonylurea or insulin, or maintained on the conventional dietary regimen, focused primarily on symptom reduction. Subjects were monitored for an average of 10 years. Although glycemic control gradually deteriorated in all groups, the intensified treatment group had lower overall mean HbA_{1c} levels than their conventionally treated counterparts (7.0% vs. 7.9%). This modest improvement was associated with 25% and 12% reductions in all microvascular complications ($P < .001$) and any diabetes-related event ($P = .03$), respectively. The intensified treatment group also experienced a 16% reduction in a combined end point—nonfatal or fatal myocardial infarction or sudden death—that did not quite reach statistical significance ($P = .052$). Epidemiologically, a continuous relationship was again noted between glycemic control and diabetic complications. Also similar to the DCCT, no glycemic threshold for microvascular complications was observed. In a smaller substudy within the UKPDS, 753 overweight patients were randomized to metformin versus diet. Metformin-treated subjects experienced relative risk reductions of 32% for any diabetes related end point ($P = .002$), 39% for myocardial infarction ($P = .01$), 42% for diabetes-related death ($P = .02$), and 36% for all-cause mortality ($P = .01$). Moreover, among patients allocated to intensive control, metformin had a greater effect than sulfonylureas or insulin on any diabetes-related end point, stroke, and overall mortality. These data suggested a cardiovascular benefit to metformin in overweight diabetic patients compared with either sulfonylureas or insulin.

In the more recent 10-year follow-up study of 3277 patients from the original UKPDS cohort, clinical outcomes were assessed using the original treatment assignment.[2] Differences in HbA_{1c} were lost between groups after the first year of follow-up, as occurred in the DCCT long-term follow-up study. Despite this, however, relative risk reductions for any diabetes-related end point (9%, $P = .04$) and microvascular disease events (24%, $P = .001$) persisted in the sulfonylurea-insulin cohort. In addition, as more events occurred over time, significant relative risk reductions for myocardial infarction (15%, $P = .001$) and all-cause mortality (13%, $P = .007$) emerged. In the metformin-assigned subjects, risk reductions of 21% ($P = .01$) were maintained throughout the follow-up period for any diabetes-related event; 33% ($P = .005$) for myocardial infarction, and 27% ($P = -.002$) for all-cause mortality. By comparison, more aggressive treatment to lower HbA_{1c} below 6.0% in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial increased 5-year mortality despite reducing the risk of nonfatal myocardial infarction.[3]

What conclusions can be drawn from these various studies? The primary message is that "glucose matters"—particularly when treated early in the course of the disease and especially for microvascular complications. In both type 1 and type 2 diabetes patients who are willing and able to participate actively in their management, the goal should be to achieve the best possible level of glycemic control as rapidly as possible without undue risk. These studies also demonstrate that most patients benefit from lower glucose levels, even if normalization is not achieved. For most type 2 patients, effective glucose reductions can be achieved by diet, oral agents, or less complicated insulin regimens than are required in type 1 diabetes. Although a statistically significant benefit on macrovascular outcomes could not be detected in the sulfonylurea-insulin tight control arm of the UKPDS, this may have been limited by the HbA_{1c} convergence during follow-up study of the initially randomized groups. Metformin had a more convincing beneficial effect in this regard. It is also noteworthy that extensive epidemiologic data have shown a linear relationship between glycemia and cardiovascular events—even into the "normal" range for glucose. Accordingly, it was theorized by some that in order to achieve substantive cardiovascular risk reduction by glycemic control, euglycemia needed to be achieved. This was the hypothesis tested by an important trio of clinical cardiovascular trials recently reported in patients with type 2 diabetes (see later). Finally, a central conclusion from the UKPDS was that β-cell function continues to decline after the diagnosis of diabetes is made, mandating more aggressive treatment regimens.

Glycemic Control and Cardiovascular Disease Outcomes

Although there is a strong and irrefutable epidemiologic association between glycemic control and cardiovascular events and mortality, clinical trial data to support an effect of glucose control to reduce macrovascular events has been generally elusive. Some had proposed that this phenomenon might reflect a failure of earlier trials to normalize glycemia, which might actually be required to influence the atherosclerotic process once it been initiated. As a result, several large randomized clinical trials (ACCORD,[4] Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation [ADVANCE],[5] and the Veterans Affairs Diabetes Trial [VADT][6]) were initiated in an attempt to answer this question. Each trial examined the potential cardiovascular benefit of more intensive glucose control (HbA_{1c} target, 6 to 6.5%) compared with standard therapy over a period of 3 to 5 years in patients with long-standing type 2 diabetes, most of whom had evidence of cardiovascular disease (CVD) (Table 237-3). In each circumstance, the study failed to reduce CVD outcomes. In ADVANCE, the primary end point, a composite of both microvascular and macrovascular events, was modestly reduced in the intensive control arm, but this was driven solely by a reduction in renal outcomes. On the other hand, in ACCORD, all-cause mortality was actually *increased* by 22% in the intensive control cohort, mainly driven by increased cardiovascular mortality.[3] The explanation for this finding remains controversial, however. Hypoglycemia was definitely more common in patients who died in both intensive and standard control groups, but subsequent analyses have not been able to demonstrate a precise cause-and-effect relationship. Whether the results may have reflected significant weight gain or the use of complex polypharmaceutical regimens (most participants in ACCORD's intensive arm were receiving at least three oral agents simultaneously with or without aggressive insulin strategies) is also not known.

Importantly, the results of ACCORD, ADVANCE, and VADT do not invalidate the earlier findings from the DCCT and UKPDS. Those studies were quite different insofar as they enrolled different types of patients—those with type 1 diabetes in the DCCT and newly diagnosed type 2 patients without underlying CVD in the UKPDS. Additionally, the patients in the UKPDS were randomized to "intensive control" strategies that were not nearly as stringent as those pursued in the more recent trials, and in the DCCT, the comparator "conventional control" group essentially had poorly controlled type 1 diabetes. So, a rational synthesis of the data would appear to be that the target of lowering HbA_{1c} to approximately 7% will result in major reductions in microvascular disease risk and, over time, a modest benefit on cardiovascular end points in patients in the early stages of the disease without preexisting cardiovascular complications. However, more intensive control in an attempt to near-normalize glucose levels, especially if applied to older patients with significant risk for or preestablished cardiovascular disease, leads to no further benefit and to apparent adverse effects[3,4] over a treatment duration of 3 to 5 years. Given that these trials examined patients at a later stage of diabetes, they cannot answer the question of whether near-normalization of blood glucose control may have a cardiovascular benefit when initiated at the time of diagnosis and maintained for a longer duration, before vascular complications can become established.

TABLE 237-3 MAJOR CLINICAL TRIALS TO TEST THE ASSOCIATION BETWEEN GLYCEMIC CONTROL AND CARDIOVASCULAR DISEASE OUTCOMES

STUDY PARAMETER	ACCORD	ADVANCE	VADT
No. of subjects	10,251	11,140	1791
Mean age (yr)	62	66	60
Body mass index (kg/m^2)	32	28	31

Glucose control and vascular complications in veterans with type 2 diabetes. *N Engl J Med*. 2009;360:129-139.

General Measures

As in individuals with type 1 diabetes, the primary long-term goals in type 2 patients are to minimize complications and to preserve the patient's sense of clinical well-being. Glucose control should not be addressed in a vacuum. Lifestyle modification should be the primary focus of the patient's care. Also, aggressive lowering of lipids and blood pressure should be routinely incorporated into the treatment program.

In many type 2 diabetic patients, diet[7] and exercise[8] are the only therapeutic interventions required to restore metabolic control. As a result, drug therapy is not required in all patients and may be avoided in motivated individuals who have embraced the important concepts of a healthy lifestyle and can achieve their glycemic targets nonpharmacologically. However, it should also be realized that diabetes tends to be progressive, and the early use of antihyperglycemic medications is usually a wise maneuver. Indeed, a consensus statement, sponsored by the ADA and EASD on the treatment of hyperglycemia in type 2 diabetes, has advised using metformin (barring any contraindications) along with lifestyle change at diagnosis.

Diet

Irrespective of initial weight, modest weight reduction (on the order of 5 kg) in obese diabetic patients leads to improved glycemic control. The dramatic impact of weight loss is mediated by changes in insulin-responsive tissues as well as by enhanced β-cell activity; insulin resistance diminishes, glucose production declines, and lower glucose levels improve glucose-stimulated insulin secretion. The beneficial effects of weight loss are not restricted to glucose; dietary therapy also yields improved lipoprotein profiles and systemic blood pressure. In general, it matters little how weight loss is achieved, provided good health is preserved and adequate nutrition is maintained. Successful weight loss (Chapter 227) is best achieved by the combination of a supportive environment that emphasizes the gradual achievement of goals, regular exercise to increase energy expenditure, and long-term behavior modification. Please see Table 236-3 in Chapter 236 for lifestyle changes advised for patients with diabetes.

In sedentary diabetic patients, maintenance calorie requirements can be as low as 20 to 25 kcal per kilogram of body weight per day. In these individuals, depending on baseline weight, the classically prescribed 1800-kcal diet is often ineffective in producing weight loss. It is sensible to begin with a nutritionally sound, individually tailored diet that is aimed at producing a calorie deficit of approximately 500 kcal/day. Because a calorie deficit of about 3500 kcal is required to lose 1 pound of body fat, weight loss by this method can be expected at 1 pound per week. Although this might sound too gradual for the individual eager to lose weight quickly, progressive success at this rate (which is admittedly, very difficult) will result in substantial weight loss after 1 year. For obese patients with a history of multiple failed weight loss attempts, very low calorie diets (<1000 kcal/day) can be useful when they are carried out under medical supervision. Orlistat, a gastrointestinal lipase inhibitor that reduces dietary fat absorption, can be a modestly effective adjunct for achieving weight loss in some patients; it may also improve glycemic control and lipoprotein profiles. It is associated, however, with unpleasant side effects. Sibutramine is another marketed weight loss agent, but it, too, has limited efficacy, may increase blood pressure, and in a large long-term clinical trial was associated with a small increase cardiovascular events. Most patients are unable to maintain low-calorie diets for an extended period; if they are successful, most patients will resume higher-calorie diets and regain lost weight. In patients with type 2 diabetes, metabolic factors may also contribute to difficulty maintaining weight loss. Dieting reduces glycosuria and therefore lessens urinary calorie loss. Also, the expected decrease in basal metabolic rate during weight loss is accentuated in diabetic patients because weight loss reverses both accelerated gluconeogenesis and the futile cycling of substrates; these conditions, commonly seen in poorly controlled diabetes, decrease use of excess energy that has been ingested in the hyperglycemic state.

A popular alternative to diet is bariatric surgery; both Roux-en-Y gastric bypass and gastric banding procedures are being performed with increased frequency in obese patients both with and without diabetes. Without question, these techniques result in greater degrees of weight loss than are usually achieved through diet or medications. Both short-term and long-term safety considerations persist, although several longitudinal studies have suggested an overall health benefit. Importantly, in patients with type 2 diabetes, very often glucose levels normalize postoperatively, and antihyperglycemic therapy can be stopped or at least markedly curtailed. The rapidity of the improvement in glucose levels, which occurs before substantial weight loss has occurred, suggests a direct metabolic benefit, perhaps owing to rapid onset of severe calorie deprivation or altered transit of nutrients through the bowel, or both, which might be promoting the actions of incretins on glucose metabolism.

Even when diabetic patients cannot lose weight, a careful meal plan is a valuable tool for reducing their risk for cardiovascular disease. This benefit is best achieved by restricting saturated fats and cholesterol and by raising the dietary content of carbohydrates and monounsaturated fats. It is now appreciated that a diet that is relatively high in carbohydrate (>45 to 50%) may improve insulin action and glycemic control, particularly in patients with mild hyperglycemia. In patients with more severe fasting hyperglycemia or with triglyceride elevations aggravated by high-carbohydrate diets, reduced carbohydrate intake (<45% of total calories) and greater reliance on monounsaturated fats may be preferable. It has also been assumed that carbohydrate intake should be focused on complex carbohydrates (starches) and that sucrose should be avoided; however, evidence supporting these assumptions is scarce. Simple sugars raise glucose levels to an extent similar to that with complex carbohydrates; thus, total carbohydrate intake, rather than type of carbohydrate, should be the primary consideration. Fiber-containing carbohydrates such as oats, legumes, and fruit pectin may also be beneficial because fiber blunts meal-induced glucose excursions by delaying gastric emptying and carbohydrate absorption. Fiber helps prevent constipation and may also contribute to lowering of triglyceride and low-density lipoprotein (LDL) cholesterol levels.

Diabetic patients with normal lipid profiles are encouraged to follow the recommendations of the National Cholesterol Education Program (NCEP) by limiting total fat intake to less than 30% of total calories, with less than 10% of calories as saturated fat and less than 300 mg/day of dietary cholesterol (see Table 237-3). If LDL levels are elevated, stricter recommendations apply (NCEP Step II diet), with less than 7% of calories as saturated fat and less than 200 mg/day of dietary cholesterol. Despite a lack of supporting scientific evidence, moderation of dietary protein is also currently recommended for patients with diabetes; this issue assumes much greater importance in patients with proteinuria and overt diabetic nephropathy.

Exercise

Regular exercise is a powerful (and often forgotten) adjunct in the treatment of type 2 diabetes. Long-term studies demonstrate consistent beneficial effects of regular exercise on carbohydrate metabolism and insulin sensitivity that can be maintained for several years. Exercise also facilitates weight loss and its maintenance, which further improves glycemic control and also has beneficial effects on cardiovascular risk and general well-being. Regular exercise lowers triglyceride-rich very low density lipoprotein (VLDL) levels, raises high-density lipoprotein (HDL) levels, and improves fibrinolytic activity. In general, "moderate" levels of exercise should be prescribed most days of the week (see Table 236-3 in Chapter 236). Limitations may be imposed by preexisting coronary or peripheral vascular disease, proliferative retinopathy, peripheral or autonomic neuropathy, and poor glycemic control.

Medical Therapy

Oral Glucose-Lowering Agents

Sulfonylureas were the only oral agents available in the United States for more than four decades. Over the decade and a half since the 1995 approval of metformin by the U.S. Food and Drug Administration (FDA), many new classes of oral agents have become available for the treatment of type 2 diabetes (Table 237-4 and Fig. 237-3). Indeed, at present there are as many classes to treat glucose in type 2 diabetes as there are antihypertensive medication categories. Currently available noninsulin classes include the sulfonylureas, nonsulfonylurea insulin secretagogues (glinides), biguanides, thiazolidinediones, α-glucosidase inhibitors, glucagon-like peptide (GLP)-1 agonists, amylin mimetics, dipeptidyl peptidase (DPP)-4 inhibitors, bile acid sequestrants, and dopamine-2 agonists. Oral agents are indicated in patients in whom diet and exercise fail to achieve treatment goals and may be favored over insulin in older patients with relatively mild degrees of hyperglycemia. Patients with more severe hyperglycemia may require insulin during the initial phases of treatment; once glucose levels have stabilized and the "toxic" effects of severe hyperglycemia on β-cell function and insulin action have been minimized, many of these patients may then be converted to oral agents. Of these agents, rosiglitazone must be used cautiously because of its increased risk of heart failure and myocardial infarction compared with other agents.[9,10] By comparison, pioglitazone appears to be protective.[11]

For a detailed review of the oral antihyperglycemic agents, refer to the online version of this chapter. Table 237-4 summarizes the key aspects of each drug class.

Sulfonylureas

Sulfonylureas are insulin "secretagogues" that act through specific receptors on the β-cell membrane. Drug-receptor binding acts to close adenosine triphosphate-dependent potassium channels, resulting in cellular depolarization, calcium influx, and translocation of insulin secretory granules to the β-cell surface. The resulting release of insulin into the portal vein rapidly suppresses hepatic glucose production and later facilitates peripheral glucose utilization. Insulin resistance may diminish as well, but as a secondary consequence of the reversal of glucotoxicity. Because sulfonylureas rely on a preserved β-cell response, they are ineffective in the treatment of type 1 diabetes. They are also ineffective in type 2 diabetic patients with markedly impaired β-cell function.

Although the sulfonylureas differ in relative potency, effective dosage, metabolism, and duration of action, these differences have marginal significance from a clinical standpoint (see Table 237-3). Each drug has similar hypoglycemic effects; at maximally effective doses, an average drop in HbA_{1c} of 1 to 2% is expected, correlating to average fasting plasma glucose reductions of 40 to 80 mg/dL. Drugs that are hepatically metabolized and have a shorter

TABLE 237-4 ORAL AGENTS AVAILABLE FOR TREATMENT OF DIABETES MELLITUS

AGENT	EXAMPLES	MECHANISM	ACTION	↓ IN HEMOGLOBIN A_{1c} (%)	ADVANTAGES	DISADVANTAGES	COST
Sulfonylureas	*First generation:* Chlorpropamide Tolazamide Tolbutamide *Second generation:* Glyburide Glipizide Glimepiride	Closes K_{ATP} channels	↑ Pancreatic insulin secretion	1-2%	↓ Microvascular risk Convenience	Hypoglycemia Weight gain May blunt myocardial ischemic preconditioning ? β-cell "exhaustion"	$
Glinides	Repaglinide Nateglinide	Closes K_{ATP} channels	↑ Pancreatic insulin secretion	1-1.5%	More physiologic ↓ Postprandial glucose	Hypoglycemia, weight gain, May blunt myocardial ischemic preconditioning ? β-cell "exhaustion" Dosing frequency	$$$
Biguanides	Metformin	Activates AMPK	↓ Hepatic glucose production	1-2%	Weight loss/weight neutrality No hypoglycemia ↓ CVD	Diarrhea, abdominal cramping Lactic acidosis risk (rare) Vitamin B_{12} deficiency Multiple contraindications to consider (e.g., CKD)	$
Thiazolidinediones	Rosiglitazone Pioglitazone	Activates PPAR-γ	↑ Peripheral insulin sensitivity	0.5-1.5%	No hypoglycemia β-cell preservation ↑ HDL-C ↓ Triglycerides ? ↓CVD (pioglitazone)	Weight gain Edema/heart failure ↑ Bone fractures (women) ↑ LDL-C ? ↑CVD (rosiglitazone)	$$$
α-Glucosidase inhibitors	Acarbose Miglitol	Blocks SB α-glucosidase	↓ Intestinal carbohydrate absorption	0.5-1%	? ↓ CVD Nonsystemic medication ↓ Postprandial glucose	Gas, abdominal bloating Dosing frequency	$$
GLP-1 receptor agonists	Exenatide Liraglutide	Activates GLP-1 receptors	↑ Insulin secretion ↓ Glucagon secretion Slows gastric emptying ↑ Satiety	1%	Weight loss ? β-cell preservation ? Cardiovascular benefits	Nausea/vomiting ? Pancreatitis ? C-cell hyperplasia/tumors Injectable	$$$
Amylin mimetics	Pramlintide	Activates amylin receptors	↓ Glucagon secretion Slows gastric emptying ↑ Satiety	0.5%	Weight loss ↓ Postprandial glucose	Nausea/vomiting Dosing frequency Injectable	$$$
DPP-4 inhibitors	Sitagliptin Saxagliptin	Inhibits DPP-4, ↑ endogenous incretins	↑ Insulin secretion ↓ Glucagon secretion	0.5-0.8%	No hypoglycemia	? Urticaria/angioedema ? Pancreatitis	$$$
Bile acid sequestrants	Colesevelam	Binds bile acid cholesterol	Unknown	0.5%	No hypoglycemia ↓LDL-C	Constipation ↑ Triglycerides	$$$
D2 agonists	Bromocriptine	Activates dopaminergic receptors	Alters hypothalamic regulation of metabolism ↑Insulin sensitivity	0.5%	No hypoglycemia	Dizziness/syncope Nausea Fatigue Rhinitis	?

AMPK = adenosine monophosphate–activated protein kinase; ATP = adenosine triphosphate; CKD = chronic kidney disease; CVD = cardiovascular disease; GLP = glucagon-like peptide; D2 = dopamine-2; DPP = dipeptidyl peptidase; HDL-C = high-density lipoprotein cholesterol; LDL-C = low-density lipoprotein cholesterol; PPAR = peroxisome proliferator–activated receptor; SB = small bowel.

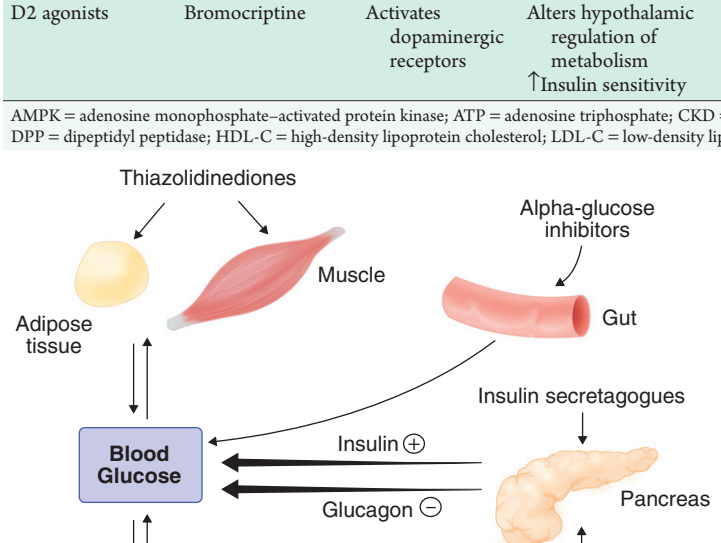

FIGURE 237-3. Sites of action of the most widely used oral antihyperglycemic agents.

duration of action have advantages in elderly patients with impaired renal function (who are more vulnerable to hypoglycemia) but may be less effective in practice because of noncompliance with multiple dosing schedules. Conversely, longer-acting agents can be dosed once daily, enhancing compliance but increasing the risk for prolonged hypoglycemia. After the appropriate drug is chosen, treatment is initiated at low doses, with dose increases every 1 to 2 weeks until either treatment goals are met or "maximally effective" doses are reached. Note that for all sulfonylureas, efficacy plateaus at about 50% of the listed maximal dose; above these maximally effective doses, little clinical benefit is derived from dose escalation, and additional therapies should be considered.

Most patients with type 2 diabetes initially respond to sulfonylureas with improved glycemic control. However, 10 to 20% of patients show little or no response and are referred to as primary drug failures. Many other patients experience the loss of drug effect after years of successful therapy; these secondary drug failures occur at rates of 5 to 10% per year mainly because of progressive β-cell failure, which is a well-recognized feature of the underlying disease process. Whether sulfonylurea drugs tax the β cell and hasten its demise (β-cell exhaustion) is a point of controversy. Recent studies do suggest that this class of agents, although very effective, has less durability than agents that focus on the body's response to insulin, such as metformin or thiazolidinediones.

In clinical practice, early signs of secondary drug failure should provoke renewed attempts to reinforce diet and exercise as well as a reassessment of drug dosage. The reappearance of hyperglycemia despite maximally effective

drug doses signals the need to add another class of oral agent or to transition to insulin therapy. Overall, only about 25% of patients reach long-term glucose targets with a sulfonylurea alone; stated another way, three of four patients will require additional modes of therapy. As shown in Table 237-3, advantages of sulfonylureas include low cost (especially with generics), convenience (once-daily dosing), and proven reduction of microvascular end points (retinopathy, nephropathy, and probably neuropathy). Additional disadvantages include hypoglycemia and weight gain.

Nonsulfonylurea Secretagogues

Repaglinide and nateglinide are nonsulfonylurea-based drugs that interact with a different portion of the sulfonylurea receptor to stimulate insulin secretion. Their major advantage is their rapid and relatively short duration of action, which may attenuate postprandial glucose excursions and reduce the risk of fasting hypoglycemia. Both drugs require frequent daily dosing and should be taken 0 to 15 minutes before meals. Repaglinide is a somewhat stronger secretagogue than nateglinide and similar to the sulfonylureas in glucose-lowering power, with an expected average HbA_{1c} improvement of 1 to 1.5%. Both agents have a favorable side effect profile and typically produce less clinical hypoglycemia than traditional sulfonylureas. As a result, they may be safer in patients with irregular meal schedules or with renal insufficiency (although any secretagogue must be used with great caution as creatinine clearance declines). The primary disadvantages of the nonsulfonylureas are their high cost and multiple dosing schedules and the lack of long-term outcomes data with these agents.

Biguanides

Metformin is the only biguanide available for use in the United States. Unlike sulfonylureas, this agent is considered an insulin sensitizer, although its precise mechanism of action is poorly understood. Metformin most likely acts at least in part by reducing hepatic glucose production by suppressing gluconeogenesis. Metformin may also augment peripheral glucose disposal, although this effect may be mostly secondary to reversal of glucotoxicity. The drug is a weak activator of adenosine monophosphate–activated protein kinase (AMPK), an enzyme that is usually triggered by adenosine monophosphate, an important intracellular signal of energy stores. Metformin exhibits a glucose-lowering effect similar to that of the sulfonylureas (HbA_{1c} of −1 to −2%). As with sulfonylureas, however, only about one fourth of patients will be adequately controlled with long-term monotherapy. Metformin has a relatively short half-life (it is eliminated exclusively by the kidney) and is therefore given in two or three divided doses with meals. Several extended-release metformin products allow more convenient once-daily dosing.

Because the effects of metformin are extrapancreatic, insulin levels generally fall, which may provide a cardiovascular advantage, as suggested in the UKPDS (see earlier). Other benefits of metformin include mild weight loss, mild (<10%) LDL and triglyceride reductions, and the absence of hypoglycemia when it is used as monotherapy.

Side effects are primarily gastrointestinal, including abdominal pain, bloating, nausea, diarrhea, and anorexia; these may be partially responsible for its mild weight loss effect. Metformin can also very rarely produce lactic acidosis (approximately 0.03 case per 1000 patient years) and should therefore not be given to patients with renal insufficiency (serum creatinine ≥1.5 in males or ≥1.4 in females), liver disease, unstable congestive heart failure, metabolic acidosis, or ongoing alcohol abuse. The drug should also be held in dehydrated patients and just before surgery or the administration of intravenous radiocontrast agents (in case a decline in renal function occurs). Recent observational data sets suggest that the current prescribing guidelines in patients with mild renal insufficiency may be to some extent overly conservative.

Thiazolidinediones

Thiazolidinediones (TZDs) reduce insulin resistance, most likely through activation of PPAR-γ, a nuclear receptor that regulates the transcription of several insulin-responsive genes that regulate carbohydrate and lipid metabolism. The biologic effect of TZDs is principally mediated by stimulation of peripheral glucose metabolism. PPAR-γ activation also attenuates lipolysis and stimulates peripheral adipocyte differentiation, thereby redistributing fat stores from the liver and muscle to subcutaneous depots. This effect may be largely responsible for the "insulin-sensitizing" effects of the TZDs. There is a concomitant modulation in the circulating levels of adipocytokines, particularly in adiponectin, which is increased two- to three-fold after TZD therapy. In 1997, troglitazone was the first TZD approved for use in the United States; although effective, the drug was withdrawn from the market 2 years later because of concerns about idiosyncratic hepatotoxicity. Rosiglitazone and pioglitazone were later approved; these agents have no significant hepatotoxicity.

Compared with sulfonylureas and metformin, TZDs, when used as monotherapy, have more delayed and somewhat less pronounced glucose-lowering effects (0.5 to 1.4% reductions in HbA_{1c}). Clinical advantages of TZDs include convenience (once-daily dosing), no hypoglycemia, and the potential cardiovascular benefits of reducing insulin resistance, with decreasing circulating insulin concentrations. TZDs have several other potentially beneficial effects: lower triglyceride levels (particularly with pioglitazone); higher HDL levels; reductions in small, dense LDL cholesterol; small reductions in blood pressure; improved endothelial function; reduced vascular inflammation; and enhanced fibrinolytic activity. At a basic level, TZDs have also been demonstrated, mainly by in vitro models, to attenuate the expression of a variety of locally derived factors that promote the atherosclerotic process. In the first outcomes study to assess the effect of TZDs on cardiovascular events (PROactive[11]), the addition of pioglitazone to baseline antihyperglycemic therapy modestly reduced the time to all-cause mortality, myocardial infarction, and stroke in high-risk patients with type 2 diabetes. In this study involving 5238 patients, the primary end point, however, consisting of more outcomes including procedure-based end points such as coronary and peripheral artery revascularizations, was not significantly altered. HbA_{1c} was 0.5% lower in the pioglitazone group, making the impact of the insulin-sensitizing properties of the TZD difficult to know fully. Moreover, an increase in heart failure diagnosis was observed in active therapy patients (see later). These data concerning a potential benefit of pioglitazone on atherosclerosis outcomes need to be confirmed.

The effects of the TZDs on cardiovascular outcomes became even more confusing in 2007 when a well-publicized meta-analysis was published demonstrating an increase in myocardial infarction events in compiled rosiglitazone studies, each of which was not powered to assess for cardiovascular events and most of which did not adjudicate these outcomes.[9] A subsequent randomized clinical trial (RECORD) did not support the meta-analysis conclusion.[10] However, in this trial, there was no cardiovascular benefit to cardiovascular outcomes from rosiglitazone. Because of this, and the generally better lipid effects of pioglitazone, the latter has been designated as the preferred option by a consensus statement from the ADA and EASD. The risk-to-benefit ratio of both drugs, however, remains controversial, especially in light of the issue of heart failure (see later).

Finally, there is some evidence that TZDs may slow the decline of β-cell function, thus delaying the clinical progression from IGT to overt diabetes mellitus. At the very least, the drugs have been demonstrated to have a more durable effectiveness when compared with sulfonylureas and, to a lesser extent, metformin (ADOPT trial).

Compared with most other oral hypoglycemic agents, TZDs are more expensive. Side effects of the TZDs are largely related to fluid retention and fat redistribution and include weight gain, edema, mild anemia, and worsening of heart failure. Reports of the development of new heart failure has led to extensive study of this issue. These investigations have concluded that although the risk for heart failure is approximately two-fold compared with non-TZD-treated patients, this appears to result mainly from an increase in extracellular fluid due to the drug's effects on sodium handling in the nephron. It is suspected that patients who decompensate on exposure to TZDs likely had previously unrecognized diastolic dysfunction, which is a common phenomenon in older patients with type 2 diabetes, especially in the setting of long-standing hypertension. These drugs are therefore contraindicated for use in patients with New York Heart Association class III and class IV heart failure and not recommended in anyone with symptomatic heart failure (i.e., class II). Notably, the side effects of weight gain, edema, and heart failure develop most commonly in patients receiving concomitant insulin therapy.

Recently, the TZDs have also been associated with bone loss and increased bone fracture rates in women. Fractures have tended to occur in peripheral bones, such as the arms, wrists, and lower legs and feet. The mechanism of this effect remains obscure but may involve an effect on stromal stem cells with preferable differentiation into adipocytes instead of osteoblasts. These agents should therefore be used cautiously in women with or at risk for osteoporosis, and routine advice regarding measures to maintain good bone health should be provided.

TZDs should also not be used in patients with active liver disease or with elevated serum transaminases (alanine transaminase ≥2.5 times the upper limit of normal). Periodic monitoring liver function tests based on clinical judgment is advised. TZDs should be discontinued if transaminases are three times or more the upper limit of normal. Somewhat paradoxically, these agents reduce hepatic fat content and might actually improve the biochemical abnormalities in the liver condition encountered most frequently in obese, type 2 diabetic patients: nonalcoholic steatohepatitis.

α-Glucosidase Inhibitors

Acarbose and miglitol are competitive inhibitors of α-glucosidases, brush border enzymes in the proximal small intestine that serve to break down complex carbohydrates into monosaccharides to facilitate transmucosal absorption. These agents delay the absorption of carbohydrates such as starch, sucrose, and maltose but do not affect the absorption of glucose and other monosaccharides. To be effective, acarbose and miglitol must be taken at the beginning of each carbohydrate-containing meal, usually three times per day. Acarbose is minimally absorbed systemically, whereas miglitol is absorbed and rapidly excreted (unchanged) in the urine. Perhaps as a result of improved glycemic control, both these agents are associated with modest (~10%) reductions in circulating triglyceride levels and have no appreciable effects on LDL or HDL cholesterol.

In controlled trials performed in patients with type 2 diabetes, α-glucosidase inhibitors reduced postprandial glucose excursions and produced small (0.5 to 0.8%) but meaningful reductions in HbA_{1c}. Their most prominent effect is on postprandial blood glucose levels. It has been suggested that the postprandial glucose level may be more closely aligned with cardiovascular risk than is fasting glucose concentration. It is of interest that in a post hoc analysis from the Study to Prevent Non-Insulin-Dependent Diabetes Mellitus (STOP-NIDDM diabetes prevention trial), acarbose therapy was associated with a marked reduction (~50%) in the incidence of cardiovascular events in these prediabetic subjects. There have been no long-term studies employing an α-glucosidase inhibitor in diabetic patients, however, to assess whether such a seemingly vasculoprotective effect might be confirmed. These drugs do not lead to any changes in weight.

The most common side effects associated with both acarbose and miglitol are abdominal pain, bloating, flatulence, and diarrhea. These effects have negatively affected their popularity in the United States, although they remain widely used in several overseas countries, including Germany and Japan. The gastrointestinal symptoms can be minimized by initiating therapy at low doses and by using a slowly escalating dose titration schedule. Their use is discouraged in patients with inflammatory bowel disease, colonic ulceration, or any other significant chronic gastrointestinal disorder. They are also to be avoided in patients with advanced liver disease.

Glucagon-like Peptide-1 Receptor Agonists

Exenatide and liraglutide are GLP-1 receptor agonists, sometimes referred to as *incretin mimetics*. They stimulate insulin secretion in a glucose-dependent fashion, inhibit glucagon secretion, slow gastric emptying, and enhance satiety centrally. These agents are available only in an injectable form, administered once (liraglutide) or twice (exenatide) daily. This class is approved for use as monotherapy and in combination with oral agents in type 2 diabetes, with an anticipated reduction in HbA_{1c} of 0.7 to 1.1% compared with placebo. The GLP-1 agonists promote an average weight loss of 4 to 5 kg in long-term studies, but there is considerable variation the response. This feature distinguishes these agents from current oral antihyperglycemic agents. Moreover, GLP-1 mimetics are not approved for use with insulin. Side effects include nausea and vomiting, but these effects tend to wane with time. Acute pancreatitis, including hemorrhagic forms, has been reported in patients taking GLP-1 agonists, but it remains unknown whether these cases actually resulted from the drug because this complication is in general more commonly seen in this patient population. These agents do not by themselves lead to hypoglycemia but may increase the risk when used with insulin secretagogues. In preliminary studies in rodent models, incretin mimetics appear to preserve β-cell function and therefore might be useful earlier in the disease course than is currently recommended. At present, however, exenatide may be considered an alternative to the initiation of insulin for those patients whose treatment with oral agents is failing, although they are increasingly popular earlier in the disease course. Other incretin mimetics under active development include several injectable long-acting GLP-1 agonists that can be given weekly.

Dipeptidyl Peptidase-4 Inhibitors

Members of this class (e.g., sitagliptin, saxagliptin, vildagliptin) inhibit the activity of DPP-4, the enzyme responsible for the breakdown of the naturally occurring incretins, GLP-1 and glucose-dependent insulinotropic peptide (GIP). As monotherapy and in combination with other oral agents, gliptins reduce HbA_{1c} by 0.5 to 0.8% versus placebo therapy. However, because the baseline HbA_{1c} in these trials (8 to 8.5%) was lower than in most studies previously conducted with more traditional agents, it is difficult to compare the results. In head-to-head comparisons, the gliptins appear to fare favorably to most other available oral antihyperglycemic medications. The advantage of this therapeutic class is the relative absence of reported major side effects, including lack of hypoglycemia and weight neutrality. They may be of greatest use in patients with mild elevations of blood glucose. The DPP-4 inhibitors are currently approved for use as monotherapy and in combination with other drugs except for insulin and GLP-1 agonists (see later). There are no data on microvascular or macrovascular outcomes, DPP-4 inhibitors are relatively expensive, and the long-term safety of DPP-4 inhibition is not known. Urticaria, angioedema, Stevens-Johnson syndrome, and acute pancreatitis have been reported, but it is not clear whether there is a causative relationship to any of these events.

Bile Acid Sequestrants

The cholesterol binding resins are drugs that can be used for the treatment of hyperlipidemia. However, they are significantly less effective than statins, and these drugs have been relatively unpopular among patients owing to their gritty consistence, high doses required for an effect, and frequent constipation. Recently, one member of this class, colesevelam, has been approved for use as monotherapy and in combination with other antihyperglycemic drugs for patients with type 2 diabetes. Its mechanism of action remains poorly understood but might involve modulation of the incretin system. It likely does not reduce carbohydrate absorption. HbA_{1c} efficacy is mild, with reductions in the 0.5% range. Benefits include a generally nonsystemic pharmacologic profile and concurrent reduction of LDL cholesterol. It is weight neutral. All bile acid sequestrants can increase triglycerides, and colesevelam is specifically contraindicated in patients with levels above 500 mg/dL and in those who have had pancreatitis related to hypertriglyceridemia. It is also contraindicated in patients with a history of bowel obstruction and should generally not be used in anyone with a significant history of gastrointestinal disease.

Dopamine-2 Receptor Agonists

Dopamine agonists have been studied for their mild antihyperglycemic effects (HbA_{1c} reduction, 0.5% or less) for years. Bromocriptine, an ergot derivative, available since the 1970s to treat hyperprolactinemia and Parkinson's disease, was recently approved in low dose as a glucose-lowering agent in type 2 diabetes. Its mechanism of action is not well understood but may involve alteration of the hypothalamic neurotransmitter milieu, with systemic effects on free fatty acid oxidation and hepatic glucose production. It is weight neutral and not associated with hypoglycemia. Potential side effects include hypotension, dizziness, syncope, exacerbations of psychotic disorders, somnolence, and nausea. Bromocriptine should not be used in patients taking dopamine antagonists.

Insulin Therapy in Type 2 Diabetes

The principles of insulin therapy and details of insulin preparations, regimens, and monitoring are discussed in the previous chapter on type 1 diabetes (Chapter 236). Insulin is commonly used as first-line therapy for nonobese, younger, or severely hyperglycemic type 2 diabetic patients and is often temporarily required during times of severe stress (e.g., injury, infection, surgery) or during pregnancy. Insulin should not be used as first-line therapy for patients who are poorly compliant, unwilling to self-monitor glucose levels, or at high risk for hypoglycemia (e.g., very elderly patients). In obese patients, profound insulin resistance often necessitates the use of large doses of insulin, which can interfere with efforts to restrict calorie intake and achieve weight loss. In leaner patients and in patients with relatively mild fasting hyperglycemia (who continue to maintain endogenous insulin secretory capacity), relatively small doses of basal insulin (e.g., 0.3 to 0.4 U per kilogram of body weight per day) given once or twice per day may be sufficient to achieve glucose targets. Many of these patients retain some degree of meal-stimulated endogenous insulin secretion and may therefore require no or less rapid-acting insulin as well.

Although a common practice has been to administer a single dose of NPH insulin in the morning, the glucose-lowering effect of this regimen does not usually extend during a full 24-hour period. Because a key element of successful insulin treatment is to counteract accelerated rates of endogenous glucose production in the morning, it is generally more effective to split the dose and to administer sufficient amounts of intermediate-acting insulin in the evening (preferably at bedtime) to optimize control. Alternatively, premixed insulins containing 70 to 75% NPH and 25 to 30% of a short- or rapid-acting insulin (e.g., regular human insulin, lispro, or aspart) can be given twice daily. Although somewhat inflexible because of their combined contents in fixed ratios, these insulins provide a level of convenience for some patients who are not able or willing to mix insulins or use strategies involving three or four injections per day. With the availability of long-acting, basal insulins over the past decade, such as glargine and detemir, one injection per day is an increasingly favored approach in many patients. This may be combined with oral glucose-lowering agents to facilitate endogenous insulin release and action. Typically these agents are offered at bedtime, but they can actually be administered at any time of day. In patients taking large doses or in whom it is suspected that the hypoglycemic effect is waning before 24 hours (as is more commonly seen with detemir), twice-daily dosing can be used.

With regard to the initiation of even more advanced insulin replacement regimens, which are required in certain insulin-deficient type 2 patients (and are similar to the optimal regimens in type 1 patients), there are several acceptable approaches. The optimal insulin strategy in type 2 diabetes is not clear. In general, the more insulin injections, the tighter the control, but this must be balanced against convenience and the commitment on the patient's part to injections and the requisite monitoring. The total daily dose of insulin should first be estimated from body weight; total insulin requirements range between 0.5 and 1.0 U/kg/day, typically higher than those used in type 1 diabetes. One classic method for starting insulin is to divide the total daily dose unevenly, with two thirds given before breakfast and the remaining third before dinner. Each of the two doses is then further subdivided: at breakfast, two thirds of the dose is given as intermediate-acting insulin and the other third as a short- or rapid-acting preparation; at dinner, the dose is divided into two equal parts. As an example, for a 90-kg man with estimated requirements of 0.67 U/kg/day, 60 U of insulin may be required. By use of this method, the patient might receive 27 units of NPH with 13 units of regular insulin or a rapid-acting insulin analogue (e.g., lispro, aspart, or glulisine) before breakfast, then 10 units of NPH with 10 units of analogue before dinner. More refined "basal-bolus" regimens using more modern insulins offer more physiologic insulin replacement. The regimen in the most motivated and capable patients is ideally adjusted on the basis of the anticipated carbohydrate intake ("carbohydrate counting") as well as the before-meal blood glucose level. These

regimens are more complex and require frequent dosage adjustments and more intensive glucose monitoring. In the absence of hyperglycemic complications, clinicians should generally begin with more conservative doses of insulin to minimize hypoglycemia and to smooth the patient's transition to multiple-dose subcutaneous insulin therapy. In short, the complexity of the regimen should be individualized according to the clinical context, the patient's abilities and capacities to perform self-care, and most important, the patient's level of education and motivation.

The Treating-To-Target in Type 2 Diabetes (4-T) trial compared glycemic outcomes from various insulin regimens in more than 700 patients whose diabetes was inadequately controlled despite therapy with metformin and sulfonylurea.[12] The participants were randomized to (1) premixed insulin analogue injections twice a day (aspart 70/30 before breakfast and supper), (2) prandial rapid-acting insulin analogue (insulin aspart) three times daily, or (3) a basal insulin analogue (insulin detemir) once (or twice) daily, with the goal of achieving an HbA_{1c} level of 6.5% or less. After 1 year, if the HbA_{1c} was not at target, the sulfonylurea was discontinued and a second type of insulin initiated. For those on the premixed regimen, once-daily aspart was added before lunch; for those on the prandial-only strategy, once-daily basal analogue was added; and for those using basal insulin alone, the regimen was advanced to incorporate three times per day prandial rapid insulin. At 3 years, the median HbA_{1c} across groups was 6.9% (premixed, 7.1%; prandial, 6.8%; basal, 6.9%); however, almost three in four patients required two types of insulin in combination. More patients who had started therapy with a basal insulin only (43.2%) or a prandial insulin only (44.8%) achieved target than those initially randomized to the premixed (31.9%). Weight gain amounted to 3.6 kg, 5.7 kg, and 6.4 kg in the basal, premixed, and prandial groups, respectively. Less hypoglycemia occurred in those randomized to the basal insulin approach (1.7 per patient year) than the premixed (3.0 per patient year) or prandial (5.7 per patient year) insulin regimens. These findings provide support for treatment to begin with basal insulin once a day, and then add mealtime insulin if glycemic targets are not met. However, in patients not able to handle more complex regimens, premixed insulin twice daily is a reasonable option as well.

Experience with the use of intensified insulin treatment, including continuous subcutaneous insulin infusion pumps and multiple subcutaneous injection regimens, is growing in patients with type 2 diabetes. Preliminary results suggest that intensified treatment may be successfully applied to selected patients.

In many cases, the combination of intensive insulin therapy with oral hypoglycemic agents (e.g., TZDs or metformin) may reduce insulin dose requirements and improve glycemic control. Although this is growing in acceptance, the potential benefit of reducing circulating insulin levels (by combination therapy) on the development of atherogenesis remains to be established. As in patients with type 1 diabetes, weight gain and hypoglycemia are potential side effects of insulin therapy. It is noteworthy, however, that the incidence of severe hypoglycemia is markedly lower (<5%) than that seen in patients with type 1 diabetes.

Pramlintide

See Chapter 236 for a brief description of this newer agent, which is also approved for insulin-requiring patients with type 2 diabetes.

Treatment Strategies for Type 2 Diabetes

In contrast to type 1 diabetes, in which insulin therapy is required, many pharmacologic options exist for the management of type 2 diabetes. The pros and cons of the various oral hypoglycemic agents have been discussed; often, it is difficult to justify the use of one oral agent over another, although the general consensus of endocrinologists is to recommend metformin as first-line therapy in the absence of contraindications, given its effectiveness, the lack of hypoglycemia associated with its use as monotherapy, its low cost, and weight neutrality. It is now believed that in most cases metformin therapy should be initiated early, is concurrent with lifestyle intervention, and is gradually increased to the maximally effective dose over 1 to 2 months. In the event these interventions fail to achieve the glycemic goals set for the patient within about 3 months, another drug should be added to the regimen (Fig. 237-4). What the next step should be is much more controversial and remains uncertain. Most studies comparing oral drugs have focused on glycemic end points, and most show modest differences, with few exceptions. Few studies, however, have compared drugs for more relevant clinical outcomes such as mortality or microvascular and macrovascular complications. To date, the largest study to address such outcomes in type 2 diabetes was the UKPDS.[1] In the UKPDS, the long-term follow-up of the study participants assigned to more intensified therapy demonstrated improved outcomes for microvascular complications and myocardial infarction and reduced mortality for patients given insulin and sulfonylureas (as well as metformin). The ability of the study to detect differences among the different treatments was limited because of drug crossovers and the frequent need for drug combinations as the study progressed. On the other hand, the long-term benefits of newer antidiabetic agents have not been established.

The choice of second-line pharmacologic therapy for type 2 diabetes should be influenced in part by the severity of fasting hyperglycemia, the presence and magnitude of hyperglycemic symptoms, and the degree of obesity. Other factors such as age, comorbid conditions, propensity to certain side effects, drug cost, and convenience should also be considered. Published clinical trials comparing drug combinations with monotherapy have generally shown additive reductions in HbA_{1c}; with few exceptions, the magnitude of HbA_{1c} reduction approximates that achieved when the added agent is used as monotherapy. As is the case with monotherapy, there is no convincing evidence favoring one combination regimen over another, and most combinations have been approved by the FDA. Triple therapy, or combining three agents to achieve glucose targets, is also used in clinical practice (although not formally with FDA approval) and appears to be effective. Ultimately, if glucose targets cannot be met by combining oral agents, insulin remains an effective treatment option.

Two published algorithms include one from a consensus group representing the ADA and the EASD (see Nathan in Suggested Readings) and one from the American Association of Clinical Endocrinologists/American College of Endocrinology (Rodbard in Suggested Readings).

Monitoring

See Chapter 236 for details. Patients with type 2 diabetes generally require less frequent self-monitoring of blood glucose concentration, particularly those managed with oral agents or less intensive insulin regimens. Glucose and HbA_{1c} targets should be the same as in type 1 diabetes (see Table 237-4), with the recently appreciated caveat that older patients (>65 to 70 years) may not benefit from more stringent goals, especially in the setting of long disease duration (>12 years) or significant underlying risk for or overt cardiovascular disease. Importantly, each patient's desirable glucose range must be an individual decision between the practitioner and the patient. Elements of this decision must take into account the motivation and capacities of the patient, propensity for hypoglycemia and its unawareness, presence or absence of complications, and, of course, other established comorbidities.

Inpatient Management of Diabetes

Much attention has been paid recently to the inpatient management of hyperglycemia, both in patients with an established diagnosis of diabetes and in those whose glucose elevations are a response to illness. Observational studies previously have correlated the degree of hyperglycemia and outcomes in a variety of settings, including after cardiac surgery, in the critically ill, and in patients with acute myocardial infarction and stroke. Acutely, hyperglycemia has a notable detrimental effect on the immune system, wound healing, endothelial function, and cardiac metabolism. When glucose elevations are severe, dangerous fluid shifts and electrolyte fluxes may occur. However, multiple studies have failed to confirm a benefit from aggressive control of inpatient glucose levels, and studies have actually raised the probability of increased mortality risk from aggressive control of inpatient glucose levels when intensive intravenous insulin therapy targets a blood glucose level lower than 108 mg/dL.[13] These adverse effects have occurred in the setting of (but are not clearly the result of) a several-fold increase in the risk for severe hypoglycemia. Whether there is any short-term benefit of tight glucose control in noncritically ill hospitalized patients is unknown because adequate clinical trials have not been conducted in this setting.

Reasonable approaches to both these patient groups have been proposed by the ADA, the American Association of Clinical Endocrinologists (AACE), and the American College of Physicians,[14] with current targets set at 140 to 180 mg/dL using intravenous insulin in the intensive care setting, and maintaining preprandial blood glucose levels lower than 140 mg/dL in other patients. As in the outpatient arena, individualization is important; patients with severe comorbidities or with short life expectancy can be reasonably kept at a more conservative range. Multidisciplinary inpatient diabetes management teams have been shown to be useful in assisting hospitals to improve the quality of their diabetes care and in reducing the length of stay of diabetic patients.

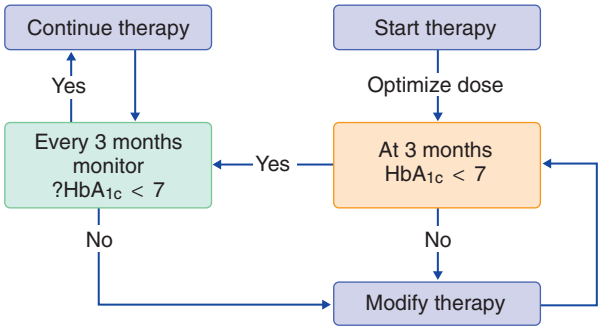

FIGURE 237-4. Overall strategy for the treatment of type 2 diabetes.

PREVENTION

With our increasing understanding of the pathogenesis of type 2 diabetes and our appreciation of the often lengthy period between impaired glucose metabolism and overt diabetes, there has been significant attention directed to the possibility of preventing this disease in at-risk individuals.

In the Diabetes Prevention Program, more than 3000 overweight subjects with IGT were randomized into four treatment arms: (1) intensive lifestyle changes aimed at reducing body weight by 7% through a low-fat diet and 150 minutes of weekly exercise; (2) treatment with metformin, 850 mg twice per day; and (3) treatment with placebo pills, twice per day.[15] The last three groups also received standard information about diet and exercise. The trial was stopped a year early because of definitive results. In the placebo group, 29% of patients developed diabetes during the average follow-up period of 3 years, compared with 22% of patients taking metformin and only 14% of patients undergoing intensive diet and exercise. The relative risk reduction for patients taking metformin was 31% versus standard care, whereas patients undergoing intensive lifestyle interventions reduced their risk by an impressive 58%. This risk reduction was identical to that measured by Finnish investigators in the Diabetes Prevention Study, involving a similar study design but focusing on lifestyle change alone. This suggests that patients with IGT can sharply lower their immediate risk for diabetes with intensive lifestyle changes (or in some cases with metformin).

Whether screening, identifying, and then treating patients with IGT in routine clinical practice is cost-effective or even doable remains somewhat controversial. Certainly, if recommendations regarding healthy lifestyle changes were followed by high-risk patients, the incidence of type 2 diabetes would decrease. If such therapy is durable, this would necessarily translate to fewer microvascular complications over time. Whether such interventions will mitigate the risk for macrovascular disease is less clear, although Diabetes Prevention Program participants on diet and exercise did experience some amelioration in cardiovascular risk factors.

How drug therapy fits into this equation is similarly a point of controversy. Notably, after metformin therapy was washed out in Diabetes Prevention Program participants for 2 weeks, 25% of those whose diabetes was apparently prevented developed the disease. Similarly, in the STOP-NIDDM diabetes prevention trial involving the α-glucosidase inhibitor acarbose, a 25% decrease in the appearance of type 2 diabetes during a 3-year period was demonstrated. In two studies involving TZDs, larger risk reductions have been observed. In DREAM, rosiglitazone therapy reduced the progression to diabetes in high-risk patients by 62%, and in the ACT NOW trial, pioglitazone was associated with an 81% risk reduction. Moreover, pioglitazone has recently been reported to diminish carotid intimal thickening by 38% in patients with IGT in a multicenter clinical trial. Importantly, no drug is currently approved by the FDA for diabetes prevention, although metformin is used not uncommonly in such efforts.

A consensus statement from the ADA and the EASD has endorsed lifestyle change in anyone identified with a prediabetic state. It also advised the consideration of metformin therapy in those at especially high risk, such as individuals with both IFG and IGT, combined with other high-risk features such as family history and characteristics that predict an effective response to metformin, based on the DPP. The latter include age younger than 60 years, body mass index greater than 35 kg/m^2, and fasting plasma glucose level of 110 mg/dL or higher. An approach that emphasizes healthy lifestyle changes is likely more cost-effective and accompanied by other health benefits than one focused on pharmacotherapy. With now more than 50 million individuals in the United States considered to be at high risk for developing diabetes, the economic implications of any broad recommendations will need careful consideration.

ACUTE METABOLIC COMPLICATIONS

Diabetic Ketoacidosis

See Chapter 236 for a discussion of diabetic ketoacidosis.

Hyperosmolar Hyperglycemic Syndrome

CLINICAL MANIFESTATIONS

The metabolic state formerly known as the hyperglycemic hyperosmolar nonketotic state or coma has been renamed the *hyperosmolar hyperglycemic syndrome* (HHS) to highlight two important points: (1) ketosis (and acidosis) may be present to varying degrees in HHS, and (2) alterations in sensorium most commonly occur in the absence of coma. In fact, only 10% of HHS patients present with frank coma, and an equal percentage show no signs whatsoever of mental status change.

As shown in Table 236-6 in Chapter 236, the hallmarks of the HHS are severe hyperosmolarity (>320 mOsm/L) and hyperglycemia (>600 mg/dL). Severe hyperglycemia occurs because patients cannot consume enough liquid to keep pace with a vigorous osmotic diuresis. The resulting impairment in renal function eventually further reduces glucose excretion through the kidney, leading to remarkable blood glucose elevations, sometimes exceeding 1000 mg/dL. In contrast to diabetic ketoacidosis, even though glucose concentrations are generally higher, severe acidosis and ketosis are generally absent in the HHS. This is probably explained by the residual insulin secretory capacity retained by patients with even several decades of type 2 diabetes. That is, their insulin levels remain sufficient to suppress lipolysis and to avoid significant keto acid production. However, some type 2 patients with depressed endogenous insulin secretion may be unable to suppress ketone production fully in the face of elevated counter-regulatory hormones produced by physical illness. Because HHS patients have higher portal vein insulin concentrations than do patients with diabetic ketoacidosis, keto acid production by the liver is relatively mild, yielding only mild acidosis. In the HHS, in the absence of concurrent acid-base disturbances, arterial pH rarely drops below 7.30, and serum bicarbonate levels typically do not fall below 18 mEq/L.

In the hyperosmolar hyperglycemic state, clinical severity and levels of consciousness generally correlate with the severity and duration of hyperosmolarity. Clinical signs indicate profound dehydration; gastrointestinal symptoms are seen less frequently than in diabetic ketoacidosis. A variety of often reversible neurologic abnormalities may exist, including grand mal or focal seizures, extensor plantar reflexes, aphasia, hemisensory or motor deficits, and worsening of a preexisting organic mental syndrome. The laboratory picture is dominated by the effects of uncontrolled diabetes and dehydration; renal function is impaired, hemoglobin and hematocrit are elevated, and liver function test results may be abnormal because of baseline hepatic steatosis. Although severe hyperglycemia would be expected to lower measured serum sodium concentration, it is not uncommon to see normal or even elevated sodium levels because of the severity of dehydration. The serum osmolarity can be measured directly or estimated by the following formula, which excludes urea because it is freely diffusible throughout the body and therefore has little influence on the osmotic pressure gradient:

$$\text{Effective osmolarity (mOsm/L)} = 2[\text{measured serum } Na^+ \text{ (mEq/L)}] + [\text{glucose (mg/dL)}/18]$$

TREATMENT

Rx

Patients with HHS should be treated as aggressively as are those with diabetic ketoacidosis, although those with the former tend to have more dramatic volume contraction (Chapter 236). By definition, acidosis is not present or is minimal in degree. Accordingly, patients may not require the coadministration of dextrose along with insulin, as is recommended in patients with diabetic ketoacidosis to allow ketones to clear and the acidosis to resolve. Also, it is important to volume-resuscitate the patient adequately before insulin is administered for fear that intracellular fluid shifts that occur as glucose levels are reduced may worsen systemic tissue perfusion. Because, by definition, there is no significant acidosis to clear in HHS, patients may be transitioned directly from insulin infusion to subcutaneous injections, without need for any coadministration of dextrose as is necessary in diabetic ketoacidosis to allow further clearance of ketone bodies. Some patients with HHS may ultimately be able to be managed with oral agents alone. However, the development of HHS signifies a significant degree of insulin deficiency. As a result, it is always best to prescribe insulin injections before the patient is discharged and to reserve judgment about the appropriateness of oral agents until the patient's progress can be monitored and reassessed in the outpatient setting.

HYPOGLYCEMIA

See Chapter 236 for a full discussion of this complication of diabetes therapy. As previously mentioned, hypoglycemia is encountered less frequently in individual patients with type 2 diabetes because of biologic as well as practical reasons. Because the typical type 2 patient retains some residual endogenous insulin secretion, the development of mild hypoglycemia will lead to its abrupt reduction. Accordingly, type 2 diabetic patients can autoregulate portal insulin levels to a degree not possible in the absolutely insulin deficient type 1 patients. Also, patients with type 2 diabetes are, almost by definition,

insulin resistant and therefore less likely to develop abnormally low blood glucose levels even when taking insulin injections. Perhaps more important, type 2 patients are more commonly treated with oral agents than with insulin. Many of these drugs reduce glucose levels through nonpancreatic mechanisms and therefore do not predispose to hypoglycemia when they are used as monotherapy or in combination with each other. On the other hand, severe hypoglycemia may be less well tolerated by the aging brain, and therefore it needs to be scrupulously avoided, particularly in elderly patients and especially given the recent clinical trial evidence of an association between hypoglycemia and increased cardiovascular mortality in those at high cardiovascular risk.

CHRONIC DIABETIC COMPLICATIONS

The pathogenesis of the microvascular and neuropathic complications of diabetes is discussed in Chapter 236. Patients with both forms of diabetes are at risk for retinopathy, nephropathy, and nerve dysfunction.

Atherosclerosis

Atherosclerosis (Chapter 70) involving the coronary, cerebral, and peripheral (lower extremity) arteries is the predominant cause of diabetes-related mortality, responsible for up to 70% of all deaths in patients with this disease. The atherosclerotic process in diabetes is essentially indistinguishable from that of the nondiabetic population, but it begins earlier and is often more extensive and more severe. A predilection to cardiovascular disease is observed over the entire spectrum of diabetes, from poorly controlled insulin-dependent patients to those with mild, diet-controlled hyperglycemia. For unclear reasons, the disparity between diabetic and nondiabetic persons is more pronounced in women. When it is accompanied by other major cardiovascular risk factors such as hypertension, dyslipidemia, and smoking, diabetes markedly augments the incidence of macrovascular complications. For example, the observed 2- to 3-fold greater risk for myocardial infarction with diabetes rises to 8-fold in the presence of hypertension and to nearly 20-fold if both hypertension and dyslipidemia are present; smoking increases these risks even further. As a result, the diagnosis of diabetes mellitus should lead to a careful review of coexisting and compounding cardiovascular risk factors and the initiation of aggressive preventive measures.

Diabetes is an *independent* risk factor for accelerated atherosclerosis. Its association with vascular disease is not solely attributable to an increased prevalence of other recognized vascular risk factors, such as hypertension and dyslipidemia. Many abnormalities induced by the diabetic state may contribute to atherosclerosis, including lipid abnormalities (e.g., increased total VLDL and LDL, increased small dense [atherogenic] LDL, decreased HDL, increased lipoprotein oxidation, increased lipoprotein glycosylation, decreased lipoprotein lipase activity), accentuated platelet aggregation and adhesion, endothelial cell dysfunction, and induced procoagulant state (e.g., increased clotting factors and fibrinogen; decreased levels of antithrombin III, protein C, and protein S; and decreased fibrinolytic activity). It has been suggested that hyperinsulinemia per se may contribute to macrovascular disease; proposed pathogenetic mechanisms include insulin-induced stimulation of vascular endothelial and smooth muscle cells, enhanced insulin-like growth factor-I expression, and augmented synthesis of atherogenic factors such as endothelin and plasminogen activator inhibitor. Moreover, insulin resistance appears to be an independent risk factor for vascular events and may exert its effect through many of these disease intermediaries.

Outcomes after cardiovascular events, including myocardial infarction, revascularization, and heart failure, are worse in those with than without diabetes. For example, compared with the general population, a higher proportion of diabetic patients die within a year of an acute myocardial infarction. Accordingly, aggressive management of cardiovascular risk factors is even more imperative in those with diabetes. After myocardial infarction, particularly in the setting of left ventricular systolic dysfunction, β-blockers and angiotensin-converting enzyme (ACE) inhibitors (or angiotensin II receptor blockers [ARBs]) likely offer additional benefits. Although angioplasty is often a viable option in diabetic patients with coronary disease, there is evidence to suggest that diabetic patients may derive greater than expected comparative benefit from coronary bypass procedures. However, with the recent development of advanced stenting procedures and the use of drug-eluting stents, which attenuate stent restenosis rates, this distinction might become less important. The Bypass Angioplasty Revascularization Investigation in Type 2 Diabetes (BARI 2D) trial examined the relative value of prompt revascularization versus initial medical therapy (followed by revascularization as clinically indicated) in patients with type 2 diabetes and stable coronary artery disease. Overall outcomes were essentially equivalent between groups. However, in the predefined stratum of patients who were referred for coronary artery bypass graft (CABG) surgery, the rate of major cardiovascular events was significantly lower with revascularization (22.4%) than with medical therapy (30.5%, $P = .01$). These data suggest that in diabetic patients with ischemic heart disease, prompt bypass surgery may be advantageous compared with medical therapy. In less severely affected patients for whom percutaneous coronary intervention is being advised, a more conservative approach with aggressive, evidence-based attention to cardiovascular risk factor reduction is very reasonable. Obviously, individualization of recommendations is important, directed by a skilled cardiology consultant.

Low-dose aspirin therapy (81 to 325 mg/day) has been routinely recommended for most adult patients with diabetes (especially with concurrent coronary artery disease) because of evidence of reduction in cardiovascular morbidity and mortality in the general population. More recent studies and meta-analyses have not confirmed a major benefit in all patients with diabetes. As a result, the ADA in conjunction with the American Heart Association and the American College of Cardiology have recently downgraded the recommendations for prophylactic aspirin. For primary prevention, aspirin (75-162 mg/day) is now advised in diabetic patients at increased cardiovascular risk, defined as a 10-year risk in excess of 10%, including men older than 50 years and women older than 60 years who have at least one additional major risk factor, such as family history, hypertension, smoking, dyslipidemia, or albuminuria.

Whether asymptomatic patients with diabetes should be routinely screened for coronary artery disease remains controversial. A study showed that more than one in five type 2 diabetic patients with no symptoms of angina and with normal findings on electrocardiography had an abnormality on screening myocardial perfusion imaging, indicative of underlying coronary artery disease. In a 5-year follow-up of this cohort, however, the event rates overall were very low and indistinguishable from an unscreened matched control group. Notably, the subjects in this study had overall very good control of CVD risk factors. It can be concluded, therefore, that in the context of modern, evidence-based care of the asymptomatic patient with type 2 diabetes, routine, indiscriminate screening with stress imaging cannot be endorsed. However, an individualized approach, especially in patients thought to be at extremely high risk and in those with atypical symptoms, proceeding to screening may still be considered, particularly in individuals about to begin an exercise program.

Unfortunately, the known association between diabetes mellitus and premature atherosclerosis may be only the "tip of the iceberg" with regard to linking glucose metabolism and vascular risk. Insulin resistance (i.e., impaired insulin-stimulated glucose metabolism) is common in "healthy" people living in Western nations; in such individuals, insulin resistance is often counterbalanced by increased insulin secretion, preventing the emergence of overt diabetes mellitus. Although this state of insulin resistance and chronic hyperinsulinemia may successfully defend against diabetes, this may come at a separate metabolic cost, with potentially adverse effects on other insulin-responsive systems, such as sympathetic nervous system activity, renal sodium reabsorption, hepatic triglyceride synthesis, vascular endothelial function, and cellular events that mediate the atherosclerotic process, including arterial smooth muscle proliferation, expression of vascular adhesion molecules, matrix metalloproteinases, and a variety of cytokines and chemokines that appear to accelerate atherogenesis. This much is known: nonobese, nondiabetic individuals with insulin resistance have higher blood pressure, glucose concentration, and triglyceride levels (and lower HDL cholesterol concentrations) than those of matched subjects with normal insulin levels. The term *metabolic syndrome* is used by some to describe this phenomenon, namely, the clustering within one person of hyperinsulinemia, mild glucose intolerance, dyslipidemia, and hypertension, each of which is probably an independent risk factor for atherosclerosis. Whether identifying such individuals as having metabolic syndrome as opposed to treating the composite risk factors individually is of any benefit remains controversial. Prospective population studies have confirmed that chronic hyperinsulinemia predicts the development of cardiovascular disease. Although such statistical associations do not prove causality, they suggest that insulin resistance may play some role in promoting atherosclerosis. If true, this hypothesis further underscores the importance of lifestyle changes in the treatment of type 2 diabetes and suggests that proper diet and exercise could also benefit insulin-resistant patients with more subtle metabolic abnormalities (i.e., metabolic syndrome, IGT, and IFG). The answer to the obvious question of whether

insulin-sensitizing drugs decrease atherosclerosis risk in this setting remains unknown. The aforementioned BARI 2D study additionally explored this question, in patients with established diabetes. In addition to differing approaches to their coronary disease, patients were also randomized to two distinct approaches to their glycemic control. The first focused on insulin provision therapy, with sulfonylureas and insulin, whereas the second consisted of insulin sensitizers, using metformin and rosiglitazone. This aspect of BARI 2D presented some challenges, including an expected crossover between groups in a substantial proportion of patients. Overall, there was no mortality benefit in those assigned originally to the insulin sensitizer strategy. However, there was a strong, but not significant, trend toward less major cardiovascular events in the patients assigned to insulin sensitizers who were randomized to the revascularization group and were in the stratum of patients referred for CABG. This group most likely included the highest-risk patients. Most would agree that, in light of the background scientific underpinnings of an association between insulin resistance and atherosclerosis in preliminary findings from clinical trials, further investigation is warranted to understand better whether improving insulin sensitivity is a worthwhile pursuit, in both patients with and without diabetes.

ASSOCIATED CONDITIONS

The prevention of cardiovascular disease in type 2 diabetes requires a comprehensive and multifactorial approach. Such an approach has been shown to reduce cardiovascular events by almost 50% (Steno-2 study[16]). Two cardinal areas for prevention concern the management of hypertension and dyslipidemia.[17,18] Figure 237-5 shows a theoretical scheme that links insulin resistance and the metabolic syndrome with cardiovascular disease. The reader is referred to the online version of this chapter and to Chapters 67 and 213 in this text for a more detailed discussion of these topics.

Hypertension

In patients with diabetes, systemic hypertension (Chapter 67) is an important cofactor in the development of cardiovascular disease, nephropathy, and retinopathy. The prevalence of hypertension in type 2 patients is more than twice that of the nondiabetic population, largely related to the clustering of both disorders in patients with obesity and insulin resistance. Type 1 patients, in contrast, are usually normotensive in the absence of renal disease; if nephropathy develops, most affected patients will then develop secondary hypertension. The importance of aggressive blood pressure management in diabetes has been established by the UKPDS (see earlier); in the study, blood pressure reduction (with ACE inhibitors or β-blockers) in type 2 diabetic patients with hypertension produced striking decreases in both cardiovascular and microvascular outcomes. Subsequent prospective trials, including the Systolic Hypertension in the Elderly Program (SHEP), the Systolic Hypertension in Europe (Sys-Eur) trial, and the Hypertension Optimal Treatment (HOT) trial, have confirmed the value of aggressive blood pressure goals in reducing major cardiovascular events in diabetic patients. On the basis of these and other studies, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) has established blood pressure targets of less than 130/80 mm Hg for patients with diabetes mellitus; even stricter reductions (<125/75 mm Hg) are recommended in the presence of established nephropathy. More recently, the ACCORD Study Group reported that targeting a systolic blood pressure of less than 120 mm Hg, as compared with less than 140 mm Hg, did not reduce the rate of composite outcome of fatal and nonfatal major cardiovascular events in patients with type 2 diabetes.[17]

The choice of antihypertensive agent for diabetic patients has for years been the subject of considerable research and debate. Among the various therapeutic options, ACE inhibitors and ARBs may offer special advantages; they have consistently demonstrated the ability to lower intraglomerular pressures and to slow the progression of albuminuria and diabetic nephropathy. These drugs are advocated by the ADA as first-line agents, including their use in normotensive diabetic patients with albuminuria. JNC 7 has additionally endorsed low-dose diuretics, β-blockers, and calcium-channel blockers as preferred agents in diabetic patients with hypertension. β-Blockers should also be strongly considered in the setting of concurrent cardiovascular disease, including prior myocardial infarction, mild to moderate congestive heart failure, and cardiac arrhythmias. There is some clinical trial data to suggest that these agents may be associated with a slightly increased risk for diabetes, possibly related to effects on insulin secretion or the promotion of insulin resistance. They are typically not, however, associated with deterioration in glycemic control. β-Blockers may blunt the adrenergic response to hypoglycemia. Accordingly, they should be used with caution in any patient with frequent hypoglycemic episodes, especially if hypoglycemia is already manifest. Prospective trials comparing antihypertensive agents in diabetic patients have yielded mixed results. In the UKPDS, β-blockers were as effective as ACE inhibitors in reducing adverse cardiac and microvascular outcomes. Conversely, several large trials, including the Appropriate Blood Pressure Control in Diabetes (ABCD) trial, the Captopril Prevention Project (CPP), the Heart Outcomes Prevention Evaluation (HOPE) study (MICRO-HOPE substudy), and the Fosinopril versus Amlodipine Cardiovascular Events Trial (FACET), suggest improved cardiovascular outcomes with the specific use of ACE inhibitors as first-line therapy. On the basis of currently available evidence, ACE inhibitors are recommended as first-line antihypertensive therapy in patients with diabetes, especially in the presence of microalbuminuria or overt nephropathy. ARBs are an excellent alternative, especially in patients who are unable to tolerate ACE inhibitors because of cough.

Dyslipidemia

Dyslipidemia (Chapter 213) is another critical therapeutic target in the management of diabetes. The most common lipid disorder associated with diabetes is an increased level of triglyceride-rich lipoproteins (e.g., VLDL), low levels of HDL, and the presence of small, dense, and, as a result, more atherogenic LDL particles. The third report of the National Cholesterol Education Program (NCEP) Adult Treatment EPanel (ATP III) continues to identify LDL cholesterol as the primary target for therapy on the basis of overwhelming evidence from clinical trials. This panel has established diabetes as a coronary heart disease "equivalent," meaning that all diabetic patients should strive for LDL levels below 100 mg/dL. In addition, HDL levels should exceed 40 mg/dL (50 mg/dL in women); triglyceride levels should fall below 150 mg/dL.

Recommendations from the ADA are similar. Both organizations endorse more aggressive LDL reduction (to below 70 mg/dL) in high-risk patients with overt cardiovascular disease. Such a target is based on the findings of randomized clinical trials in patients with known coronary artery disease. In diabetic patients with multiple additional cardiovascular risk factors, an optional goal of less than 70 mg/dL can also be considered. There is also now widespread agreement that LDL reduction should be considered part of standard diabetes management in virtually all adults older than 40 years irrespective of the baseline LDL cholesterol level, unless it is already extraordinarily low or if contraindications to such therapy are present.

Hydroxymethylglutaryl-coenzyme A (HMG CoA) reductase inhibitors (i.e., statins) are generally used as first-line therapy for lowering LDL cholesterol in patients with diabetes; of note, many of the statins at high doses have a modest triglyceride-lowering effect as well. Randomized clinical trials involving diabetic patients alone (Collaborative Atorvastatin Diabetes Study [CARDS], diabetic subset of the Heart Protection Study) have confirmed equal if not greater benefit of statin therapy in this important subgroup of patients. If statins are contraindicated or poorly tolerated, nicotinic acid

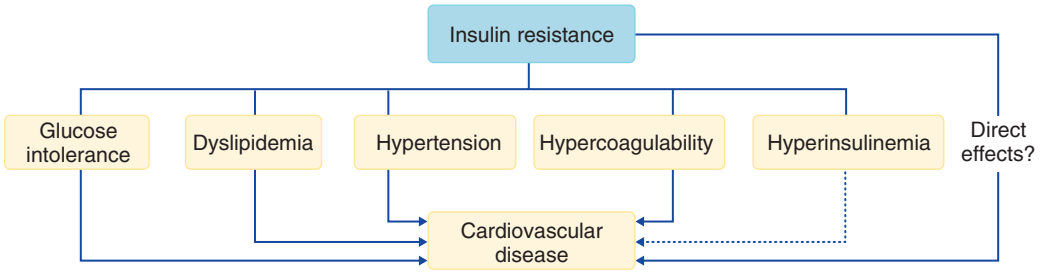

FIGURE 237-5. Theoretical construct of the link between insulin resistance (as occurs in patients with metabolic syndrome) and cardiovascular disease.

(niacin), a bile acid sequestrant ("binding resin," e.g., cholestyramine, colestipol, colesevelam), or a cholesterol absorption inhibitor (e.g., ezetimibe), can be used to lower LDL. It should be noted that the value of the latter in reducing cardiovascular disease is not established. Niacin, although it is also effective at lowering LDL (and triglycerides), may be less useful in diabetic patients because it can worsen insulin resistance and adversely affect glycemic control. Also, the binding resins are generally poorly tolerated and may increase triglycerides. Achieving some of the more stringent LDL targets noted earlier may require combination therapy with a statin plus one of these drug classes. Which to add remains controversial. Recently, a lack of effect of ezetimibe on direct measures of atherosclerosis (by carotid or intravascular ultrasound) has been found. Randomized clinical trials examining actual cardiovascular events with this drug are still under way. The ACCORD study group recently reported that the combination of fenofibrate and simvastatin did not reduce the rate of fatal cardiovascular events, nonfatal myocardial infarction, or nonfatal stroke compared with simvastatin alone in patients with type 2 diabetes.[18] Particularly given all these concerns, patients should have their statin titrated aggressively first before any consideration of combination therapy is made.

Although most published trials involving diabetic patients involve statins to lower LDL, the characteristic lipid profile in the diabetic patient is an elevated triglyceride concentration and low HDL cholesterol, both risk factors for coronary artery disease. Initial steps in treating diabetic dyslipidemia should include optimization of glycemic control, dietary reinforcement, and a prescription of aerobic exercise. Strict dietary parameters for diabetic patients with dyslipidemia call for less than 35% of daily calories as fat, with less than 7% of total calories as saturated fat and less than 200 mg/day of dietary cholesterol (the NCEP Step II diet). Regular aerobic exercise will help by raising HDL levels, and weight loss achieved through exercise can further attenuate lipid abnormalities. Prospective trials using the fibric acid derivative gemfibrozil to lower triglyceride levels and to raise HDL levels have produced improved cardiovascular outcomes (Veterans Affairs HDL Intervention Trial), although a subsequent study (FIELD) involving the fibrate fenofibrate in diabetic patients with normal to modestly elevated triglycerides yielded mixed results. On the basis of these data, although few would argue that marked hypertriglyceridemia (>400 mg/dL) should not be treated pharmacologically, it remains unclear which diabetic patient with mild to moderate hypertriglyceridemia (150 to 400 mg/dL) would benefit from aggressive intervention. Unless triglyceride levels are severely elevated, the management of hypertriglyceridemia should always begin with lifestyle change, including the incorporation of a low saturated fat diet, weight reduction, minimization of ethanol use, and, treatment of any underlying hypothyroidism when it is present.

Omega fatty acid fish oil supplements represent an additional option for patients with elevated triglycerides, particularly those with mild elevations in whom pharmacologic drug therapy may not be considered warranted. There are few outcomes data with these agents.

HYPOGLYCEMIA AND PANCREATIC ISLET CELL DISORDERS

ADRIAN VELLA, ROBERT A. RIZZA, AND F. JOHN SERVICE

HYPOGLYCEMIA

DEFINITION

Hypoglycemia is a clinical syndrome of diverse causes in which low levels of serum glucose can eventually lead to neuroglycopenia.

PATHOBIOLOGY

Regulation of Carbohydrate Metabolism

Interactions Between Insulin and Counter-Insulin Hormones

Under normal circumstances, serum glucose concentration averages 70 to 100 mg/dL before meals and rarely exceeds 140 to 150 mg/dL after meals. The brain is almost totally dependent on glucose for energy, although over the long term it can adapt to substrates other than glucose (e.g., ketone bodies). Because severe hypoglycemia can impair mental function and, if prolonged, can cause permanent brain damage, a series of well-developed, and at times redundant, homeostatic processes defend against hypoglycemia. Insulin suppresses glucose production by inhibiting both glycogenolysis and

gluconeogenesis. Insulin also stimulates glucose uptake in muscle, liver, and fat. Glucagon, epinephrine, cortisol, and growth hormone, collectively referred to as the counter-regulatory or counter-insulin hormones, oppose the effects of insulin.

In healthy nondiabetic subjects, insulin concentration increases as glucose concentration increases and falls as glucose concentration falls. In contrast, counter-regulatory hormone concentrations change (in general) in the opposite direction of insulin, by falling as glucose rises and rising as glucose falls. By doing so, insulin and the counter-insulin hormones act in concert to ensure that the amount of glucose entering and leaving the blood stream is closely matched in both the fed and the fasted state. Excess amounts of insulin or insulin-like material (e.g., insulin-like growth factor [IGF]-I or IGF-II), inadequate secretion of counter-insulin hormones, insufficient substrate, or defects in the gluconeogenic or glycogenolytic pathways alone or in combination can disrupt this balance and can cause hypoglycemia.

Regulation of Glucose Concentration in the Fed State

After an overnight fast (e.g., 8 to 10 hours), rates of glucose production and utilization average about 2 mg/kg/minute. At this time, most of the glucose is released from the liver, and a small amount is produced by the kidney. Carbohydrate ingestion increases glucose concentration, which stimulates secretion of insulin from the pancreatic β cells and suppresses secretion of glucagon from the pancreatic α cells. The resultant rise in the insulin-to-glucagon ratio increases hepatic glycogen synthesis and inhibits both glycogenolysis and gluconeogenesis, thereby increasing hepatic glycogen content. Glucose concentrations continue to rise until the rate of glucose uptake by peripheral tissues exceeds the net amount of glucose (meal-derived and endogenously produced) released from the splanchnic bed. Glucose concentration then begins to fall toward preprandial levels. This results in a progressive fall in insulin and a progressive rise in glucagon concentration, which, in turn permit a gradual increase in endogenous glucose production and a gradual fall in glucose utilization to basal rates. Depending on the amount and type of food ingested, both glucose concentration and turnover return to basal levels between 4 and 6 hours after the start of a meal.

Thus, the rate of carbohydrate absorption, the timing as well as the amount of insulin and glucagon secreted, the ability of the liver to store and subsequently release glucose, and the response of the liver, muscle, and fat to insulin and counter-insulin hormones all interact to minimize the rise in glucose concentration after a meal as well as to ensure a smooth return of glucose concentrations to preprandial levels during the transition from the fed to the postabsorptive state.

Regulation of Glucose Concentrations in the Fasted State

The contribution of gluconeogenesis becomes progressively more important as the duration of fast is extended and hepatic glycogen stores are depleted. The rate of glycogen depletion depends on a variety of factors, including antecedent diet and exercise, but the process is nearly complete after 24 to 48 hours of fasting. Anything that lowers the demand for glucose lessens the need to break down protein stores. This is accomplished by changing from a primarily carbohydrate-based metabolism in the fed state to a primarily fat-based metabolism in the fasted state.

As hepatic glycogen is depleted, the glucose concentration falls, and insulin decreases. Concentrations of glucagon, growth hormone, and cortisol all increase. This change in the hormonal milieu stimulates lipolysis and ketogenesis, which result in an increase in plasma glycerol, free fatty acid, and ketone body concentrations. Glycerol serves as a gluconeogenic substrate, thereby sparing amino acids. Free fatty acids are metabolized by muscle, liver, and other tissues in place of glucose. Free fatty acids also are converted by means of ketogenesis to acetoacetate and β-hydroxybutyrate, which can substitute for glucose as a fuel for the brain. These metabolic adaptations normally permit glucose to decrease gradually to 40 to 50 mg/dL during a fast without provoking symptoms of hypoglycemia. Inadequate glycogen stores or breakdown, insufficient gluconeogenesis resulting from defects in enzyme activity, lack of substrate availability, and persistent elevations of insulin or of insulin-like activity, alone or in combination, can cause or exacerbate hypoglycemia.

Recovery from Hypoglycemia

If counter-regulation is intact, hypoglycemia (regardless of the cause) will result in a decrease in insulin secretion and an increase in glucagon, epinephrine, cortisol, and growth hormone secretion. Glucagon provides the major defense against acute hypoglycemia. Epinephrine appears to become progressively more important when hypoglycemia is prolonged or severe. Permissive amounts of cortisol and growth hormone are required for a normal hepatic response to glucagon and epinephrine. Drugs or diseases that inhibit counter-regulatory secretion or action predispose patients to hypoglycemia.

CLINICAL MANIFESTATIONS

Symptoms of hypoglycemia have been classified into two major groups: those arising from activation of the autonomic nervous system (autonomic) and those related to insufficient glucose supply to the brain (neuroglycopenic). During acute insulin-induced hypoglycemia in healthy persons, autonomic symptoms are recognized at a threshold of approximately 60 mg/dL (3 mM), and impairment of brain function manifested by neuroglycopenic symptoms occurs at a threshold of approximately 50 mg/dL (2.8 mM) in arterialized venous blood (Fig. 238-1). Comparable venous levels would be about 3 mg/dL (0.16 mM) less. The rate of glucose descent has little if any influence on the occurrence of symptoms and signs of hypoglycemia in nondiabetic persons.

Variations among reports regarding allocation of symptoms to the autonomic and neuroglycopenic types may be ascribed to the specific groups of patients examined. These include patients with diabetes versus those without it, patients with type 1 versus type 2 diabetes, clinical versus experimental conditions, and, most important, differences among persons regarding their perception of symptoms. During experimentally induced hypoglycemia in 20 persons with and 25 persons without diabetes, a principal component analysis allocated sweating, trembling, feeling of warmth, anxiety, and nausea to the autonomic group and dizziness, confusion, tiredness, difficulty with speaking, headache, and inability to concentrate to the neuroglycopenic group. Hunger, blurred vision, drowsiness, and weakness could not be allocated to either group with any confidence. In another study of 10 nondiabetic persons, partitioning of symptoms during insulin-induced hypoglycemia allocated the categories of shaky/tremulous, heart pounding, nervous/anxious, sweaty, hungry, and tingling to the autonomic group and warm, weak, difficulty thinking/confused, and tired/drowsy to the neuroglycopenic group.

In a retrospective analysis of 60 patients with insulinoma, 85% had various combinations of diplopia, blurred vision, sweating, palpitations, and weakness; 80% had confusion or abnormal behavior; 50% were amnesic for the episode or had coma; and 12% had generalized seizures. None of the symptoms noted earlier, regardless of type, is specific for hypoglycemia. It is

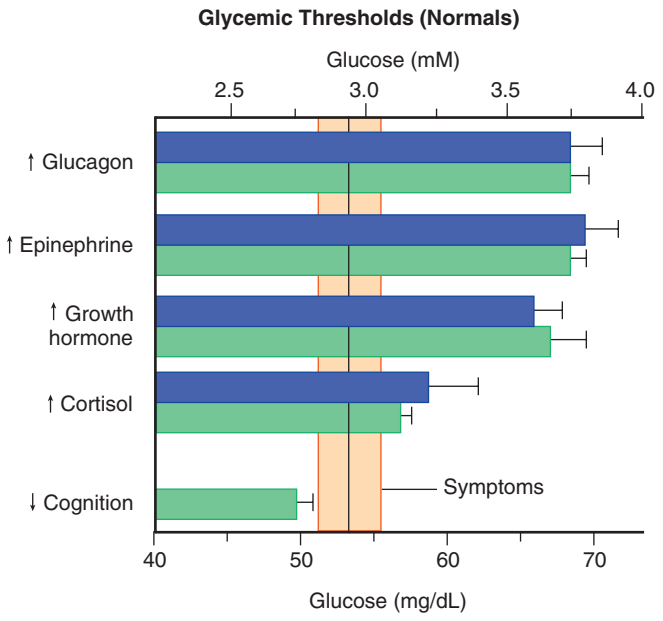

FIGURE 238-1. **Arterialized (*blue*) and venous (*green*) glycemic (mean ± standard error) thresholds for increments in plasma glucagon, epinephrine, growth hormone, and cortisol for symptoms of hypoglycemia and for impairment of cognitive function during decrements in serum glucose in normal humans from two independent studies.** (From Cryer PE. Glucose counterregulation: the physiological mechanisms that prevent or correct hypoglycemia. In: Frier B, Fisher BM, eds. *Hypoglycaemia and Diabetes: Clinical and Physiological Aspects.* London: Edward Arnold; 1993:34-55.)

unlikely that autonomic symptoms alone, in the absence of at least one event of neuroglycopenia, are indicative of a hypoglycemic disorder.

DIAGNOSIS

Classification

A useful approach for the clinician is a classification based on clinical characteristics (Table 238-1). Persons who appear healthy are likely to have hypoglycemic disorders that are different from those of persons who are ill. Hospitalized patients are at additional risk for hypoglycemia, often from iatrogenic factors.

TABLE 238-1 CLINICAL CLASSIFICATION OF HYPOGLYCEMIC DISORDERS

I. PATIENT APPEARS HEALTHY*

- A. No coexistent disease
  - 1. Drugs
    - a. Ethanol
    - b. Salicylates
    - c. Quinine
    - d. Haloperidol
  - 2. Insulinoma
  - 3. Islet hypertrophy/nesidioblastosis
  - 4. Noninsulinoma pancreatogenous hypoglycemia syndrome
  - 5. Post–gastric bypass hypoglycemia
  - 6. Factitial hypoglycemia from insulin or sulfonylurea use
  - 7. Exercise
  - 8. Autoimmune insulin syndrome
- B. Compensated coexistent disease
  - 1. Drugs
    - a. Dispensing error

II. PATIENT APPEARS ILL

- A. Drugs
  - 1. Pentamidine and *Pneumocystis* pneumonia
  - 2. Sulfamethoxazole-trimethoprim and renal failure
  - 3. Propoxyphene and renal failure
  - 4. Quinine and cerebral malaria
  - 5. Quinine and malaria
  - 6. Topical salicylates and renal failure
  - 7. Unripe ackee fruit and undernutrition
- B. Predisposing illness
  - 1. Infant small for gestational age
  - 2. Beckwith-Wiedemann syndrome
  - 3. Erythroblastosis fetalis
  - 4. Infant of diabetic mother
  - 5. Glycogen storage disease
  - 6. Defects in amino acid and fatty acid metabolism
  - 7. Reye's syndrome
  - 8. Cyanotic congenital heart disease
  - 9. Hypopituitarism
  - 10. Isolated growth hormone deficiency
  - 11. Isolated adrenocorticotropic hormone deficiency
  - 12. Addison's disease
  - 13. Hereditary fructose intolerance
  - 14. Carnitine deficiency
  - 15. Defective type 1 glucose transporter in the brain
  - 16. Acquired severe liver disease
  - 17. Non–islet cell tumor hypoglycemia
  - 18. Sepsis
  - 19. Renal failure
  - 20. Congestive heart failure
  - 21. Lactic acidosis
  - 22. Starvation
  - 23. Anorexia nervosa
  - 24. Postoperative removal of pheochromocytoma
  - 25. Insulin receptor antibody hypoglycemia
  - 26. Spinal muscular atrophy
- C. Hospitalized patient
  - 1. Diseases predisposing to hypoglycemia
  - 2. Total parenteral nutrition and insulin therapy
  - 3. Questran interference with glucocorticoid absorption
  - 4. Shock

*Mutations in the β-cell sulfonylurea receptor gene, glutamate dehydrogenase gene, and glucokinase gene are rare causes of hyperinsulinemic hypoglycemia, usually manifested in infancy or childhood.

Evaluation

The direction and extent of evaluation depend on the clinical presentation. The healthy-appearing patient with no coexistent disease who has a history of episodic symptoms suggestive of hypoglycemia requires an approach quite different from the hospitalized patient with acute hypoglycemia.

The Healthy-Appearing Patient

Serum Glucose

Because symptoms of hypoglycemia are not specific, it is essential to document a low serum glucose concentration at the time of the occurrence of spontaneous symptoms and relief of symptoms through correction of the low serum glucose concentration before concluding that a patient has a hypoglycemic disorder. Furthermore, reliance solely on a low blood glucose value to diagnose a hypoglycemic disorder fails to take into consideration the possibility of laboratory error, artifactual hypoglycemia, and, indeed, the finding that physiologically normal persons may have serum glucose levels much lower than 50 mg/dL (2.8 mM) during prolonged fasting. A normal serum glucose concentration (when measured reliably) obtained during the occurrence of spontaneous symptoms absolutely eliminates the possibility of a hypoglycemic disorder; no further evaluation is required. Although hypoglycemic disorders are uncommon, symptoms suggestive of hypoglycemia are quite common.

Recently published evidence-based guidelines recommend evaluation and management of hypoglycemia only in patients in whom Whipple's triad is documented. Often, however, measurement of serum glucose is not feasible while spontaneous symptoms are occurring during ordinary life activities. Under such circumstances, judging whether to proceed with further evaluation depends on a detailed history. Elicitation of a history of neuroglycopenic symptoms or evidence of a confirmed low serum glucose concentration warrants further testing. If a venipuncture sample cannot be obtained during the spontaneous occurrence of suspected hypoglycemia, the circumstances observed to provoke hypoglycemia should be reproduced: a 72-hour fast for persons with hypoglycemia in the food-deprived state and a mixed-meal test for persons with postprandial hypoglycemia.

Seventy-Two-Hour Fast

The prolonged supervised (72-hour) fast is an important diagnostic test. It should be conducted in a standardized fashion. A suggested protocol is shown in Table 238-2. For patients who experience signs or symptoms of hypoglycemia and who have simultaneously measured serum glucose in the hypoglycemic range, the fast should be terminated at that point. Studies in patients who have neither should not be extended beyond 72 hours.

The decision to end the fast may not be easy. Some patients have slightly depressed glycemic levels without symptoms or signs of hypoglycemia. Other patients may experience the symptoms they have had in ordinary life but have serum glucose levels higher than the hypoglycemic range. Young, lean, healthy women and, to a lesser degree, men may have serum glucose levels in the range of 40 mg/dL during prolonged fasting. Careful examination and testing for subtle signs of symptoms of neuroglycopenia should be conducted repeatedly when the patient's serum glucose level is near or in the hypoglycemic range. The 72-hour fast may be ended when the serum glucose concentration is

TABLE 238-2 PROTOCOL FOR 72-HOUR FAST

1. Date the onset of the fast as of the last ingestion of calories; discontinue all nonessential medications.
2. The patient may drink calorie-free and caffeine-free beverages.
3. The patient must be active during waking hours.
4. Measure plasma glucose, insulin, C-peptide, and β-hydroxybutyrate (on the same venipuncture specimen) every 6 hours until plasma glucose reaches ≤60 mg/dL (3.3 mM), when frequency should be every 1 to 2 hours.
5. End the fast when the plasma glucose is ≤45 mg/dL (2.5 mM) and the patient has symptoms or signs of hypoglycemia, or plasma glucose is ≤55 mg/dL if Whipple's triad* had been demonstrated previously.
6. At the end of the fast, measure plasma glucose, insulin, C-peptide, β-hydroxybutyrate, and sulfonylurea (on the same venipuncture specimen); then inject glucagon, 1 mg intravenously, and measure plasma glucose every 10 minutes three times. After this, feed the patient.

*Whipple's triad is: (a) symptoms or signs consistent with hypoglycemia, (b) a low plasma glucose concentration, and (c) resolution of those symptoms or signs after the plasma glucose concentration is raised.

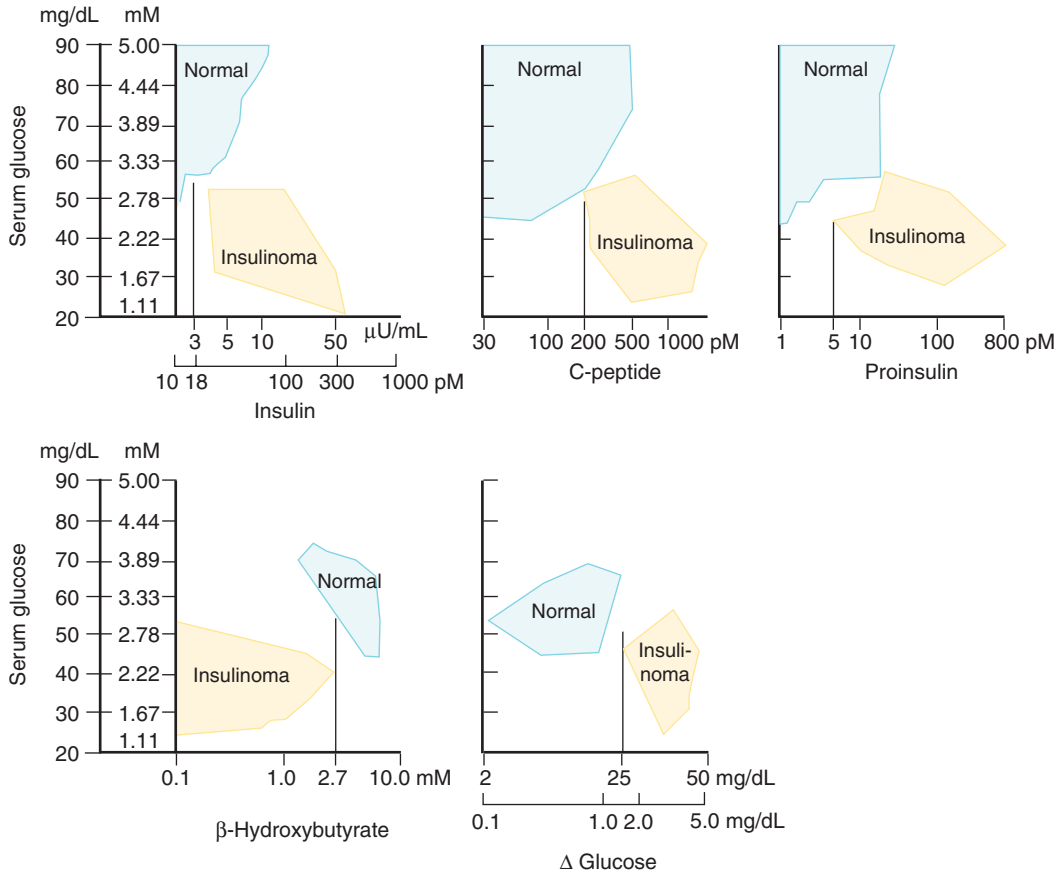

FIGURE 238-2. Distributions of plasma insulin, C-peptide, proinsulin, β-hydroxybutyrate, and serum glucose (Δ glucose) response to intravenous glucagon versus serum glucose at the end of the prolonged fast (72 hours in normal persons [*n* = 25] or at Whipple's triad for patients with histologically confirmed insulinoma [*n* = 40]). The *shaded area* represents serum glucose level less than or equal to 50 mg/dL (2.8 mM). The *vertical line* represents the diagnostic level for insulinoma. Criteria for insulinoma are insulin level greater than or equal to 3 µU/mL (18 pM), C-peptide level greater than or equal to 200 pM, proinsulin level greater than or equal to 5 pM, β-hydroxybutyrate level less than or equal to 2.7 mM, and Δ glucose level greater than or equal to 25 mg/dL (1.4 mM).

55 mg/dL or less if Whipple's triad (see Table 238-2) had previously been demonstrated. β-Cell polypeptides are suppressed in healthy persons when serum glucose is 55 mg/dL or less. Although most patients with insulinoma become hypoglycemic before 72 hours (33% in 12 hours, 65% in 24 hours, 84% in 36 hours, 93% in 48 hours, and 99% in 72 hours in a group of 170 patients with insulinoma), continuation of the fast to 72 hours is necessary to rule out the likelihood of organic hypoglycemia. Although the 72-hour fast has usually been considered to be an inpatient procedure, it may be initiated in an endocrine testing center after an overnight fast. Forty percent of patients have had positive results of the fast in the outpatient setting. Those patients whose fast result is not positive by the end of the outpatient evaluation period are admitted to the hospital to complete the 72-hour fast.

The interpretation of concentrations of β-cell polypeptides (insulin, C-peptide, and proinsulin) during the 72-hour fast is predicated on the concomitant serum glucose concentration. The normal overnight fasting ranges for these polypeptides do not apply when the serum glucose level is less than 55 mg/dL.

Insulin-mediated hypoglycemic disorders are characterized by plasma insulin concentrations greater than or equal to 3 µU/mL (immunochemiluminometric assay) (Fig. 238-2). Persons with insulinomas have insulin concentrations that rarely exceed 100 µU/mL. Values of 1000 µU/mL or greater suggest recent insulin administration or the presence of insulin antibodies. Ratios of glucose to insulin, and vice versa, including the "amended ratio," have been used in an effort to identify relative hyperinsulinemia when the insulin concentration is in the normal overnight fasting range. Unfortunately, these ratios have very poor diagnostic utility (see Fig. 238-2).

Criteria for hyperinsulinemia using C-peptide and proinsulin (each measured by immunochemiluminometric assays) are 200 pmol/L or more and 5 pmol/L or more, respectively (see Fig. 238-2). The molar ratio of insulin to C-peptide is the same for patients with insulinomas as it is for healthy individuals (~0.2). Although the molar ratio of proinsulin to insulin is increased in patients with insulinoma, it appears to have no diagnostic utility.

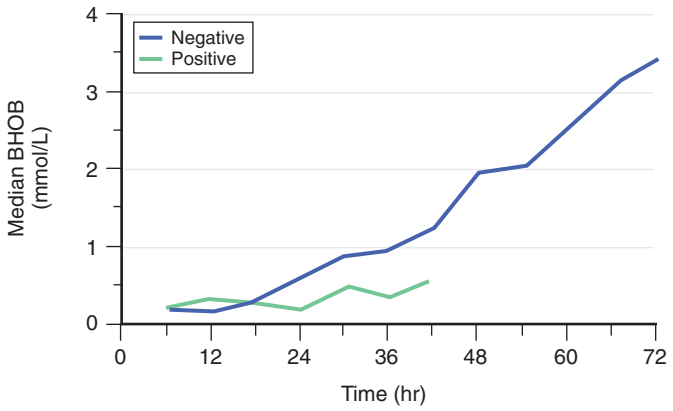

FIGURE 238-3. Median concentrations of β-hydroxybutyrate (BHOB) during 72-hour fasts are shown for patients with insulinoma, all of whom had positive fasts, and for persons with negative fasts. (From Service F. Increasing serum B-hydroxybutyrate. *J Clin Endocrinol Metab.* 2005;90:4555-4558. Copyright 2005, The Endocrine Society.)

Because of the antiketogenic effect of insulin, plasma β-hydroxybutyrate measurement at the end of the fast (72 hours in healthy individuals and when Whipple's triad is fulfilled in patients during a diagnostic fast) is useful. This parameter is considered to be an insulin surrogate. Patients with insulin-mediated hypoglycemia have concentrations of less than 2.7 mmol/L, whereas others (healthy individuals and those with non–insulin-mediated hypoglycemia) have higher levels (see Fig. 238-2). The progressive rise of β-hydroxybutyrate concentration early in the 72-hour fast in persons destined to have a negative test, in contrast to the sustained suppressed level in patients with insulinoma (Fig. 238-3), provides the opportunity to end the

fast before the 72-hour point either by attaining a level of 2.7 mmol/L or higher or by having two successive concentrations measured at 6-hour intervals that exceed the concentration at the 18-hour time point. Another insulin surrogate is the response of serum glucose to 1 mg of glucagon injected intravenously at the end of the fast. The rationale for this procedure is that insulin is glycogenic and antiglycogenolytic. Patients with insulin-mediated hypoglycemia have a maximal increment at least 25 mg/dL greater than the terminal fasting serum glucose, whereas others (healthy individuals and those with non–insulin-mediated hypoglycemia) have lower increments (see Fig. 238-2). When the serum glucose concentration exceeds 60 mg/dL at the end of the fast, measurement of the β-cell polypeptides and insulin surrogates is uninformative and unnecessary.

Measurement of sulfonylureas and meglitinides in the plasma when a patient develops hypoglycemia is an essential component of the prolonged supervised fast. The pattern of serum glucose and β-cell polypeptides in sulfonylurea-induced hypoglycemia is identical to that observed in persons with insulinoma. A liquid chromatographic tandem mass spectrography method provides a sensitive measurement of first- and second-generation sulfonylureas and meglitinides (Table 238-3 provides diagnostic interpretation).

Mixed-Meal Test

For persons with a history of neuroglycopenic symptoms within 5 hours of food ingestion, a mixed-meal test may be conducted. The patient should eat a meal similar to that leading to symptoms during ordinary life activities. The test result is positive when the patient experiences neuroglycopenic symptoms and a concomitant serum glucose level is low (e.g., ≤50 mg/dL). No standards exist for the interpretation of levels of β-cell polypeptides measured during this test. However, one can expect insulin levels to be suppressed during postprandial hypoglycemia, provided five half-lives (~30 minutes) have elapsed from peak insulinemia. A positive mixed-meal test in and of itself does not provide a diagnosis, only biochemical confirmation of the history. A surprisingly high percentage of patients (~10%) with insulinoma report neuroglycopenic symptoms after meals, and in some instances only after meals. Patients with a positive mixed-meal test may require a 72-hour fast to document both fasting and postprandial hypoglycemia. For those patients with a positive mixed-meal test result and a negative 72-hour fast result, glucagon levels during the mixed-meal test should be determined to ensure a counter-regulatory response to the low serum glucose concentration. Gastric emptying studies may be performed to look for accelerated transit as a cause of postprandial hypoglycemia. If this is found, measurement of prokinetic gastrointestinal hormones may be indicated. The combination of a positive mixed-meal test and a negative 72-hour fast may occur in a patient with insulinoma or with noninsulinoma pancreatogenous hypoglycemia syndrome. The 5-hour oral glucose tolerance test should not be used as a diagnostic test for hypoglycemia because a substantial percentage of healthy persons may have a serum glucose nadir less than or equal to 50 mg/dL. Similarly, in patients who are experiencing hypoglycemia-like symptoms after Roux-en-Y gastric bypass, it is important to ensure that the test meal avoids simple carbohydrates and liquid calories, which can provoke symptoms in most patients who have had such surgery.

C-Peptide Suppression Test

The C-peptide suppression test is based on the observation that β-cell secretion (as measured by levels of C-peptide) is suppressed during hypoglycemia to a lesser degree in persons with an insulinoma than in physiologically normal persons. It is rarely used because interpretation requires normative data adjusted for the patient's body mass index and age.

Insulin Antibodies

The detection of insulin antibodies was once considered to be firm evidence of factitious hypoglycemia resulting from inappropriate self-administration of insulin, especially when animal insulin was the only commercially available type. Because of the use of human insulin, which is less antigenic than that derived from animals, such patients usually have no detectable insulin antibodies. Hypoglycemia that can be directly attributed to the spontaneous generation of antibodies to native insulin has been reported to occur primarily in Asians and rarely in whites. In patients with insulin autoimmune hypoglycemia from the spontaneous generation of insulin antibodies, such antibodies may be monoclonal or polyclonal and are present in very high titers, in contrast to the much lower titers in insulin-treated diabetes. It is important to test for the presence of insulin antibodies because even low titers, which may have no diagnostic significance, may cause spurious results of the assay for insulin. Hypoglycemia in such instances may have a variable association with fasting or meal ingestion.

Glycated Hemoglobin

Although glycated hemoglobin concentrations are statistically significantly lower in patients with insulinomas than in physiologically normal subjects, too much overlap exists to provide a diagnostic criterion.

TABLE 238-3 DIAGNOSTIC INTERPRETATION OF THE RESULTS OF A 72-HOUR FAST*

	SIGNS AND SYMPTOMS	GLUCOSE† (MG/DL)	INSULIN‡‡ (μU/ML)	C-PEPTIDE‡§ (PMOL/L)	PROINSULIN‡‖ (PMOL/L)	β-HYDROXYBUTYRATE (MMOL/L)	GLUCOSE¶ (MG/DL)	SULFONYLUREA IN PLASMA
Normal	No	≥40	<3	<200	<5	>2.7	<25	No
Insulinoma	Yes	≤45	≥3†	≥200	≥5	≤2.7	≤25	No
Factitious hypoglycemia from insulin	Yes	≤45	≥3**	<200	<5	≤2.7	≥25	No
Sulfonylurea-induced hypoglycemia	Yes	≤45	≥3	≥200	≥5	≤2.7	≥25	Yes††
Hypoglycemia mediated by insulin-like growth factor	Yes	≤45	≤3	<200	<5	≤2.7	≥25	No
Non–insulin-mediated hypoglycemia	Yes	≤45	<3	<200	<5	>2.7	<25	No
Inadvertent feeding during the fast	No	≤45	<3	<200	<5	≤2.7	≥25	No
Nonhypoglycemic disorder	Yes	≥40	<3	<200	<5	>2.7	<25	No

*Measurements are made at the point the decision is made to end the fast.
†Sequential plasma glucose measurements in the hypoglycemic range fluctuate. Plasma glucose levels ≤45 mg/dL at the time a decision is made to end the fast may rise to as much as 56 mg/dL when the fast is actually ended approximately 1 hour later. Plasma glucose levels may be as low as 40 mg/dL during prolonged fasting in normal women.
‡In normal subjects, plasma insulin, C-peptide, and proinsulin levels may be higher if the plasma glucose level is >60 mg/dL.
§Measured by the immunochemiluminometric technique (lower limit of detection, 33 pmol/L).
‖Measured by the immunochemiluminometric technique (lower limit of detection, 0.2 pmol/L).
¶In response to intravenous glucagon (peak value minus value at end of fast).
†Ratios of insulin to glucose are of no diagnostic value in patients with insulinomas.
**Plasma insulin levels may be very high (>100 μU/mL or even = 1000 μU/mL) in factitious hypoglycemia produced by insulin.
††Unlike the first generation of sulfonylurea drugs, which were easily measured, second-generation drugs are difficult to measure.
‡‡Measured by immunochemiluminometric assay, lower limit of detection is 0.1 μU/mL.

Insulin Response to Selective Arterial Calcium Injection

The diagnosis of a hypoglycemic disorder is made entirely from biochemical evidence. Should the data document hyperinsulinemic hypoglycemia, localization procedures are undertaken. Standard radiologic tests are conducted solely in an effort to localize a lesion, rather than for diagnostic purposes. With the availability of the selective arterial calcium stimulation test, which is predicated on hyper-responsive β cells for a positive result, the purposes of regionalization and diagnosis of β-cell hyperfunction may both be served. This test requires access to various intra-abdominal vessels, including the right hepatic vein, splenic artery, gastroduodenal artery, and superior mesenteric artery. A two- to three-fold increase in insulin concentration in the right hepatic vein in response to calcium injection into one or more of the arteries supplying the pancreas suggests that the region served by that artery harbors abnormally functioning β cells, whether from insulinoma or islet hypertrophy or nesidioblastosis.

The Ill-Appearing Patient

Hypoglycemia in persons with coexistent disease sometimes occurs as a discrete episode, which may be asymptomatic if the patient has preexisting blunting of consciousness. Recognition of the underlying disease and its propensity for hypoglycemia and action taken to minimize recurrence may be sufficient. Confirmation of the suspected mechanism for the hypoglycemia may be pursued. Mechanisms may include low insulin and C-peptide levels in cases of non–insulin-mediated hypoglycemia (e.g., ethanol hypoglycemia), elevated IGF-II in cases of non–β-cell tumor-related hypoglycemia, low levels of cortisol in cases of adrenal insufficiency, and blunted serum glucose responses to intravenous glucagon in cases of hypoglycemia resulting from abnormal liver function, glycogen storage disease, sepsis, or congestive heart failure.

Patients who are in hospitals today generally are severely ill and have multisystem disease. These patients are at risk for iatrogenic hypoglycemia in addition to the potential risk generated from the underlying disease. In one tertiary medical center, 1.2% of all patients admitted over a 6-month period experienced hypoglycemia (serum glucose ≤49 mg/dL). The primary causes among persons without diabetes were renal insufficiency, malnutrition, liver disease, infection, and shock. Several patients had more than one risk factor. Not infrequently, nondiabetic patients become hyperglycemic because of treatment with enteral or parenteral nutrition or glucocorticoids. Use of insulin to control hyperglycemia puts patients at risk for hypoglycemia, especially if feedings are interrupted, the dose of glucocorticoid is abruptly reduced or stopped, or glucocorticoid availability is diminished through simultaneous administration of a bile acid sequestrant. In ferreting out the cause of hypoglycemia in the seriously ill hospitalized patient, diligent examination of the record is profitable.

TREATMENT

Rx

The treatment of hypoglycemic disorders encompasses two distinct components: (1) relief of neuroglycopenic systems by restoration of the low serum glucose level to the normal range, and (2) correction of the underlying cause of the hypoglycemia. Unlike diabetes, in which restoration of euglycemia is the ideal goal, overtreatment of hypoglycemia in a nondiabetic person has no sequelae. For the patient with an as-yet undiagnosed disorder, blood by venipuncture should be obtained for measurement of glucose, β-cell polypeptides, and β-hydroxybutyrate before treatment. Both diagnosis and treatment can be achieved by intravenous injection of glucagon with monitoring of the serum glucose response. Depending on the response, the patient may require intravenous glucose administration as a bolus of 50% or a continuous infusion of 5 or 10% or may recover sufficiently to take oral nutrition.

Treatment of the underlying cause of the hypoglycemia depends on the specific cause. Once a biochemical diagnosis of insulinoma has been made, preoperative localization should be attempted. Because of the rarity of insulinoma, only a few referral centers have generated sufficient experience to assess the effectiveness of various localization procedures: computed tomography, magnetic resonance imaging, endoscopic and transabdominal ultrasonography, octreotide scan, celiac axis angiography, and selective arterial calcium stimulation and transhepatic portal venous sampling. Experts differ in their preferred approaches because of differences in experience and skill level. Ultrasonography has the advantage of precise localization, especially in relation to the pancreatic duct. Magnetic resonance imaging and octreotide scanning are not useful. Transhepatic portal venous sampling has been abandoned in centers that once used this technique. There is general agreement that intraoperative ultrasonography combined with careful palpation of the pancreas by an experienced surgeon provides the highest success rate in localization.

Specific Causes

Insulinoma

Insulinoma is a rare tumor. The incidence is estimated to be 4 cases per 1 million person years, similar to that of pheochromocytoma. Insulinoma occurs at any age, is slightly more common in women (59%), and is associated with low rates of malignancy (6%), multiplicity (9%), multiple endocrine neoplasia syndrome (Chapter 239) (8%), and recurrence (8%). After successful removal of an insulinoma, the patient can look forward to a normal life expectancy. Medical therapy for the patient whose insulinoma is missed at pancreatic exploration, or for the patient unsuitable for surgery, or for the patient with metastatic insulinoma may include diazoxide, verapamil, phenytoin, propranolol, or octreotide. Insulinoma is occasionally suspected in patients with labile diabetes, especially when insulin therapy has apparently been suspended. One case of documented insulinoma in a person with type 1 diabetes and a few cases in persons with type 2 diabetes have been reported. Optimal treatment is surgical resection.

Noninsulinoma Pancreatogenous Hypoglycemia

Adults with episodes of hyperinsulinemic hypoglycemia resulting in neuroglycopenia may harbor islet hypertrophy/nesidioblastosis but no insulinoma (noninsulinoma pancreatogenous hypoglycemia syndrome). The clinical features are uniquely different from those of insulinoma: predominance of male patients, postprandial neuroglycopenia, negative 72-hour fast result, negative radiologic localization studies, positive selective arterial calcium stimulation test, and relief of symptoms with gradient-guided partial pancreatectomy. A subgroup of these patients has been identified who have the unique characteristic of a history of Roux-en-Y gastric bypass surgery.

Insulin Factitial Hypoglycemia

Insulin factitial hypoglycemia usually is manifested by neuroglycopenic symptoms that occur erratically. This disorder is observed more often in women, usually those in a health-related occupation. Once confronted with the diagnosis, about half of the patients admit to self-abuse, and most cease this activity. Insulin autoimmune hypoglycemia may be very difficult to distinguish from insulin factitial hypoglycemia because of similar biochemical features. However, some patients with the former have evidence of another autoimmune disease, and the insulin antibody titers are very high.

Other Causes

Mutations in the β-cell sulfonylurea receptor gene, glutamate dehydrogenase gene, and glucokinase gene have been reported to cause hyperinsulinemic hypoglycemia (i.e., inappropriately elevated insulin and C-peptide concentrations). Patients usually present at an early age, and often a familial pattern is detected. Physical exercise–induced hypoglycemia also has been described in some families. Insulin-like material can be secreted by some malignant tumors (e.g., hemangiopericytomas, fibromas, fibrosarcomas, hepatomas). In such instances, plasma insulin and C-peptide concentrations are low at the time of hypoglycemia, whereas pro-IGF-II concentrations are elevated.

ISLET CELL TUMORS

DEFINITION

Tumors of the endocrine pancreas generally are malignant. Insulin-producing tumors are the exception because they are usually benign. Islet cell tumors are commonly referred to as either functioning or nonfunctioning. Functioning tumors release one or more hormones in amounts sufficient to raise plasma concentrations. Nonfunctioning tumors may contain one or more hormones but, by definition, do not release substantial amounts into the systemic circulation.

Functioning tumors generally manifest with symptoms relating to the hormones secreted, whereas nonfunctioning tumors generally manifest as a pancreatic mass or as a metastasis. Nonfunctioning tumors tend to be larger and more advanced at the time of diagnosis because their presence is not heralded by symptoms generated by hormone excess.

PATHOBIOLOGY

Functioning islet cell tumors are commonly associated with one of five widely recognized syndromes (Table 238-4). The insulinoma, Zollinger-Ellison, glucagonoma, VIPoma, and somatostatinoma syndromes are believed to result (at least in part) from excess secretion of insulin, gastrin, glucagon, vasoactive intestinal polypeptide (VIP), and somatostatin, respectively.

TABLE 238-4 CHARACTERISTICS OF FUNCTIONING ISLET CELL CARCINOMAS

SYNDROME	CLINICAL PRESENTATION	BIOCHEMICAL DIAGNOSIS	RATE OF MALIGNANCY (%)	METASTASES AT DIAGNOSIS (%)	LOCALIZATION (RADIOGRAPHIC)	ECTOPIC SITES (NONPANCREATIC)
Insulinoma	Neuroglycopenia Adrenergic response	Blood glucose ≤45 mg/dL Insulin >3 μU/mL Absence of insulin antibodies Elevated C-peptide	<10	<10	Ultrasonography Spiral CT Selective calcium stimulation test	Rare
Zollinger-Ellison syndrome	Dyspepsia/ulcer Diarrhea	Elevated basal gastrin Elevated basal acid output Positive secretin test	50-60	50-80	Ultrasonography, CT, angiography, PVS	Duodenum, rarely other
WDHA (VIPoma)	Profuse, secretory diarrhea Hypokalemia Hypochlorhydria/achlorhydria Hypercalcemia Hyperglycemia	Elevated VIP	50	50	CT, PVS, angiography	Retroperitoneum, occasionally lung
Glucagonoma	Dermatitis Diabetes Weight loss Anemia	Elevated glucagon	75	60-70	CT	Rare
Somatostatinoma	Diabetes Cholelithiasis Diarrhea Steatorrhea	Elevated somatostatin	90-100	50-75	CT	Duodenum

CT = computed tomography; PVS = portal venous sampling; VIP = vasoactive intestinal peptide; WDHA = watery diarrhea, hypokalemia, achlorhydria.
Adapted from Grant CS. Surgical management of malignant islet cell tumors. *World J Surg.* 1993;17:498-503.

However, additional symptoms also can occur because these tumors frequently secrete more than one hormone (e.g., pancreatic polypeptide, adrenocorticotropin, calcitonin, neurotensin, human chorionic gonadotropin, growth hormone–releasing factor, prostaglandins, and parathyroid hormone), and the amount and type of the hormone secreted can change over time. Islet cell tumors either are sporadic or can occur in association with other known genetic syndromes, such as multiple endocrine neoplasia type 1. Sporadic tumors occur at any age but most commonly are detected between 40 and 60 years of age. The diagnosis can be confirmed by obtaining tissue during surgical resection or by needle biopsy.

TREATMENT

Rx

With the exception perhaps of insulinomas, the optimal treatment of islet cell tumors is currently not known because their rarity has made the conduct of randomized therapeutic trials extremely difficult. Furthermore, in the absence of metastases, no reliable histologic criteria distinguish benign from malignant lesions. Islet cell tumors most commonly metastasize to the liver and adjacent lymph nodes. Metastases to lung, bone, adrenal gland, kidney, and ovary may also occur. Fortunately, the rate of growth of malignant islet cell tumors is generally slow. Therefore, many clinicians recommend surgery if the pancreatic tumor is resectable and if the extent of metastatic disease (if present) is limited. "Debulking" of metastases, whether by surgery or by hepatic embolization, may improve symptoms by lowering circulating hormone concentrations. Treatment with chemotherapeutic agents such streptozotocin (alone or in combination with 5-fluorouracil), doxorubicin, dacarbazine, or interferon-β also may improve symptoms and, in some instances, perhaps improve survival. Somatostatin is a potent inhibitor of hormone secretion. Treatment with long-acting analogues of somatostatin can result in a dramatic, albeit at times temporary, decrease in symptoms, particularly those associated with glucagonomas and VIPomas.

POLYGLANDULAR DISORDERS

HENRY M. KRONENBERG

Internists need to recognize diseases that involve independent abnormalities of more than one endocrine gland, for several reasons. First, the known patterns of multiglandular disease can alert the clinician to look for a second disorder when one is diagnosed. Second, the treatment of many of the individual diseases that occur in polyglandular disorders may differ from the appropriate treatment for the same diseases when they manifest in isolation. Third, because many of these diseases appear in characteristic familial patterns, recognition of the syndromes can lead to useful family screening. Fourth, an understanding of the pathogenesis of these unusual disorders is likely to clarify the pathogenesis of more common single-gland disorders as well. This chapter discusses the best-characterized polyglandular disorders, with these four considerations as the primary focus. Other chapters should be consulted for more detailed discussion of the diseases of individual glands.

NEOPLASTIC SYNDROMES

Three mechanistically distinct neoplastic syndromes involve more than one endocrine gland. Although known by a variety of different names in the past, they are now most frequently called multiple endocrine neoplasia type 1, multiple endocrine neoplasia types 2a and 2b, and McCune-Albright syndrome.

Multiple Endocrine Neoplasia Type 1

DEFINITION

Multiple endocrine neoplasia type 1 (MEN 1) is an autosomal dominant disorder characteristically involving the parathyroid glands, the pancreatic islets, and the anterior pituitary. Less commonly, adrenal cortical neoplasia and foregut carcinoids (primarily of thymus and lung) occur. Nonendocrine manifestations include lipomas, facial angiofibromas, and collagenomas.

PATHOGENESIS

The gene for MEN 1 is located at chromosome 11, band 11q13, and it encodes a 610–amino acid protein called menin. Menin is a widely expressed nuclear protein that forms complexes with proteins that methylate histones in chromatin and also binds many transcription factors. Menin increases gene transcription by poorly understood mechanisms. Although the normal physiologic roles of menin are poorly understood, the abnormalities in MEN 1 suggest that the menin gene is a tumor suppressor gene. The inherited mutations in the menin gene vary widely, are located throughout the gene, and often generate truncated, presumably nonfunctional, menin peptides. In addition to this genetic abnormality, which is present in all cells in the body, MEN 1 tumors usually harbor deletions of the normal allele of the menin gene. Presumably, loss of both copies of the tumor suppressor gene, one by inherited mutation and one by mutation in one particular cell, confers a selective advantage to the cell that proliferates to become a clonal tumor. Such clonal deletions have been found in 100% of parathyroid tumors removed at surgery from patients with MEN 1. Other acquired genetic abnormalities accumulate in these tumors; thus, the tumors in MEN 1 follow the pattern of multistep tumorigenesis found in malignant tumors. The two-hit tumor suppressor model has been confirmed by the generation of mice missing one or both copies of the menin gene in specific target cell types.

The two-hit tumor suppressor model can explain many of the clinical features of MEN 1. Clinical presentation of an inherited disorder in adulthood can be explained by the requirement for a second mutation before clonal expansion. The asymmetrical but relentless nature of the parathyroid disease may be explained by asynchronous but inevitable somatic mutations in each of the parathyroid glands. Multiple islet tumors may result from the same process. What remains completely unexplained is the particular vulnerability of parathyroid, pancreatic islet, and pituitary cells, given the widespread expression of the menin gene.

The menin gene is mutated in about 20% of sporadic parathyroid adenomas, a fraction of sporadic malignant endocrine tumors of the pancreas, and some sporadic carcinoid tumors of the lung as well. Because these mutations occur only in the tumor and not in the patient's normal cells, no familial clustering occurs in these sporadic tumors.

DIAGNOSIS

Screening

Genetic screening for menin gene mutations is now available in reference laboratories. Because inactivating mutations can occur anywhere within the gene, standard surveys of the borders of exons and introns detect only 70% of the genetic abnormalities in families affected by MEN 1. Occasional families inherit mutations in the gene encoding the cyclin-dependent kinase inhibitor p27, but the abnormal genes in a small fraction of MEN 1 patients remain unknown. Thus, the specific mutation in menin in an index case should be ascertained before family members are screened. Because no safe and effective therapies are available for asymptomatic MEN 1 tumors, the precise role for genetic screening has not been established.

To detect active disease, the most useful test to complement a thorough history and physical examination is measurement of blood calcium, particularly ionized calcium, at intervals after age 15 years. Prolactin, gastrin, and fasting blood glucose measurements can also be useful.

PARATHYROID DISEASE. Hyperparathyroidism (Chapter 253), the most common abnormality in MEN 1, is found in more than 90% of patients. Elevated blood calcium levels usually first appear between age 20 and 40 years, considerably earlier than in sporadic primary hyperparathyroidism; however, the disease usually does not present during childhood. At first, the disease is asymptomatic, but it subsequently leads to all the expected consequences of primary hyperparathyroidism. Unlike sporadic hyperparathyroidism, the disease is relentlessly progressive and, with prolonged follow-up, always involves all four parathyroid glands. The involvement is characteristically asymmetrical and asynchronous. This pattern can lead to inappropriately limited parathyroid surgery. If fewer than three parathyroid glands are removed, hypercalcemia always recurs, although not necessarily immediately. Surgical results in patients with MEN 1 are generally less satisfactory than in patients with sporadic four-gland parathyroid disease. At some centers, all four glands are removed, and a portion of one gland is reimplanted in the easily accessible forearm in an attempt to avoid the hazards of too much or too little surgery. The difficulty in attaining long-term normocalcemia has led many clinicians to postpone surgery when the disease is asymptomatic. This strategy may need to be modified if the patient develops Zollinger-Ellison syndrome (see later), because hypercalcemia can dramatically increase the gastrin levels in such patients.

PANCREATIC ISLET DISEASE. As many as 80% of patients have pancreatic abnormalities at autopsy; many correspondingly have increased blood levels of gastrin, insulin, pancreatic polypeptide, somatostatin, vasoactive intestinal polypeptide, or glucagon during stimulation or suppression tests. The pancreas is often diffusely involved with microadenomas and macroadenomas and apparently hyperplastic lesions. Endoscopic ultrasound can now detect very small tumors of the head or body of the pancreas; the precise role of such early detection is an area of great research interest. Characteristically, more than one islet hormone is secreted from the multiple tumors often present in MEN 1. Despite this underlying pattern of multiple cellular involvement, patients characteristically present with symptoms of only one hormonal disorder. The most common disease is Zollinger-Ellison syndrome (Chapter 201), a peptic ulcer disease associated with gastrin-producing tumors. Identification of disease-causing tumors has proved difficult. The gastrinomas in MEN 1 are often multiple, are very small, and are found in the duodenal wall considerably more often than in the pancreas. Macroadenomas observed in the pancreas by computed tomography (CT) or intraoperative ultrasonography in patients with MEN 1 who have Zollinger-Ellison syndrome may well synthesize hormones other than gastrin.

Although some centers continue to experiment with aggressive attempts at surgical cure, the high recurrence rate after surgery limits its role in this disease. Medical therapy with histamine (H_2)-receptor antagonists and hydrogen, potassium–adenosine triphosphatase inhibitors can usually adequately control the secretion of stomach acid. The tumors are slow growing but frequently metastasize locally and to the liver. Chemotherapy is only partially effective and does not cure the disease.

Insulinomas are the second most common, clinically important islet tumor in patients with MEN 1. These tumors are often small and multiple and are much less frequently malignant than are gastrinomas. Despite the frequently diffuse nature of the disease, dominant insulin-producing tumors can often be identified by selective portal venous sampling. Removal of the dominant tissue or, if necessary, subtotal (80%) pancreatectomy is the primary therapeutic strategy.

PITUITARY DISEASE. As in sporadic disease, pituitary disease (Chapter 231) can manifest with a hypersecretion syndrome or with symptoms resulting from a sellar mass or from hypopituitarism. Pituitary tumors occur in about one third of patients with MEN 1. Prolactinomas are the most common tumors. Adrenocortical hyperfunction can result from a pituitary adenoma or from production of adrenocorticotropic hormone or corticotropin-releasing hormone by a foregut carcinoid. Although nonfunctioning adrenal neoplasms are common in patients with MEN 1, primary adrenal neoplasms causing glucocorticoid excess are rare. Acromegaly can result from a pituitary neoplasm or as a consequence of the production of growth hormone–releasing hormone by pancreatic islet tumors. After consideration of ectopic hormone and releasing hormone production by nonpituitary tumors, the course and treatment of pituitary disease in MEN 1 resemble those of sporadic pituitary disease.

PROGNOSIS

The most life-limiting disorders in MEN 1 are the malignant tumors of the pancreatic islets. Whereas sporadic gastrinomas causing Zollinger-Ellison syndrome can sometimes be cured surgically, the gastrinomas in MEN 1 have not been cured by any surgical approach reported thus far. Although vigorous acid control is possible and has dramatically increased life expectancy, these tumors metastasize to the liver and have been poorly responsive to chemotherapy. Other functioning and nonfunctioning pancreatic islet tumors can metastasize and cause death as well. Thus, periodic CT and/or magnetic resonance imaging (MRI) of the abdomen to detect, monitor, and remove growing islet tumors is common practice. The parathyroid tumors are almost always benign, but they recur with a relentlessness much greater than in sporadic multiple-gland parathyroid disease. Thus, even after resection of three and a half glands, recurrence of hyperparathyroidism is common. The course of pituitary tumors, in contrast, resembles the course of sporadic pituitary tumors of an analogous hormonal type.

Multiple Endocrine Neoplasia Types 2a and 2b

DEFINITION

Multiple endocrine neoplasia type 2a (MEN 2a) is an autosomal dominant disease that manifests with medullary carcinoma of the thyroid (MCT;

Chapter 254), pheochromocytoma (Chapter 235), and, less commonly, hyperparathyroidism (Chapter 253). MEN 2b is closely related to MEN 2a because it also manifests with MCT and pheochromocytoma and because both diseases involve mutations in the *RET* proto-oncogene (see later). Patients with MEN 2b present with certain abnormalities not found in patients with MEN 2a, however. These include mucosal neuromas of the tongue, lips, eyelids, and gastrointestinal tract and a marfanoid habitus. Hyperparathyroidism rarely occurs in patients with MEN 2b. MEN 2b is less common than MEN 2a.

PATHOGENESIS

In MEN 2a and 2b, the MCTs and pheochromocytomas often appear bilaterally. Careful prospective analysis of families with MEN 2a has demonstrated that diffuse C-cell hyperplasia precedes a clinically obvious appearance of MCT. C-cell hyperplasia can be detected during the first decade of life by measuring calcitonin after the administration of gastrin, although this test has been supplanted clinically by genetic screening (see later). Virtually all patients with MEN 2a eventually develop C-cell disease. Complete thyroidectomy of patients with C-cell hyperplasia has dramatically decreased the incidence of MCT, which has been the major cause of death in patients with MEN 2a.

Almost all patients with MEN 2a harbor point mutations in the *RET* proto-oncogene, found in the pericentromeric region of chromosome 10. *RET* encodes a member of the tyrosine protein kinase family of cell surface receptors. The gene is expressed in spinal cord, in certain cultured blood cell lines, and in all tested MCT and pheochromocytoma cell lines (both from patients with MEN 2 and from those with sporadic tumors). *RET* interacts with other transmembrane receptors, which in turn bind ligands of the glial cell line–derived neurotrophic factor (GCNF) family. This complicated system of ligands and receptors controls the migration, proliferation, and survival of neural crest cells that populate the thyroid gland, the adrenal gland, and the intrinsic nervous system of the gut. Mutations in *RET* have been found in five different cysteines located in the portion of the receptor that forms the extracellular, ligand-binding domain. The mutant *RET* gene signals in a ligand-independent manner, thereby acting as an oncogene. The mutant *RET* genes can transform cultured cells and cause MCT in transgenic mice.

The transition from diffuse hyperplasia of thyroidal C cells or adrenal medullary cells to clonal neoplasms of the thyroid or adrenal gland probably requires subsequent somatic mutations. Such mutations include the loss of genetic markers on chromosomes 1p, 3p, 3q, and 22q, which frequently occur in these tumors.

Patients with MEN 2b harbor point mutations in the substrate binding pocket of the *RET* kinase, most commonly a change of methionine-918 to threonine. These mutations activate the kinase and change its substrate specificity.

Familial MCT, without tumors of the adrenal or parathyroid gland, is also caused by mutations of the *RET* gene. These mutations include the same mutations that cause MEN 2a, as well as unique mutations in the *RET* gene's kinase domain. Systematic analysis of the *RET* gene has demonstrated that inheritable *RET* gene abnormalities can occur in patients with apparently sporadic MCT as well. Inherited *RET* gene abnormalities are sometimes found in patients with apparently isolated pheochromocytomas, but not in those with sporadic parathyroid adenomas. Remarkably, some patients with familial Hirschsprung's disease (Chapter 138), associated with the absence of neurons in the enteric sympathetic nervous system, have inactive *RET* genes.

DIAGNOSIS

Screening

Direct genetic testing has replaced calcitonin testing as a screening tool in families with MEN 2. These genetic studies have shown that calcitonin testing and even histologic analysis of thyroid tissue can lead to false-positive and false-negative assignment of disease within families. The limited number of sites in the *RET* gene that cause inherited disease makes genetic testing routinely feasible.

Half the patients with MEN 2a develop pheochromocytomas. Family screening allows the detection of pheochromocytoma before the development of hypertension. Plasma metanephrine levels are consistently elevated in patients with MEN 2a pheochromocytomas, as they are in patients with sporadic pheochromocytomas. The tumors are usually found in the adrenal glands and can be documented preoperatively by CT, MRI, and iodine-131-metaiodobenzylguanidine scanning.

TREATMENT Rx

Surgery to prevent MCT is now generally performed before age 5 years in patients with MEN 2a (with some variation, depending on the specific *RET* mutation) and before 6 months of age in patients with the more severe MEN 2b disease.

PROGNOSIS

Because of early detection and curative surgery, MCT can be prevented or cured in virtually all children with MEN 2a or 2b after appropriate genetic testing at a young age. When tumors are seen clinically, however, because such testing was not performed or because the patient represents an index case in a family, the prognosis resembles that of sporadic tumors, except for the high frequency of multiple primary tumors. Similarly, the pheochromocytomas and parathyroid tumors are multiple but otherwise resemble their sporadic counterparts in terms of prognosis.

McCune-Albright Syndrome

DEFINITION

McCune-Albright syndrome is a noninherited disorder consisting of the triad of polyostotic fibrous dysplasia, light brown pigmented skin lesions (café au lait spots), and an endocrinopathy, usually precocious puberty. Multiple endocrine abnormalities can occur.

PATHOGENESIS

Precocious puberty, seen more often in girls than in boys, is gonadotropin independent. Hyperthyroidism is caused by autonomous thyroid nodules. Acromegaly is caused by pituitary adenomas that produce growth hormone and, usually, prolactin. Adrenocortical hyperfunction is caused by adrenocorticotropic hormone–independent adrenal adenomas. Hypophosphatemic rickets, with normal blood calcium levels, phosphate wasting, and low or inappropriately normal levels of 1,25-dihydroxyvitamin D, results from the release of fibroblast growth factor 23 from the dysplastic fibrous tissue.

This somewhat bewildering array of endocrine abnormalities has been rationalized by the observation that cells in the involved tissues harbor mutations in the α-subunit of the G_s protein. The G_s protein links cell surface receptors to the activation of adenylate cyclase. The mutations in McCune-Albright syndrome are point mutations at arginine-201 in the G_s subunit; these mutations lead to prolonged activity of G_s and inappropriate activation of adenylate cyclase. Increased levels of cyclic adenosine monophosphate (cyclic AMP) lead to cellular proliferation and hormone secretion. Patients with McCune-Albright are genetic mosaics. Presumably, at an early stage in embryonic development, a point mutation occurs in the G_s gene of a cell that then proliferates, differentiates, and variably populates normal bone, skin, and endocrine tissues. In cell types in which elevations in cyclic AMP lead to proliferation, abnormal cells become predominant and lead to disease. Because the disease is never inherited, the mutation is presumably lethal when it is present in all cells of the embryo. In contrast, the same mutations at arginine-201 have been found in cases of isolated acromegaly and autonomous thyroid nodules. One can therefore speculate that McCune-Albright syndrome is the most dramatic example of a spectrum of disorders that vary in severity and presentation, depending on the stage of development of the original mutant cell.

TREATMENT Rx

The treatment of the individual hormonal disorders is identical to that of the corresponding sporadic tumor. The polyostotic bone lesions require orthopedic correction when functional disability occurs, and bisphosphonate therapy may slow their growth.

PROGNOSIS

The prognosis of each hormonal component of the syndrome is similar to that of the corresponding sporadically occurring disorder.

AUTOIMMUNE SYNDROMES

Organ-specific autoimmune disease, characterized by lymphocytic infiltration and organ-specific autoantibodies, commonly results in endocrine hypofunction or hyperfunction. Clinical manifestations of disease are usually limited to one gland. Not uncommonly, however, disorders of more than one

TABLE 239-1 CLINICAL FEATURES OF AUTOIMMUNE POLYGLANDULAR SYNDROMES

FEATURE	TYPE 1	TYPE 2
Mucocutaneous candidiasis	Very common	Not seen
Hypoparathyroidism	Common	Rare
Addison's disease	Common	Common
Primary hypogonadism	Common	Occurs
Autoimmune thyroid disease	Rare	Common
Autoimmune diabetes	Occurs	Common
Hypophysitis	Occurs	Occurs
Autoimmune hepatitis	Occurs	Not seen
Pernicious anemia	Occurs	Occurs
Vitiligo	Occurs	Occurs

Myasthenia gravis	Not seen	Occurs
Keratopathy	Common	Not seen
Tympanic membrane calcification	Common	Not seen
Inheritance	Autosomal recessive	HLA association
Age at onset	Usually childhood	Usually adulthood

HLA = human leukocyte antigen.

endocrine gland appear in families or in individual patients. Characteristic patterns of disease presentation and genetic inheritance allow the definition of two syndromes with overlapping manifestations (Table 239-1).

Autoimmune Polyglandular Syndrome Type 1

DEFINITION

Autoimmune polyglandular syndrome type 1 is a rare disease that is also known as autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy syndrome. It typically manifests in early childhood.

PATHOGENESIS

Autoimmune polyglandular syndrome type 1 is an autosomal recessive disorder caused by a variety of inactivating mutations in the gene encoding autoimmune regulator-1 (AIRE-1), a nuclear protein that influences gene transcription, perhaps by acting as an enzyme—an E3 ubiquitin ligase—that ligates the protein ubiquitin to other nuclear proteins. AIRE-1 is expressed in epithelial cells of the thymus, cells that normally express a wide variety of genes usually expressed only in peripheral tissues. The synthesis of these "peripheral" proteins by thymic epithelial cells may be important for the normal ablation of lymphocytes reactive to these "self-proteins." In an animal model of AIRE-1 gene ablation, the thymic epithelial cells fail to express many of these "peripheral" proteins, perhaps leading to the persistence of lymphocytes responsible for autoimmune attack. The appearance of organ-specific autoantibodies precedes disease presentation and predicts the development of specific end-organ damage. The role of these antibodies is unknown, however.

CLINICAL MANIFESTATIONS

Mucocutaneous candidiasis (Chapter 346) occurs in virtually all patients and is usually the first manifestation of disease. Hypoparathyroidism and Addison's disease are the most common endocrine manifestations; each of these diseases occurs in 70 to 80% of patients. Hypoparathyroidism usually precedes Addison's disease; both diseases typically manifest before age 15 years. Premature ovarian failure (in 60% of affected women) usually presents as secondary amenorrhea; testicular failure occurs less frequently. Insulin-dependent diabetes mellitus occurs in 12% of patients, usually in adulthood; hypothyroidism is uncommon.

Nonendocrine components of this syndrome, in addition to the mucocutaneous candidiasis, include alopecia, vitiligo, corneal opacities, autoimmune hepatitis, enamel hypoplasia of teeth, tympanic membrane calcification, nail dystrophy that correlates only loosely with obvious candidiasis, parietal cell atrophy and vitamin B_{12} malabsorption, and more general intestinal malabsorption with steatorrhea. Asplenism, with Howell-Jolly bodies on peripheral blood smears (Chapter 160), has been noted in several patients. Each of the disease components should be sought when any patient presents with hypoparathyroidism, primary adrenal insufficiency, or mucocutaneous candidiasis.

TREATMENT

Rx

The hypoparathyroidism is treated like the sporadic disease with oral calcium and 1,25-dihydroxyvitamin D, although variable intestinal malabsorption can present a particular therapeutic challenge. The candidiasis can be satisfactorily controlled with ketoconazole.

PROGNOSIS

The prognosis of the variably expressed hormonal disorders is similar to that of their sporadic counterparts. When the diagnosis of autoimmune polyglandular syndrome type 1 is made, surveys for other components of the syndrome can allow earlier treatment than would otherwise occur.

Autoimmune Polyglandular Syndrome Type 2

PATHOGENESIS

Autoimmune polyglandular syndrome type 2 is usually inherited in families with characteristic (normal) variants of genes that regulate the presentation of antigens to T cells and subsequent T-cell function. The most common genetic locus associated with this syndrome is the human leukocyte antigen (HLA) locus. The HLA associations do not predict disease absolutely, even in identical twins, so environmental factors must contribute to disease presentation. Abnormal expression of the gene encoding cytotoxic T-lymphocyte antigen-4 (CTLA-4) can also predispose to autoimmune polyglandular syndrome type 2. The protein tyrosine phosphatase nonreceptor type 22 gene that encodes the lymphoid tyrosine phosphatase opposes signaling from the activated T-cell receptor. A variant of this gene is enriched in families with both type 1 diabetes mellitus and autoimmune thyroid disease. Genome-wide association studies have identified a large number of genes associated with type 1 diabetes. Although this approach has not yet been used for autoimmune polyglandular syndrome type 2, it seems likely that many of the genes identified in these studies will prove relevant because a large fraction of them appear to influence immune responsiveness.

CLINICAL MANIFESTATIONS

Autoimmune polyglandular syndrome type 2 is considerably more common than type 1 and typically manifests in adulthood. Insulin-dependent diabetes mellitus and thyroid dysfunction, either autoimmune hypothyroidism or Graves' disease, are the most frequent manifestations. Addison's disease (Chapter 234) is the third major endocrine component of this disorder. Although most patients who present with autoimmune diabetes or thyroid disease have clinical involvement of only one gland, many patients with autoimmune Addison's disease develop clinically evident disease in other endocrine glands. Less common components of the type 2 polyglandular syndrome include primary hypogonadism and hypophysitis. Pernicious anemia, vitiligo, celiac disease, alopecia, and myasthenia gravis are also associated with this syndrome.

Organ-specific antibodies appear before clinical disease and predict subsequent disease. The role of these antibodies in organ hypofunction has not been established, however.

TREATMENT

Rx

The treatment of each component of this syndrome is identical to the treatment of each disorder in isolation, although possible clustering of diseases must be kept in mind during the evaluation and follow-up of all patients with each individual component disorder. Thyroid hormone therapy can precipitate symptoms of adrenal insufficiency in patients with both disorders. Consequently, a careful history, including family history; physical examination; and a low threshold for specific laboratory testing for adrenal insufficiency should be part of the evaluation of every patient with autoimmune hypothyroidism. Further, combinations of hypothyroidism, adrenal insufficiency, and hypogonadism can mimic hypopituitarism, although specific hormonal testing can easily distinguish these disorders. Because multiple components of the syndrome can appear asynchronously, periodic evaluation for the early appearance of additional disease components is indicated.

PROGNOSIS

The prognosis of the individual components of autoimmune polyglandular syndrome type 2 is the same as for the sporadic versions of each component.

240 CARCINOID SYNDROME

KENNETH R. HANDE

The term *carcinoid syndrome* refers to the systemic signs and symptoms resulting from the release of neuroendocrine mediators by some carcinoid tumors. Cutaneous flushing, diarrhea, and cardiac valvular lesions are the most common manifestations of the carcinoid syndrome.

THE NEOPLASMS

Carcinoids are neuroendocrine tumors that arise from enterochromaffin cells. These cells are located throughout the body; however, carcinoid tumors occur most often in the lung (15% of all carcinoid tumors), stomach (5%), small intestine (25%), appendix (25%), and rectum (15%). Carcinoid tumors demonstrate a histologic pattern of dense nests of cells of uniform size and nuclear appearance that contain secretory granules. The neurosecretory granules may contain various amines, such as 5-hydroxytryptamine (serotonin), peptides, tachykinins, and prostaglandins. Only 8 to 10% of all carcinoid tumors are associated with the carcinoid syndrome, usually ileal carcinoids with hepatic metastasis. Carcinoid tumors arising from organs of the embryonic foregut (e.g., bronchus, stomach, pancreas, thyroid) are infrequently associated with the carcinoid syndrome; carcinoids from the distal large intestine may metastasize but do not exhibit endocrine effects. The incidence of carcinoid tumors (2 to 5 per 100,000 population) has been increasing over the past 20 years. Because carcinoid tumors are relatively slow growing, their prevalence is actually greater than that of esophageal, gastric, or pancreatic cancers.

PATHOBIOLOGY

Endocrine Function of Carcinoid Tumors

SEROTONIN. Most carcinoid tumors contain the enzyme tryptophan hydroxylase, which catalyzes the formation of 5-hydroxytryptophan (5-HTP) from tryptophan (Fig. 240-1). The typical ileal carcinoid tumor also contains aromatic L-amino acid decarboxylase, which catalyzes the conversion of 5-HTP to 5-hydroxytryptamine (5-HT or serotonin). Gastric carcinoids are frequently deficient in this decarboxylase and release 5-HTP from the tumor. Following its release from carcinoid tumors, serotonin is oxidized to 5-hydroxyindoleacetaldehyde, which is rapidly converted to 5-hydroxyindoleacetic acid (5-HIAA) by aldehyde dehydrogenase (see Fig. 240-1). This acid is excreted into the urine, and almost all circulating serotonin can be accounted for as urinary 5-HIAA.

TACHYKININS. Peptides of the tachykinin family are stored in carcinoid tumors and are released during flushing. Several tachykinins are derived from a common precursor, β-preprotachykinin; of these, neuropeptide K, neurokinins A and B, and substance P have been identified in tumors and blood from patients with the carcinoid syndrome.

OTHER BIOLOGICALLY ACTIVE SUBSTANCES. Some carcinoid tumors, particularly those of gastric origin, release excessive amounts of histamine. This can be detected by an increased urinary excretion of histamine or its metabolite, *N*-methylhistamine. Carcinoid tumors have been associated with a number of ectopic endocrine syndromes, including hyperadrenocorticism, which results from the ectopic production of adrenocorticotropic hormone, and acromegaly in response to the secretion of growth hormone–releasing hormone by the tumor. Secretion of a variety of prostaglandins by carcinoids has also been demonstrated.

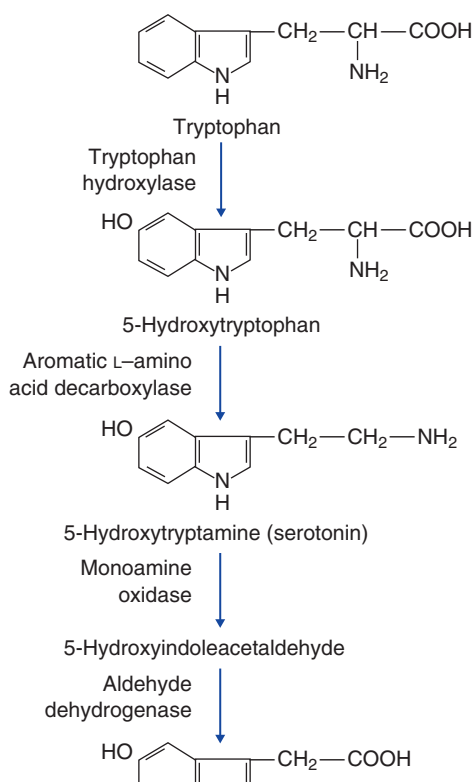

FIGURE 240-1. Synthesis and degradation of serotonin.

PATHOPHYSIOLOGY OF SEROTONIN OVERPRODUCTION. Serotonin contributes to the intestinal hypermotility and diarrhea associated with the carcinoid syndrome. A secondary effect of serotonin overproduction occurs when a large fraction of dietary tryptophan is shunted into the hydroxylation pathway, leaving less tryptophan available for the formation of nicotinic acid and protein. When urinary excretion of 5-HIAA exceeds 100 mg/day, low levels of plasma tryptophan and evidence of nicotinic acid deficiency (pellagra) can be seen. The interaction of serotonin with platelets and the cardiac endothelium is considered the cause of carcinoid heart disease. This hypothesis is supported by the finding of valvular heart disease in patients taking appetite suppressants, such as fenfluramine, that release serotonin. The risk of valvular heart disease in patients with the carcinoid syndrome is correlated with the amount of 5-HIAA excreted in the urine.

MECHANISM OF THE FLUSH. Most evidence points to the tachykinins as mediators of the carcinoid flush. Tachykinins, particularly neuropeptide K, can be identified in plasma during flushing. Tachykinin levels have been shown to be increased during pentagastrin-induced flushing; when pentagastrin-induced flushing is inhibited by somatostatin, the rise in tachykinin levels is also blocked. Tachykinins are known vasodilators. Serotonin does not appear to be the mediator of flushing. Flushing attacks can be attributed to histamine in certain gastric carcinoids.

Flushing can be triggered by catecholamines, and this probably accounts for the association of flushing with exercise and emotional stimuli. Injection of isoproterenol or pentagastrin can also trigger flushing, an action that may explain the provocation of flushes by eating in some patients. Because the hemodynamic changes associated with such pharmacologically induced attacks can be severe, epinephrine and other β-adrenergic amines, as well as pentagastrin, should be administered with great caution. Flushing episodes can be blocked by somatostatin.

CLINICAL MANIFESTATIONS

Carcinoid tumors typically have a slow rate of growth, and many patients with the carcinoid syndrome survive for years after the disease is recognized. The carcinoid syndrome occurs when mediators produced by the tumor and normally metabolized by the liver escape into the systemic circulation. Thus, most patients with the carcinoid syndrome have hepatic metastasis. For much of the duration of the illness, morbidity results largely from the endocrine functions of the tumor. Death is usually caused by cardiac or hepatic failure and by complications associated with tumor growth.

VASODILATOR PAROXYSMS. Cutaneous flushing, which occurs in 80% of patients with the carcinoid syndrome, is the most common clinical feature. The typical flush is dark red to violaceous and involves the head, neck, and upper trunk (blush area). The flush usually lasts for 30 seconds to 3 minutes. Carcinoid tumors of the foregut produce a slightly different flush, characteristically bright salmon pink to red. Prolonged flushing attacks may be associated with lacrimation and periorbital edema. The flush may be accompanied by tachycardia. The blood pressure usually falls or does not change. A rise in blood pressure during flushing is rare, and the carcinoid syndrome is not a cause of sustained hypertension. Flushing may be provoked by excitement, exertion, eating, and ethanol ingestion. In patients with the bronchial carcinoid variant, flushing may last for hours.

TELANGIECTASIA. In addition to paroxysms of cutaneous vasodilation, some patients develop telangiectasia, primarily on the face and neck, which is most marked in the malar area. These patients may have the characteristic features of rosacea.

PELLAGRA. Tryptophan is normally used to form nicotinic acid. In patients with the carcinoid syndrome, up to 60% of dietary tryptophan may be used to form 5-HTP and 5-HT. Nicotinic acid levels are occasionally depleted, resulting in symptoms of pellagra (dermatitis, diarrhea, and dementia) (Chapter 225).

GASTROINTESTINAL SYMPTOMS. Intestinal hypermotility with borborygmi and cramping occurs in 50 to 70% of patients with the carcinoid syndrome. Explosive secretory diarrhea may occur, although chronic diarrhea with a secretory component is more common (Chapter 142). When diarrhea is severe, malabsorption may occur. Gastrointestinal transit times through the small and large bowel are two- to six-fold faster than in physiologically normal patients.

CARDIAC MANIFESTATIONS. Symptomatic valvular heart disease is present in 15 to 20% of patients with the carcinoid syndrome. Up to 50% of patients have echocardiographic evidence of heart disease (Chapter 60). Plaque-like thickening of the endocardium of the valvular cusps and cardiac chambers occurs primarily on the right side of the heart but may rarely involve the left side (<10%). The endocardial thickening is composed of smooth muscle cells embedded in a stroma rich in mucopolysaccharides. The thickening and deformation of the valve cusps, chordae tendineae, and papillary muscles interfere with valvular function and may lead to regurgitation, stenosis, or combined functional lesions. Lesions of the tricuspid valve (usually regurgitation) are present in 65% of patients with carcinoid heart disease, and pulmonic valvular disease (again, usually regurgitation) is seen in 20% of those with heart disease. Cardiac function may be further compromised by impaired atrial and ventricular compliance and by the occasional occurrence of a high cardiac output that probably results from continuing release of a vasodilator.

PULMONARY SYMPTOMS. Bronchoconstriction, usually most pronounced during flushing attacks, is a less common feature of the syndrome, but it may be severe.

GENERAL FEATURES. Intestinal obstruction may result from the primary tumor or from the desmoplastic reaction in the surrounding mesentery. The desmoplastic reaction is believed to develop in response to the secretion of growth factors, such as platelet-derived growth factor, insulin-like growth factor, epidermal growth factor, and transforming growth factor-β, or by interstitial cells in response to 5-HT. Infrequently, the primary tumors cause gastrointestinal bleeding. Necrosis of hepatic tumor masses may produce an acute syndrome of abdominal pain, tenderness, fever, and leukocytosis. Hepatomegaly from the metastatic disease is often present. Generalized fatigue and debilitation are underappreciated features of the carcinoid syndrome. Attacks of severe and sustained flushing with life-threatening hemodynamic compromise and bronchoconstriction may occur and are referred to as *carcinoid crisis*. Precipitating factors include anesthesia, surgery, tumor necrosis, and catecholamine infusion.

DIAGNOSIS

When all its clinical features are present, the carcinoid syndrome is easily recognized. The diagnosis also must be considered when any one of its clinical manifestations is present.

The diagnostic hallmark consists of overproduction of 5-hydroxyindoles accompanied by increased excretion of urinary 5-HIAA in a patient with a biopsy-proven carcinoid tumor. Normally, excretion of 5-HIAA does not exceed 9 mg/day. Ingestion of foods containing serotonin may complicate the biochemical diagnosis of the carcinoid syndrome; bananas, walnuts, and certain other foods contain enough serotonin to produce abnormally elevated urinary excretion of 5-HIAA after their ingestion. Selected drugs (e.g., guaifenesin, acetaminophen) may also falsely elevate urinary 5-HIAA measurements. Instructing the patient to avoid these foods and medications during the collection of urine for analysis of 5-HIAA can prevent falsely elevated levels. When dietary 5-hydroxyindoles are excluded, urinary excretion of 25 mg/day of 5-HIAA is diagnostic of the carcinoid syndrome. Elevation in the range of 9 to 25 mg/day may be seen with the carcinoid syndrome, nontropical sprue, vomiting, or acute intestinal obstruction. Measurement of serotonin in blood or platelets is of interest but has less diagnostic value than assay of the major metabolite of serotonin in the urine.

Plasma chromogranin A concentrations are often elevated in carcinoid patients, including those who do not have the carcinoid syndrome, and may serve as a marker of tumor mass. The diagnostic value of plasma chromogranin A is relatively low, however, because this substance may be elevated in a variety of neuroendocrine tumors and is increased in patients with renal failure, those with atrophic gastritis, and patients taking proton pump inhibitors. Assessment of the extent and localization of both primary and metastatic tumor is aided by computed tomography of the abdomen and chest and by imaging with radionuclide-labeled somatostatin receptor ligands.

Differential Diagnosis

Attacks of flushing in a patient with normal urinary excretion of 5-HIAA raise other diagnostic possibilities. Systemic mastocyte activation disorders, including systemic mastocytosis and idiopathic anaphylaxis, produce flushing and diarrhea and should be considered when 5-HIAA excretion is not elevated. Flushing also occurs in genetically predisposed individuals following ethanol ingestion, in the postmenopausal state, and in conjunction with other neuroendocrine tumors such as VIPomas (tumors that produce excessive vasoactive intestinal peptide) and medullary carcinomas of the thyroid.

Variants of the Carcinoid Syndrome

The origin of the tumor influences the biologically active substances produced and their storage and release. The typical carcinoid syndrome usually results from tumors of midgut origin, which almost invariably secrete serotonin. In contrast, tumors arising from the embryonic foregut have a lower serotonin content and may secrete 5-HTP. Patients with gastric carcinoids may exhibit unique flushing, which begins as bright, patchy erythema with sharply delineated serpentine borders; these patches tend to coalesce as the blush heightens. Food ingestion is especially likely to produce flushes. Ectopic hormone production (e.g., Cushing's syndrome, acromegaly) and multiple endocrine adenomas are more likely to be associated with tumors of embryonic foregut. Roughly 10% of patients with multiple endocrine neoplasia type 1 (MEN 1) develop a carcinoid tumor. With carcinoid tumors arising from the bronchus, attacks of flushing tend to be prolonged and severe and may be associated with periorbital edema, excessive lacrimation and salivation, hypotension, tachycardia and tachyarrhythmias, anxiety, and tremulousness. Nausea, vomiting, explosive diarrhea, and bronchoconstriction may progress and become severe. This group is therapeutically unique, in that severe flushes can often be prevented by corticosteroids.

TREATMENT Rx

Treatment of the carcinoid syndrome is directed toward pharmacologic therapy for humorally mediated symptoms and reduction of the tumor mass.

Somatostatin Analogues

More than 80% of carcinoid tumors have somatostatin receptors on the cell surface. Somatostatin can bind to these receptors and prevent the flushing and other endocrine symptoms of the carcinoid syndrome. However, the half-life of somatostatin is short. The development of analogues of somatostatin with longer biologic half-lives than the native hormone has made

subcutaneous administration feasible and has been a major advance in the treatment of these patients.

Octreotide

One of the somatostatin analogues, octreotide, improves the flushing and other endocrine manifestations in most patients with the carcinoid syndrome. This therapy is frequently associated with a reduction in urinary 5-HIAA excretion and in tachykinin levels in blood. With the improvement of these endocrine symptoms, including fatigue, a considerable improvement in quality of life may be achieved. Long-acting somatostatin analogues (octreotide LAR and lanreotide) have been developed, permitting once-monthly dosing. Two to 4 weeks may be required to achieve steady-state levels of octreotide following the administration of octreotide LAR, during which time supplementation with subcutaneous octreotide may be needed. An uncommon but severe adverse effect of octreotide is hypoglycemia, probably as a result of the inhibition of glucagon and growth hormone secretion. The suppression of pancreatic exocrine function by octreotide can cause steatorrhea, and inhibition of the release of cholecystokinin can cause cholelithiasis. Octreotide should be used to prevent or treat carcinoid crises that accompany the massive release of mediators that may occur during operative procedures and tumor necrosis. In patients with histamine-secreting gastric carcinoids, blockade of both H_1 and H_2 receptors markedly ameliorates flushing. In patients receiving octreotide, about 5% achieve a regression in tumor mass. Octreotide has recently been demonstrated to slow the growth rate of carcinoid tumors.■

Surgery

Early diagnosis of the carcinoid syndrome has led to complete surgical cure in a few patients with tumors arising in ovarian or testicular teratomas or in the bronchus. By releasing their humoral mediators directly into the systemic circulation, these tumors can produce the syndrome before metastatic disease occurs. In contrast, tumors that release humoral substances into the portal circulation, to be largely metabolized by the liver, usually produce the syndrome only after liver metastases occur. Given the slow progression of this neoplasm, effective reduction in tumor mass can ameliorate morbidity and improve quality of life even after metastases have occurred. In selected patients, this goal can be achieved by surgical debulking of tumor, including partial hepatectomy for unilobar metastases, excision of large superficial hepatic metastases, and removal of the primary tumor together with regional lymph nodes containing metastases. Elective cholecystectomy during the surgical intervention prevents the cholelithiasis that may result from octreotide treatment. Because the blood supply of hepatic metastases is largely arterial, percutaneous embolization of the hepatic arterial supply to the most involved hepatic lobe can sometimes reduce inoperable hepatic metastases; the procedure carries a risk of serious complications.

Chemotherapy

Chemotherapy with single or combination cytotoxic agents given on a short-term basis has produced little benefit. For patients who exhibit tumor progression or whose clinical syndrome has failed to improve following cytoreduction and octreotide, interferon-α and antiangiogenic agents (bevacizumab and sunitinib) have been considered as palliative therapy.

PROGNOSIS

A concerted strategy consisting of removal of the primary tumor, reduction in tumor bulk, and administration of octreotide can lead to considerable amelioration of symptoms, improvement in the quality of life, reduction in the release of the humoral substances that engender cardiac lesions, and prolongation of survival. The median survival of patients with metastatic carcinoid tumor and the carcinoid syndrome now exceeds 5 years in carefully managed patients.

DISORDERS OF SEXUAL DEVELOPMENT

PERRIN C. WHITE

DEFINITION

This chapter reviews the concepts underlying the initial evaluation and management of patients with disorders of sexual development (DSD). By definition, such an individual has lack of concordance of various aspects of gender. These include chromosomal sex (46,XX, 46,XY, or other), gonadal or reproductive sex (ovaries, fallopian tubes, and uterus versus testes, seminal vesicles, prostate gland, and ejaculatory ducts), genital sex (vagina and clitoris versus scrotum and penis), and gender-specific behavior. Depending on chromosomal sex, most patients can be classified as incompletely masculinized 46,XY males, virilized 46,XX females, and patients with abnormalities of sex chromosomes, such as those with mixed gonadal dysgenesis. (In the past, 46,XY and 46,XX DSD patients were referred to as male and female pseudohermaphrodites, respectively, but these terms are no longer preferred.) Many conditions can cause DSD (Table 241-1).

Normal Sexual Differentiation

Gonadal Differentiation

At 5 to 6 weeks' gestation, the gonadal primordia (gonadal ridges) develop from the coelomic epithelium overlying the medial surface of the mesonephros (primitive kidneys; Fig. 241-1). These primitive gonads are identical in both sexes. Germ cells form at 3 to 4 weeks' gestation and migrate through the gut mesentery into the gonads at this early bipotential stage. Whether germ cells are directed toward male or female gametogenesis depends largely on the environment generated by surrounding somatic cells rather than on factors intrinsic to the germ cells.

During the seventh week, XY male gonads begin to differentiate under the influence of testis-determining genes. The first to be expressed is *SRY*, the key gene on the Y chromosome controlling male differentiation, which initiates the development of Sertoli cells. Sertoli cells surround germ cells to form testis cords, which nourish primordial germ cells and direct them into the pathway for male gametogenesis. Recruitment of endothelial cells leads to development of a testis-specific vasculature that is required for normal organization of the testis.

Steroidogenic cells develop from the mesonephros and migrate into the developing adrenal cortex and testis at 8 weeks. In the testis, they become Leydig cells, which secrete the testosterone required for subsequent male reproductive development. In the first trimester, testosterone secretion is mainly under the control of human chorionic gonadotropin (HCG); it subsequently requires luteinizing hormone (LH) secreted by the fetal anterior pituitary.

Ovaries are recognizable at about 10 weeks. The signaling molecule WNT4 plays an active role in ovarian development, repressing expression of testis-specific genes and vascular development. Germ cells in the ovary continue into the first meiotic prophase beginning at 12 weeks' gestation and continuing until 7 months' gestation.

Development of Male and Female Internal Reproductive Tracts

The reproductive tracts are derived from intermediate mesoderm. The male reproductive tract develops from the mesonephric (wolffian) ducts, whereas the female reproductive tract develops from the paramesonephric (müllerian) ducts (Fig. 241-2). Both sets of ducts are present in normal embryos.

Development of wolffian or müllerian structures depends on the presence or absence of normally functioning testes. The Sertoli cells secrete antimüllerian hormone (AMH, also termed müllerian inhibiting substance) starting when the testes differentiate. Expression of AMH is controlled by several

TABLE 241-1 DISORDERS OF SEXUAL DEVELOPMENT*

VIRILIZATION OR SEX REVERSAL IN XX FEMALES

Virilizing forms of congenital adrenal hyperplasia
- 21-Hydroxylase deficiency (1:15,000 births) [*CYP21*]: salt-wasting or simple virilizing forms
- 11β-Hydroxylase deficiency [*CYP11B1*]
- 3β-Hydroxysteroid dehydrogenase deficiency [*HSD3B2*]
- Cytochrome P-450 oxidoreductase deficiency (also has a maternal effect) [*POR*]

Maternal or exogenous androgens
- Drugs (danazol, progestins)
- Luteoma
- Aromatase deficiency [*CYP19*]
- Transcription factor mutations

Mutations in genes affecting gonadal differentiation
- *SRY* (translocation to X)
- *SOX9* (duplication)
- *WT1* (Denys-Drash syndrome)

Structural/idiopathic

UNDERVIRILIZATION OR SEX REVERSAL IN XY MALES

Biosynthetic defects
- Lipoid adrenal hyperplasia [*STAR*]
- 17α-Hydroxylase/17,20 lyase [*CYP17*]
- 3β-Hydroxysteroid dehydrogenase [*HSD3B2*]
- 17-Ketosteroid reductase [*HSD17B3*]
- 5α-Reductase [*SRD5A2*]
- Cytochrome P-450 oxidoreductase deficiency [*POR*]
- Smith-Lemli-Opitz syndrome (1:20,000) [*DHCR7*]

Androgen insensitivity (1:20,000) [*AR*]: complete or partial

Luteinizing hormone insensitivity [*LHR*]

Mutations in genes affecting gonadal differentiation
- *SRY*
- *SOX9* (camptomelic dysplasia)
- *SF1* (sometimes associated with adrenal hypoplasia)
- *WT1* (WAGR and Denys-Drash syndromes)
- *DAX1* or *WNT4* duplications
- *DHH* (associated with peripheral neuropathy)
- *ATRX* (X-linked α-thalassemia and mental retardation)

Exposure to 5α-reductase inhibitors, other endocrine disruptors

MICROPENIS

Panhypopituitarism [including *PROP1* mutations]

Septo-optic dysplasia [including *HESX* mutations]

Hypogonadotropic hypogonadism
- Kallmann's syndrome [*KAL1*]
- Prader-Willi syndrome [paternal chromosome 15q11 deletion]
- Adrenal hypoplasia congenita [*DAX1*]

Vanishing testes (may also cause ambiguous genitalia)

OTHER SYNDROMES AFFECTING REPRODUCTIVE SYSTEMS

Chromosomal aneuploidy
- Turner's syndrome (1:2500): 45,X; 45,X/46,XX mosaics; 46,XXr; 46,XXq–
- Klinefelter's syndrome (1:1000): 47,XXY
- Mixed gonadal dysgenesis: 45,X/46,XY; 45,X/47,XXY
- Other: trisomy 13, trisomy 18, triploidy, 4p–, 13q–

Persistent müllerian duct syndrome in XY males
- Type 1 [*AMH*]
- Type 2 [*AMHR2*]

Mayer-Rokitansky-Küster-Hauser syndrome (vaginal atresia) [*WNT4*]

*Frequencies of relatively common (at least 1:20,000) diseases are noted in parentheses. When causative genetic mutations have been identified, the affected locus is noted in square brackets. WAGR = Wilms' tumor, aniridia, genitourinary abnormalities or gonadoblastoma, and mental retardation.

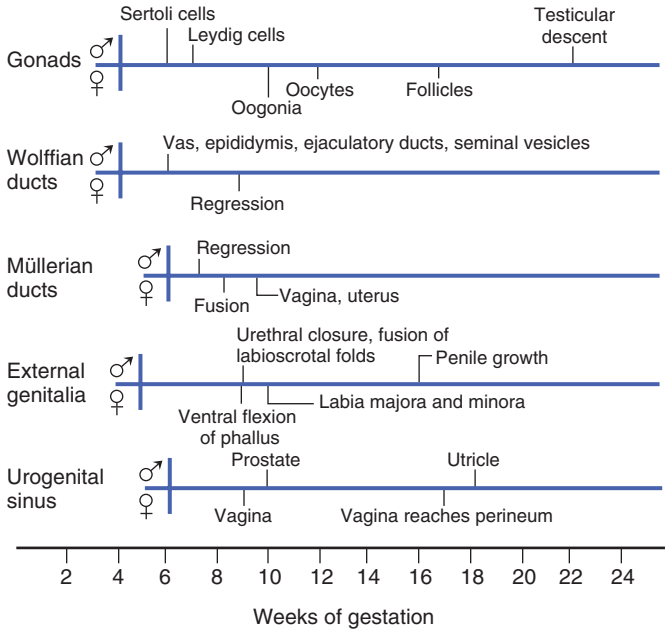

FIGURE 241-1. Time course of prenatal sexual differentiation in male and female fetuses. (Adapted from Barthold JS, Gonzalez R. Intersex states. In: Gonzales ET, Bauer SB, eds. *Pediatric Urology Practice*. Philadelphia: Lippincott Williams & Wilkins; 1999.)

transcription factors: SF1 and WT1 (Wilms' tumor locus) synergize to promote transcription, whereas DAX1 antagonizes it. The overall effect of AMH is to induce regression of müllerian structures between 8 and 12 weeks' gestation. In its absence, development of the müllerian ducts proceeds, and the female internal structures (fallopian tubes, uterus, cervix, and upper vagina) are formed.

Development of the structures derived from the wolffian ducts, including the epididymis, ductus deferens, ejaculatory ducts, and seminiferous tubules, requires high local concentrations of testosterone secreted from Leydig cells of the testis beginning at about 7 weeks' gestation. In the absence of testosterone, wolffian ducts regress. Levels of testosterone in the circulation are insufficient to develop wolffian structures. Thus, in conditions in which the gonads develop asymmetrically (e.g., true hermaphroditism or mixed gonadal dysgenesis; see later), wolffian structures develop asymmetrically as well. Development of wolffian structures requires an intact androgen receptor.

Development of the External Genitalia

External genital structures are also bipotential in early gestation and consist of the genital tubercle, genital folds (later, urethral-labial folds), and genital swelling (later, labioscrotal folds) (see Fig. 241-2). Differentiation to male genitalia occurs from about 8 to 14 weeks' gestation under the influence of dihydrotestosterone, which must interact with an intact androgen receptor. The genital tubercle becomes the glans penis; the genital folds fuse to become the shaft of the penis and penile urethra, and the labioscrotal folds (derived from the genital swelling) fuse to become the scrotum. Without androgens, these structures become the clitoris, labia minora, and labia majora, respectively.

Normal Gonadal and Adrenal Steroidogenesis

Many forms of genital ambiguity result from defects in steroid biosynthesis in the testes or adrenal cortex or from defective steroid metabolism in the placenta or in target tissues (Fig. 241-3 and E-Fig. 241-1).

Steroid biosynthesis in the testes and adrenals begins with the importation of cholesterol into mitochondria, a highly regulated process controlled largely by the steroidogenic acute regulatory (StAR) protein; levels of StAR are controlled within the adrenals by adrenocorticotropic hormone (ACTH) and within the testis by HCG during the first trimester and by LH later in pregnancy.

Within mitochondria, the side chain of cholesterol is cleaved between carbons 20 and 22 by the cholesterol side-chain cleavage enzyme (cholesterol desmolase, CYP11A), a cytochrome P-450 enzyme. The product is pregnenolone, which is transported to the endoplasmic reticulum. Some pregnenolone is converted by 17α-hydroxylase (CYP17) to 17-hydroxypregnenolone. Both 17-hydroxypregnenolone and the remaining pregnenolone are converted by 3ß-hydroxysteroid dehydrogenase (HSD3B2) to 17-hydroxyprogesterone and progesterone, respectively. The side chain of 17-hydroxypregnenolone is cleaved by the 17,20-lyase activity of CYP17 to dehydroepiandrosterone (DHEA). DHEA may also be converted to androstenedione by HSD3B2.

All the preceding steps can occur in the adrenal cortex, in Leydig cells of the testis, and (after puberty) in theca cells of ovarian follicles. Subsequent biosynthetic steps are specific to different glands. In the adrenal cortex, 17-hydroxyprogesterone is converted by 21-hydroxylase (CYP21, a

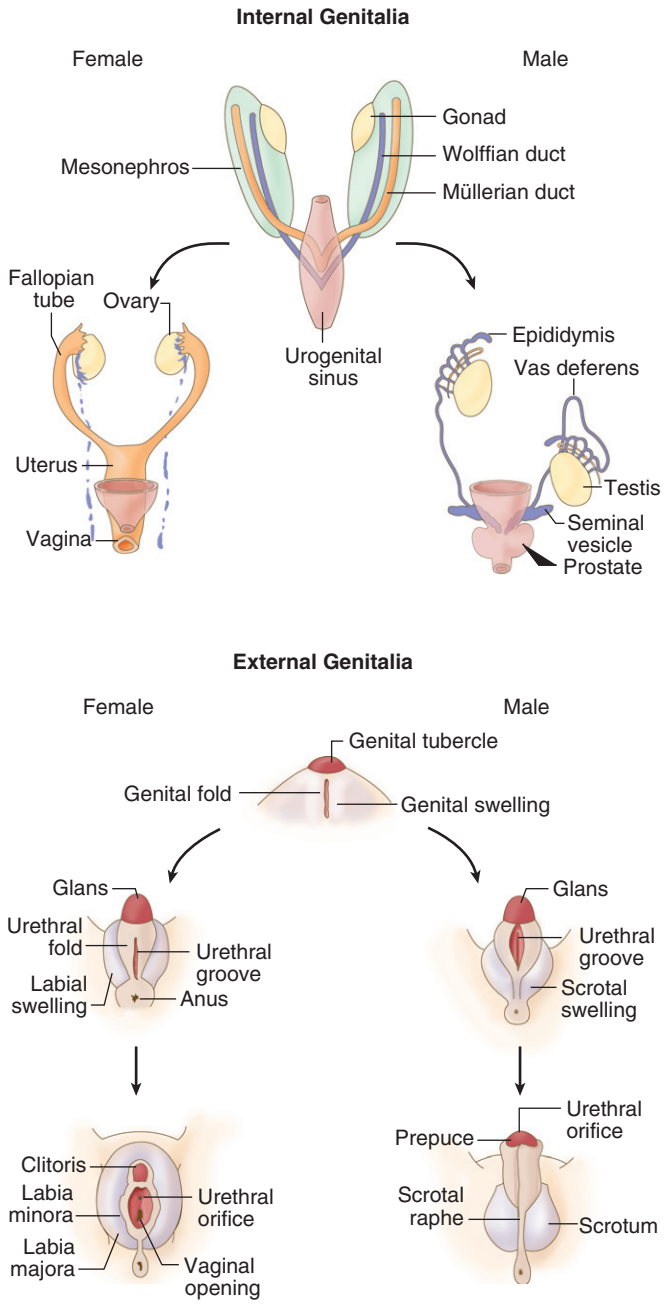

FIGURE 241-2. Differentiation of the internal and external genitalia of the human fetus. (Adapted from Griffen JE, Ojeda SR, eds. *Textbook of Endocrine Physiology*. New York: Oxford University Press; 1996.)

microsomal P-450) to 11-deoxycortisol, which is then converted in mitochondria to cortisol by 11ß-hydroxylase (CYP11B1). Additionally, progesterone is converted to deoxycorticosterone by CYP21, which is then converted to aldosterone by aldosterone synthase (CYP11B2).

In Leydig cells of the testis, androstenedione is converted to testosterone by 17-ketosteroid reductase (17ß-hydroxysteroid dehydrogenase type 3 [HSD17B3]); the same reaction occurs in theca cells of the ovary, catalyzed by 17ß-hydroxysteroid dehydrogenase type 1 (HSD17B1). In granulosa cells of the ovary (after puberty), androstenedione and testosterone are converted by aromatase (CYP19) to estrone and estradiol, respectively. In skin of the developing male external genitalia, steroid 5α-reductase (SRD5A2) converts testosterone to a more potent androgen, dihydrotestosterone.

The placenta is a steroid-synthesizing and -metabolizing tissue as well; it has high steroid sulfatase activity that converts DHEA sulfate from the fetal adrenal gland back to DHEA. This is then successively converted by 3ß-hydroxysteroid dehydrogenase type 1 (HSD3B1) and aromatase (CYP19) to androstenedione and estrone, respectively, which are then converted to estradiol by HSD17B1.

DEFECTS OF SEX DIFFERENTIATION

Defects of Steroidogenesis

PATHOBIOLOGY

Genital ambiguity in genetic females is usually the result of exposure to excessive levels of androgens. Virilizing congenital adrenal hyperplasia (CAH), the most common cause of genital ambiguity in female infants, occurs in 1 in 15,000 births.

Conversely, severe deficiencies of androgens, if present early in gestation, cause ambiguous or female-appearing external genitalia in male infants. Usually, müllerian structures such as the uterus, cervix, and upper vagina are not present because the testes are able to secrete müllerian inhibitory substance. Thus, individuals with these conditions have a short vagina ending in a blind pouch.

CONGENITAL ADRENAL HYPERPLASIA

The fundamental defect among patients with any form of CAH is inadequate synthesis of cortisol (see Fig. 241-3 and E-Fig. 241-1). Inefficient cortisol synthesis signals the hypothalamus and pituitary to increase corticotropin-releasing hormone and ACTH, respectively (Chapter 230). Consequently, the adrenal glands become hyperplastic, and steroid precursors accumulate proximal to the block in biosynthesis. In some conditions, these precursors can be converted to androgens.

LIPOID HYPERPLASIA. Lipoid hyperplasia results from mutations in the *STAR* gene. Cholesterol is not imported efficiently into mitochondria and thus accumulates in cells. Steroid biosynthesis is drastically reduced because of the lack of substrate, and the lipid accumulation quickly kills steroid-synthesizing cells in both the adrenals and the testes. Thus, affected male patients are born as phenotypically female because they cannot synthesize testosterone. Affected female patients may undergo transient spontaneous puberty because human ovarian granulosa cells do not synthesize steroid hormones (and thus do not accumulate cholesterol) until puberty. Both sexes have adrenal insufficiency and are unable to synthesize either cortisol or aldosterone.

17α-HYDROXYLASE/17,20 LYASE DEFICIENCY. Severe mutations in the *CYP17* gene prevent the synthesis of any sex hormones. Affected male patients have female-appearing external genitalia but have no müllerian structures because the testes synthesize AMH. Affected female patients remain sexually infantile without hormone replacement. Milder mutations result in ambiguous genitalia in male patients. Although cortisol synthesis is also abolished, even severely affected individuals are able to synthesize corticosterone, an active glucocorticoid, as well as aldosterone. Thus, they do not develop adrenal insufficiency. On the contrary, they secrete excessive levels of deoxycorticosterone, which has mineralocorticoid activity, and are therefore prone to develop hypertension.

3β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY. Severe mutations in the *HSD3B2* gene prevent the synthesis of aldosterone, cortisol, testosterone, and estrogens. Because DHEA, a weak androgen, is synthesized and secreted at high levels, some degree of phallic growth is present. Thus, affected male patients have severely ambiguous genitalia, but affected female patients may have clitorimegaly. Both sexes develop adrenal insufficiency if they are untreated.

Because many children with premature adrenarche (early development of axillary and pubic hair), as well as many women with polycystic ovary syndrome, have elevated levels of DHEA, it was once thought that such individuals could have a mild form of HSD3B2 deficiency. However, mutations in *HSD3B2* are rarely if ever found in such individuals, who have an imbalance in the relative levels of HSD3B2 and CYP17 activity within the adrenal cortex.

21-HYDROXYLASE DEFICIENCY. More than 90% of cases of CAH are caused by 21-hydroxylase deficiency resulting from mutations in the *CYP21* (or *CYP21A2*) gene. The relatively high incidence of this condition is a consequence of the proximity of a highly homologous pseudogene, *CYP21P* (or *CYP21A1P*), which contains approximately 10 mutations that are deleterious to expression, messenger RNA processing, or enzymatic activity. *CYP21* and *CYP21P* are located within the major histocompatibility complex on chromosome 6p21.3, a genomic region noteworthy for a high rate of recombination. More than 90% of all mutations are the result of intergenic recombination between *CYP21* and *CYP21P*. Most are transfers of deleterious mutations from *CYP21P* to *CYP21*, whereas 20% are net deletions of *CYP21* resulting from unequal meiotic crossover.

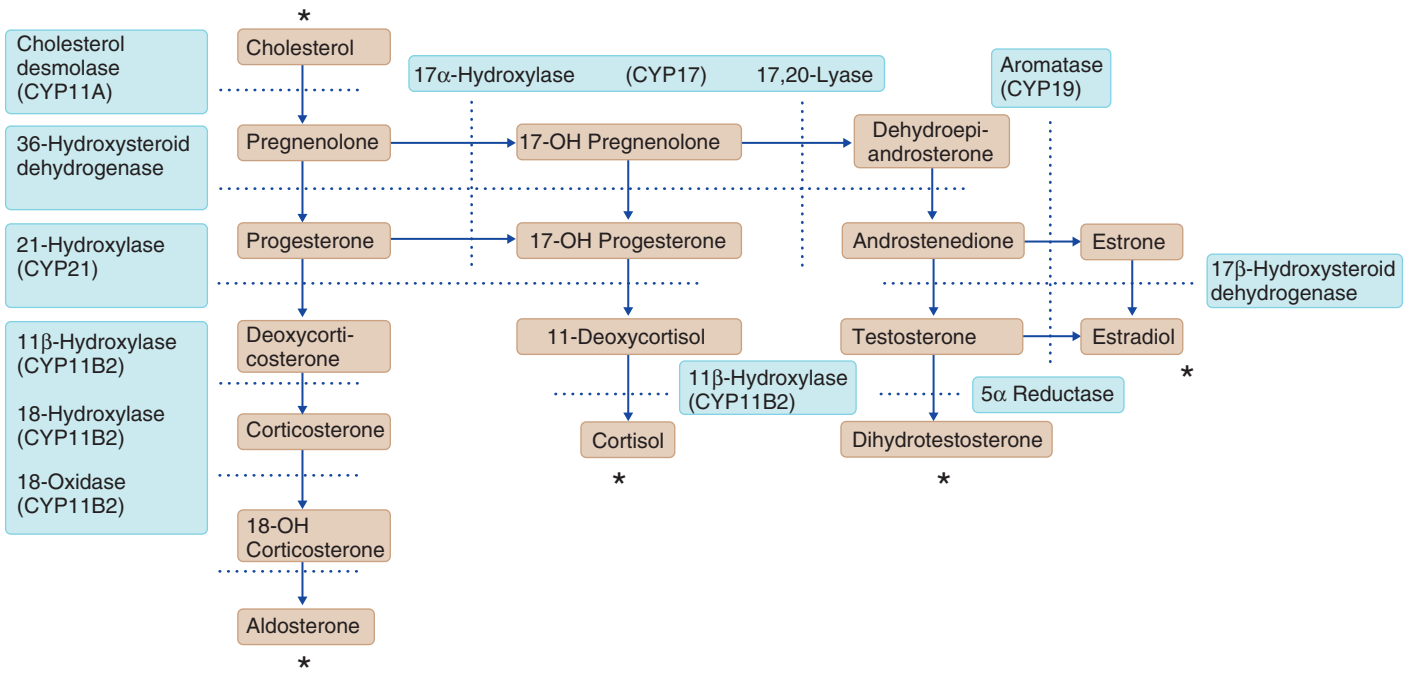

FIGURE 241-3. Steroidogenesis. Pathways for the synthesis of progesterone and mineralocorticoids (aldosterone), glucocorticoids (cortisol), androgens (testosterone and dihydrotestosterone), and estrogens (estradiol) are arranged from left to right. The enzymatic activities catalyzing each bioconversion are written in boxes. For those activities mediated by specific cytochrome P-450 subsets, the systematic name of the enzyme (CYP followed by a number) is listed in parentheses. CYP11B2 and CYP17 have multiple activities. *For an expanded version of this image, including planar structures for cholesterol and the end products of each pathway, see E-Figure 241-1.

In patients with 21-hydroxylase deficiency, the adrenals produce excess 17-hydroxyprogesterone, 17-hydroxypregnenolone, and progesterone, which are further metabolized to DHEA and androstenedione. Once secreted, these substances are further metabolized to active androgens (testosterone and dihydrotestosterone) and, to a lesser extent, to estrogens (estrone and estradiol).

Adrenal secretion of excess androgen precursors does not significantly affect male sexual differentiation. In affected female patients, the urogenital sinus is in the process of septation when the fetal adrenal begins to produce excess androgens, which function to prevent the formation of separate vaginal and urethral canals. Further adrenal-derived androgens interact with androgen receptors in genital skin and induce clitoral enlargement, promote fusion of the labial folds, and cause rostral migration of the urethral/vaginal perineal orifice. However, internal wolffian structures such as the prostate gland and spermatic ducts are usually not virilized, presumably because development of the wolffian ducts requires markedly higher local concentrations of testosterone than the external genitalia. Nevertheless, severely affected female patients occasionally have some development of typically male internal genital structures.

Thus, the typical result in severely affected girls is ambiguous or male-appearing external genitalia with perineal hypospadias and chordee, but without palpable testes (Fig. 241-4). The severity of virilization is often quantitated using a five-point scale developed by Prader (Fig. 241-5). Not all female patients with classic CAH develop the same degree of genital ambiguity. One could speculate that the physical signs of androgen excess depend not only on direct adrenal secretion of androgen precursors but also on the efficiency with which such hormones are converted to more potent products, such as dihydrotestosterone, by peripheral enzymes such as 5α-reductase. Additionally, the concentration and transcriptional activity of androgen receptors may play a role in determining genital phenotype.

Most patients (75%) cannot synthesize sufficient aldosterone to maintain sodium balance and are termed *salt wasters.* These patients are predisposed to episodic and potentially life-threatening hyponatremic dehydration. Patients with sufficient aldosterone production to prevent salt wasting and who have signs of prenatal virilization and/or markedly increased production of hormonal substrates of 21-hydroxylase (e.g., 17-hydroxyprogesterone) are termed *simple virilizers.*

11β-HYDROXYLASE DEFICIENCY. Patients with 11β-hydroxylase deficiency have mutations in the *CYP11B1* gene. They have elevated levels of deoxycorticosterone and 11-deoxycortisol, as well as earlier cortisol precursors such as 17-hydroxyprogesterone. These patients secrete excess adrenal androgens, with consequences similar to those seen in 21-hydroxylase deficiency. However, patients with 11β-hydroxylase deficiency synthesize aldosterone normally and do not have problems with salt wasting. Instead, they are likely to become hypertensive as a result of elevated levels of deoxycorticosterone and its metabolites.

FIGURE 241-4. Virilized external genitalia in a female infant with congenital adrenal hyperplasia caused by 21-hydroxylase deficiency. No gonads are present in the scrotum.

DEFECTS OF ANDROGEN BIOSYNTHESIS

Lipoid hyperplasia, 17-hydroxylase/17,20 lyase deficiency, and HSD3B2 deficiency affect the biosynthesis of both corticosteroids and sex hormones. In contrast, two enzymatic defects affect only androgen biosynthesis. They have similar phenotypes. Affected male patients are born with ambiguous genitalia, but they virilize at puberty and often reassign themselves to a male gender if they were raised as females. They have absent müllerian structures as a result of the secretion of AMH by the testes.

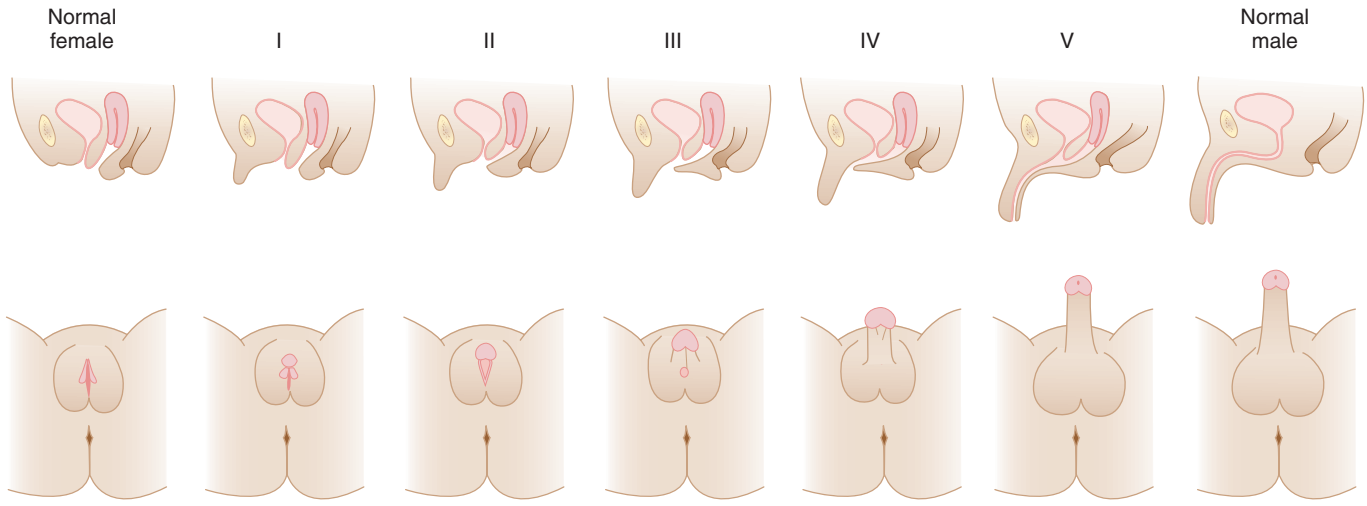

FIGURE 241-5. Abnormal differentiation of the urogenital sinus and external genitalia. Schematic representations of normal female and male anatomy flank a series of schematics illustrating different degrees of virilization of females, graded using the scale developed by Prader. The uterus (shaded) persists in virilized females even when the external genitalia have a completely masculine appearance (Prader grade V). (Adapted from Prader A. Der Genitalbefund beim Pseudohermaphroditismus femininus der kengenitalen adrenogenitalen Syndroms. *Helv Paediatr Acta*. 1954;9:231-248.)

17-KETOSTEROID REDUCTASE (17-HYDROXYSTEROID DEHYDROGENASE 3) DEFICIENCY. This disorder is caused by mutations in the *HSD17B3* gene. Although testosterone is not synthesized well, androstenedione, an active androgen, is synthesized. Because several other isozymes have 17-ketosteroid reductase activity in other tissues, some testosterone is invariably synthesized, especially at puberty, when circulating levels of androstenedione increase.

5α-REDUCTASE DEFICIENCY. Patients with 5α-reductase deficiency resulting from mutations in the *SRD5A2* gene synthesize entirely normal amounts of testosterone, but they cannot synthesize adequate amounts of dihydrotestosterone, the most potent naturally occurring androgen. This enzyme is not expressed at high levels in the testes (circulating levels of dihydrotestosterone are relatively low); instead, it is expressed in genital skin. Internal wolffian structures do not require this enzyme and are intact; high testosterone levels at puberty induce significant phallic growth without 5α-reductase activity.

OTHER DEFECTS OF STEROIDOGENESIS

AROMATASE DEFICIENCY. Mutations in *CYP19* cause aromatase deficiency in both the fetus and the placenta. The placenta can convert DHEA sulfate to androstenedione and testosterone normally, but it cannot convert these androgens to estrone and estradiol. These androgens accumulate in both the fetal and the maternal circulations and virilize both the mother and the affected fetus if it is female. Affected male infants are phenotypically normal. Affected female patients virilize further at puberty if they are untreated. The lack of aromatase activity within bone leads to tall stature in both sexes (because estrogens are required to close the growth plates) and later to osteoporosis.

CYTOCHROME P-450 OXIDOREDUCTASE DEFICIENCY. This deficiency is one form of Antley-Bixler syndrome, which is characterized by skeletal anomalies and craniosynostosis; most patients also have ambiguous genitalia associated with mutations in the *POR* gene. Antley-Bixler syndrome without genital abnormalities is caused by mutations in the FGF receptor (*FGFR2*) gene.

Because this disorder affects the activity of all microsomal cytochrome P-450 subsets, complete deficiency of cytochrome P-450 oxidoreductase (POR) is lethal, and identified mutations in humans yield POR with partial activity. *POR* mutations may cause skeletal anomalies by interfering with cholesterol synthesis. Genital ambiguity is caused by several mechanisms. Decreased activity of 17α-hydroxylase/17,20 lyase (CYP17) affects androgen synthesis and leads to undervirilization in males. Conversely, decreased activity of 21-hydroxylase (CYP21) can virilize affected females. These two deficiencies can also cause adrenal insufficiency. Finally, decreased activity of placental aromatase (CYP19) virilizes both the mother and the affected fetus (if female).

SMITH-LEMLI-OPITZ SYNDROME. This relatively frequent (1 in 20,000 northern Europeans) disorder of the final step of cholesterol biosynthesis (conversion from 7-dehydrocholesterol) is caused by mutations in the *DHCR7* gene encoding 7-dehydrocholesterol reductase. The syndrome is characterized by multiple congenital anomalies, including short stature, microcephaly, mental retardation, aggressive behavior, seizures, hypotonia, polydactyly, cleft palate, cardiac defects, lung hypoplasia, and renal anomalies. Male patients have ambiguous genitalia. The range of clinical severity is wide and depends on the nature of the mutations. Pathogenetic mechanisms for the ambiguous genitalia may include insufficient provision of cholesterol for steroid hormone biosynthesis or toxic effects of the precursor, 7-dehydrocholesterol, on steroidogenic cells.

MATERNAL CONDITIONS AFFECTING THE FETUS

Luteoma of Pregnancy

Luteomas are the most common causes of maternal virilization during pregnancy. They often occur bilaterally. Although many luteomas are discovered incidentally during cesarean sections or postpartum tubal ligations, one fourth of mothers virilize during the latter half of pregnancy, and half of female infants born to these mothers also exhibit signs of virilization, most typically clitorimegaly and labial fusion. Spontaneous regression of the luteoma generally begins within days after delivery.

Drug Exposure

Depending on the agent, maternal drug exposure may affect either male or female fetuses. Females may be virilized by androgens such as 19-nortestosterone or progestins administered to prevent spontaneous abortion. Undervirilized males can be born to women exposed to 5α-reductase inhibitors such as finasteride. The antifungal agent fluconazole can inhibit many cytochrome P-450 enzymes and can lead to a condition closely resembling Antley-Bixler syndrome.

The synthetic estrogen diethylstilbestrol was used several decades ago to prevent spontaneous abortion (it was actually ineffective for this purpose). Males exposed to this agent in utero were born with testicular hypoplasia, cryptorchidism, hypospadias, and/or microphallus. Females had uterine, cervical, and vaginal abnormalities and an increased risk of clear cell adenocarcinoma of the vagina. Considering that many cases of genital ambiguity are idiopathic, it is likely that additional endocrine disruptors in the environment have not yet been identified.

HORMONE INSENSITIVITY SYNDROMES AND OTHER HORMONE DEFICIENCIES

Androgen Insensitivity

Males normally carry a single copy of the X-linked androgen receptor gene. Thus, a single mutation can completely inactivate the receptor in males and lead to complete androgen insensitivity (formerly termed *testicular*

feminization syndrome). This is one of the most frequent forms of 46,XY DSD, occurring in approximately 1 in 20,000 male births.

Patients with the complete form of androgen insensitivity have normal female external genitalia. Unless suspicion is raised by prior knowledge of the infant's karyotype, the condition is rarely discovered before puberty unless the testes are palpated in the groin or labia on routine examination. Because the testes secrete AMH, müllerian structures are absent, including the uterus, fallopian tubes, and cervix. Thus, the vagina is usually shallow and ends blindly. Wolffian structures are also absent. The testes may be located in the abdomen or in the labia majora and do not undergo spermatogenesis. AMH levels are elevated during the first year and (if the testes have not been removed) after puberty. Testosterone and LH levels in infancy and at puberty are elevated as a result of defective feedback regulation caused by androgen resistance at the level of the hypothalamus.

At puberty, pubic and axillary hair is scant or absent. Testosterone can be aromatized to estradiol by CYP19 in breast fat, and estrogen receptors are unaffected in this condition. Thus, breast development is that of a normal female.

Partial androgen insensitivity (Reifenstein's syndrome) is characterized by a variable degree of genital ambiguity, and both virilization and breast development occur at puberty. Mild androgen insensitivity can also occur with a male phenotype, with gynecomastia and infertility as the sole manifestations. Mutations in the androgen receptor are not detected in many mild cases, which may result from defects in other factors affecting actions of the receptor.

Leydig Cell Agenesis

Leydig cell agenesis or hypoplasia is a rare autosomal recessive syndrome caused by mutations in the *LHGCR* gene encoding the LH receptor. Without stimulation by LH (or by HCG early in gestation), Leydig cells do not differentiate normally and do not secrete testosterone. Thus, affected male infants are born with female-appearing or ambiguous external genitalia. Müllerian structures are absent because of unaffected secretion of AMH by Sertoli cells. LH levels are high in infancy and at puberty, and they respond normally to gonadotropin-releasing hormone, whereas testosterone levels are low and do not respond to stimulation by HCG. Affected females are phenotypically normal but may have oligomenorrhea resulting from primary ovarian dysfunction.

Persistent Müllerian Duct Syndrome

Persistent müllerian duct syndrome (PMDS) is a rare autosomal recessive condition that results from mutations in the genes for either AMH (PMDS type I) or the AMH receptor (*AMHR2* gene, PMDS type II). The two are distinguished clinically by low or absent AMH levels in patients with AMH mutations and by AMH levels in the high-normal range in those with AMH receptor mutations.

Affected male patients have unimpaired testosterone secretion and thus have normal external genitalia and wolffian structures. However, the lack of AMH action prevents regression of müllerian structures, so these patients also retain a uterus and fallopian tubes. These structures are often closely approximated to the vas deferens. The müllerian structures are usually dragged into the inguinal canal by the descending testes. However, these structures typically prevent the testes from descending into the scrotum and thus cause bilateral inguinal hernias (with the uterus on one side) and bilateral or occasionally unilateral cryptorchidism. The condition is usually discovered only at surgery. Fertility in affected patients may be normal or impaired, with an increased risk of malignant disease in undescended testes left in the abdomen.

Hypogonadotropic Hypogonadism

Milder or later-appearing deficiencies of androgen biosynthesis (after 13 to 14 weeks) may allow complete fusion of the labioscrotal folds and normal positioning of the urethral meatus, but subsequent growth of the phallus is suboptimal. Such individuals have a micropenis. The most common cause is lack of gonadotropin (specifically, LH) secretion; even when LH is lacking, early male development is normal because testosterone secretion is controlled mostly by HCG during the first trimester.

Defective LH and follicle-stimulating hormone secretion can result when the neurons that normally secrete gonadotropin-releasing hormone fail to migrate into the hypothalamus. This condition, Kallmann's syndrome, is most often X-linked, resulting from mutations in the *KAL1* gene. It is often associated with anosmia. Other conditions that affect hypothalamic development and cause hypogonadotropic hypogonadism include Prader-Willi syndrome, which is a result of paternal deletions, methylation defects, and maternal uniparental disomy of imprinted loci on chromosome 15q12. Children with this syndrome have a characteristic appearance consisting of a narrow bitemporal diameter, almond-shaped eyes with an antimongoloid slant, and small hands and feet. They typically have marked hypotonia as infants, with subsequent moderate developmental delay and slow somatic growth. Hypothalamic obesity develops during childhood. Patients with adrenal hypoplasia congenita resulting from mutations in the DAX1 transcription factor have defective development of the ventromedial hypothalamus and consequent hypogonadotropic hypogonadism, associated with adrenal insufficiency that typically presents with aldosterone deficiency and salt wasting.

Hypogonadotropic hypogonadism often results from failure of the entire anterior pituitary gland, or particular cellular populations therein, to develop. Pituitary gland abnormalities can be associated with other midline defects, including hypoplasia of the optic nerves and the septum pellucidum, a condition termed *septo-optic dysplasia.* Associated pituitary hormone deficiencies may include growth hormone, ACTH, and thyroid-stimulating hormone. These deficiencies may present in the neonatal period as hypoglycemia or hypothyroidism (detected by newborn screening programs). Optic nerve dysfunction is difficult to detect by routine examination in the neonatal period, but it causes a characteristic wandering nystagmus after a few months of age.

Although panhypopituitarism is most often sporadic, mutations in transcription factors controlling pituitary development have been documented (Chapter 231), particularly PROP1, and septo-optic dysplasia has been associated with mutations in the *HESX* gene. Rarely, mutations in the gene encoding the β-subunit of LH may yield a phenotype similar to hypogonadotropic hypogonadism.

OTHER GENETIC CONDITIONS

Aneuploidy of Sex Chromosomes

TURNER'S SYNDROME. Patients with Turner's syndrome have normal female external genitalia and a normal uterus and fallopian tubes, but they have dysgenetic streak ovaries. Most fetuses with Turner's syndrome spontaneously abort, but the incidence in live births is approximately 1 in 2500. Classically, the karyotype is 45,X, but many patients retain an abnormal second X chromosome or even a fragment of a Y chromosome lacking *SRY*. Other patients are mosaic for 46,XX and 45,X cells and may have relatively mild phenotypes.

Untreated patients are short. Many have typical dysmorphic features, including lymphedema of the neck at birth, webbed neck, low posterior hairline, increased carrying angle of the arms, shield chest with widely spaced nipples, low-set ears, and micrognathia. Patients typically have primary amenorrhea and are infertile, but they occasionally have menarche followed by premature ovarian failure.

KLINEFELTER'S SYNDROME. In this condition, male patients have normal development of the penis and scrotum, but the testes are small and firm. Patients tend to be tall. At adolescence, gynecomastia is frequent. Signs of testosterone deficiency occur in most affected adults, and most have azoospermia. The usual karyotype is 47,XXY. Hormonal findings include elevated gonadotropin levels and a decreased serum testosterone concentration. Klinefelter's syndrome is a common disorder that occurs in 1 in 500 to 1000 men.

Mixed Gonadal Dysgenesis

Mixed gonadal dysgenesis, a frequent cause of sexual ambiguity, occurs in approximately 1 in 20,000 births. The karyotype is usually mosaic 45,X/46,XY. Gonadal pathologic features can vary from fibrous streaks indistinguishable from those in Turner's syndrome to normally developed testes and a normal male phenotype. Typically, patients have a testis on one side and a fibrous streak on the other. Some patients may have a Turner-like phenotype. A fallopian tube is usually present on the side of the streak gonad. Leydig cell function, evaluated by testosterone response to HCG, and Sertoli cell function, evaluated by serum AMH levels, vary from poor to normal.

XX Male Syndrome

Males with a 46,XX karyotype have normal external and internal male genitalia; however, they resemble patients with Klinefelter's syndrome in that they have small testes, azoospermia, and infertility. Translocation of the *SRY* gene to the X chromosome is detected in 75 to 90% of sporadic cases; this

can occur because the gene is located very near the pseudoautosomal region, where the short arms of the X and Y chromosomes are homologous and meiotic recombination is possible. Duplication of the SOX9 transcription factor may be responsible for some familial cases of XX sex reversal.

XY Female Syndromes

Patients with pure XY gonadal dysgenesis (Swyer's syndrome) have a normal female phenotype, including a uterus and fallopian tubes, but they have streak gonads. These patients are free of Turner-like malformations and attain normal height. Mutations of the *SRY* gene have been identified in 15% of cases. Unlike 45,X patients with Turner's syndrome, these patients have an increased risk of gonadoblastoma.

Similar phenotypes result from duplication of the region of the X chromosome containing the *DAX1* gene, from duplication of the *WNT4* gene, or from haploinsufficiency of the SF1 transcription factor (associated in some cases with adrenal hypoplasia). XY sex reversal can also result from mutations in the SOX9 transcription factor that are associated with camptomelic dysplasia, a form of dwarfism. Mutations of *DHH* cause XY gonadal dysgenesis, associated with peripheral neuropathy.

Other 46,XY patients with absent gonads have various degrees of sexual ambiguity and no müllerian derivatives. The implication that some testicular tissue was functional at least up to 10 weeks' gestation and subsequently regressed led to the name *fetal testicular regression syndrome.* Testicular regression may occur in late pregnancy or even postnatally; these fully virilized male patients have isolated anorchia.

Vaginal Atresia

Mutation of *WNT4* affects the development of müllerian structures but permits normal ovarian development, thus causing vaginal atresia and uterine abnormalities. This disorder is termed *Mayer-Rokitansky-Küster-Hauser syndrome.*

True Hermaphroditism

True hermaphroditism, a rare and usually sporadic disorder, is defined as the coexistence of seminiferous tubules and ovarian follicles. Most patients have an ovotestis with either an ovary or a testis on the opposite side; a gonad in the scrotum is usually a testis but may be an ovotestis.

The genitalia are usually ambiguous, but they may appear completely masculine or feminine. The anatomy of the internal reproductive tract depends on the nature of the gonads, particularly whether they secrete AMH. A uterus or uterine horn is present in 90% of cases. Testosterone response to HCG is variable, and AMH levels are usually low. Most patients experience breast development, ovulation, and even menstruation at puberty; pregnancy and successful childbirth are possible if selective removal of testicular tissue is feasible. Unless sex of rearing has already been chosen, male gender assignment should be restricted to patients with no uterus and descended testicular tissue because the latter is usually dysgenetic and prone to malignant degeneration. Most true hermaphrodites have a 46,XX karyotype. Despite the presence of testicular tissue, true hermaphrodites usually lack *SRY;* this suggests that the condition is the result of constitutive activation of a gene normally triggered by *SRY.*

MANAGEMENT OF INDIVIDUALS WITH DISORDERS OF SEXUAL DEVELOPMENT: GENDER ROLE AND IDENTITY

The influence of prenatal sex steroid exposure on personality is controversial. In considering this question, it is important to distinguish among gender role, sexual orientation, and gender identity.

Gender Role

Gender role refers to gender-stereotyped behaviors, such as the choice of toys by young children. For example, parents of young girls with CAH often report that their daughters prefer to play with trucks rather than dolls and tend to be tomboyish later in childhood. Decreased interest in maternal behavior, beginning with infrequent doll play in early childhood and extending to lack of interest in child rearing in older girls and women, occurs frequently.

Sexual Orientation

Sexual orientation refers to homosexual versus heterosexual preferences. In many studies, a significant minority of women with CAH are actively homosexual or bisexual or have an increased tendency toward homoerotic fantasies. These characteristics occur more frequently in women with the salt-wasting form of 21-hydroxylase deficiency.

Gender Identity

Gender identity refers to self-identification as male or female. Gender self-reassignment back to male has been reported in cases of male patients with penile trauma or exstrophy of the bladder who were raised as girls. This may also occur in 46,XY DSD patients raised as girls, especially in cases of 5α-reductase or 17-ketosteroid reductase deficiencies, in which the brain may be exposed to high circulating levels of androgens. Conversely, female-to-male transsexuals may have relatively high levels of androgens and a high incidence of polycystic ovary syndrome. Self-reassignment to the male gender is unusual in women with CAH. When it occurs, it may be related to delays in gender assignment or genital surgery or to inadequate suppression of adrenal androgens with glucocorticoid therapy. Severely virilized girls are more likely to be raised as boys in cultures that value boys more highly or in developing countries owing to a delay in diagnosis. Few studies have directly compared psychosexual functioning in severely virilized genetic female patients with CAH who were raised as girls versus boys, but those raised as boys are not psychologically better adjusted than those raised as girls. The role of external genital anatomy before and after genital surgery in causing gender identity problems is unclear compared with the roles of prenatal hormone exposure, rearing by the family, and community attitudes.

DIAGNOSIS

Management of a child born with ambiguous genitalia presents a difficult challenge to medical personnel. It is important to refrain from assigning sex until diagnostic information can be gathered. Usually, test results can be obtained within 24 to 48 hours, and parents can be advised about the child's chromosomal and gonadal sex and the anatomy of internal sexual structures.

In addition, the physician must keep in mind that DSD may be associated with life-threatening biochemical or anatomic abnormalities. In particular, the most common cause of severely masculinized external genitalia in females, the salt-wasting form of CAH resulting from steroid 21-hydroxylase deficiency, may cause hyponatremia, hyperkalemia, hypovolemia, and shock. In contrast, male patients with ambiguous genitalia may have lipoid adrenal hyperplasia or a salt-wasting form of HSD3B2 deficiency. Males with micropenis may have panhypopituitarism, in which case they are at risk for significant hypoglycemia resulting from low cortisol (because of low ACTH) and low growth hormone levels, or they may have adrenal hypoplasia congenita, in which case they could have adrenal insufficiency. Finally, patients with ambiguous genitalia are at increased risk for renal anomalies, or they may have chromosomal syndromes with other associated anomalies.

History

The gestational history should concentrate on potential exposure to agents that could interfere with normal sexual differentiation. For a female infant with virilized genitalia, these include progestational agents, whereas the mother of a male with incompletely masculinized genitalia may have been exposed to a 5α-reductase inhibitor through her husband's use of such an agent for male pattern baldness or prostate enlargement. It should be determined whether amniocentesis and karyotyping have been performed. A family history should elicit similar cases of genital ambiguity or cases of sudden death, which could raise suspicion of undiagnosed salt-wasting CAH.

Physical Examination

The physical examination should document the size of the phallus (clitoris or penis), the degree of chordee (ventral bowing of the phallus), and the extent of fusion of the labioscrotal folds. The urethral meatus should be identified, and there must be careful palpation for gonads in the inguinal canals and labia or scrotum. Bilateral cryptorchidism, even if an isolated finding in a phenotypic male patient, should always lead to evaluation for a possible DSD.

Biochemical Evaluation of the Virilized Female

The minimal diagnostic tests should include measurement of basal serum 17-hydroxyprogesterone, androstenedione, and testosterone. Preferably, a complete profile of adrenocortical hormones is obtained before and 1 hour after stimulation of the adrenal cortex with 125 to 250 μg of cosyntropin ($ACTH_{1\text{-}24}$). These assays should be deferred until after the first 24 hours of life. They will identify potential defects in adrenal steroidogenesis

(i.e., CAH); 21-hydroxylase deficiency is identified by elevations in 17-hydroxyprogesterone, whereas 11-deoxycortisol and 11-deoxycorticosterone are high in 11β-hydroxylase deficiency.

Biochemical Evaluation of the Undervirilized Male

In 46,XY DSD patients, it is necessary to test adrenal and gonadal function as well as extragonadal androgen metabolism. With regard to adrenal defects, 11-deoxycorticosterone and the ratio of pregnenolone to 17-hydroxypregnenolone are high in 17α-hydroxylase deficiency, 17-hydroxypregnenolone and DHEA are high in HSD3B2 deficiency, and all steroids are low in lipoid hyperplasia.

Defects in gonadal steroidogenesis are best evaluated after stimulation with HCG (1500 IU intramuscularly on days 1, 3, and 5, with blood drawn on day 6). However, 17-hydroxylase and HSD3B2 deficiencies affect both the gonads and the adrenal cortex and thus are often diagnosed by cosyntropin stimulation testing. Low levels of all androgen precursors suggest lipoid hyperplasia, 17α-hydroxylase/17,20 lyase deficiency, or a generalized defect in testicular function, such as the vanishing testis syndrome or gonadotropin insensitivity. A high ratio of androstenedione to testosterone is indicative of 17-ketosteroid reductase (HSD17B3) deficiency, and a high ratio of testosterone to dihydrotestosterone is diagnostic of 5α-reductase deficiency. The diagnosis of androgen insensitivity syndrome is suspected when a 46,XY patient has ambiguous or female-appearing external genitalia despite normal or high circulating levels of testosterone and dihydrotestosterone.

Gonadal Biopsies

Patients with mixed gonadal dysgenesis, true hermaphroditism, or unclear diagnoses should undergo bilateral gonadal biopsies (histology of the two gonads is often not identical). Dysgenetic gonads have a high potential for malignant transformation and usually need to be removed in childhood.

TREATMENT

Rx

Initial Medical Management

Patients with CAH resulting from 21-hydroxylase or HSD3B2 deficiencies or those with lipoid hyperplasia require replacement of both glucocorticoids and mineralocorticoids, usually with hydrocortisone (15 to 20 mg/m^2/day in divided doses) and fludrocortisone (usually 0.1 mg/day, but as much as 0.4 mg/day in neonates with salt-wasting crises), respectively. Neonates with severe salt losses may require sodium chloride supplementation (≤8 mEq/kg/day). Patients with 11ß-hydroxylase or 17α-hydroxylase deficiencies have normal aldosterone biosynthesis and usually require only glucocorticoids. Patients with panhypopituitarism usually require treatment with hydrocortisone, thyroxine, and growth hormone.

All male infants with ambiguous genitalia or micropenis in whom rearing as a boy is contemplated should have a 3-month therapeutic trial of monthly depot testosterone injections (25 mg) to attempt to increase the size of the phallus during infancy. This treatment may improve social acceptability of the genitalia later in childhood and adolescence and may make reconstructive surgery easier. In cases of suspected partial androgen insensitivity, this treatment also documents the degree to which the patient is androgen responsive and thus may provide useful information about whether rearing as a boy is feasible. Higher doses of testosterone (75 mg every 4 weeks) may be used under these circumstances.

Considerations Related to Sex Assignment

In large medical centers, a team consisting of a neonatologist, a pediatric endocrinologist, a urologist, and preferably an experienced social worker and/or child psychiatrist should promptly review the early diagnostic data and make a recommendation to the family as to the sex of rearing and any medical or surgical treatments. These recommendations should be based on both current knowledge of psychosexual development in DSD individuals and the feasibility of surgical correction (see later).

In general, the recommended sex assignment should be that of the genetic/gonadal sex, if for no other reason than to retain the possibility of reproductive function. This is especially true for female infants with CAH who have normal internal genital structures and the potential for childbearing. An exception may be considered in a genetically female infant with completely male-appearing genitalia, especially if the child has been raised as a boy for more than a few months. Such children need to be castrated at puberty to avoid feminization.

Conversely, genetic male infants with completely female-appearing external genitalia (usually resulting from complete androgen insensitivity syndrome, but also seen with severe testosterone biosynthetic defects) should be raised as female because the potential for reconstruction of male genitalia is poor. They, too, need to be castrated by early adulthood to avoid malignant transformation of the testes. However, male infants with 17-ketosteroid reductase or 5α-reductase deficiency should usually be reared as boys because they have normal levels of androstenedione or testosterone, respectively, and often virilize significantly at puberty. Indeed, many of these patients reassign themselves to the male gender when they are made aware of the diagnosis. The same considerations pertain to male patients with normal testosterone biosynthesis who have penile trauma or anatomic abnormalities such as bladder exstrophy.

Recommendations for sex assignment are to some extent culture specific. In cultures that value boys over girls, parents may strongly resist rearing a female infant with ambiguous genitalia as a girl, and many girls with severely virilized external genitalia will be raised as boys.

Corrective Surgery

Surgery for Ambiguous Genitalia

Whether, how, and when to intervene surgically in the correction of genital anomalies are the subject of continuing debate. Some adult patients with DSD conditions are unhappy with their gender assignments or surgical outcomes. Some physicians advocate postponing cosmetic genital surgery until the affected individual is able to provide informed consent, thus keeping all the options open if the adult patient wishes to function sexually with abnormal genitalia that nevertheless have sensation undiminished by surgery or chooses to reassign his or her gender. Declining or postponing surgery should not be confused with raising the child with an indeterminate gender, a concept currently well outside the mainstream. The option of deferring surgery should always be presented as part of the informed consent process. Nevertheless, most parents want their child to look as "normal" as possible, and they often resist suggestions to postpone corrective surgery.

In addressing this question, it is best to consider the various general types of genital surgery separately. The greatest change in practice over the past few decades probably pertains to male infants with ambiguous (but not completely female) external genitalia. Physicians are far less likely to recommend that such patients be reared as female because it is now recognized that many of these patients reassign themselves as male at puberty. Thus, the ambiguous genitalia in such patients should rarely be "corrected" to female. On the contrary, surgical techniques for hypospadias repair have advanced significantly, and reconstruction of male genitalia is attempted more often, particularly if the infant responds to a course of testosterone with significant phallic growth.

Surgery for female infants with ambiguous genitalia may need to address an enlarged clitoris, the lack of a vaginal introitus, and the presence of a urogenital sinus. The clitoris is normally prominent in many infant girls. Even when enlarged in a girl with virilizing CAH, the clitoris can be prevented from growing larger with adequate suppression of adrenal androgens by glucocorticoids, and it will become less prominent as the patient grows. Thus, mild to moderate clitorimegaly is often best managed without surgery. When clitoroplasty is attempted, one must keep in mind the important role of clitoral sensation in the female sexual response. Such surgery must be performed only by experienced operators with scrupulous attention to the preservation of clitoral innervation.

Consensus is still lacking regarding the best age for vaginoplasty. Although many surgeons advocate a first procedure in infancy, it is difficult to maintain a functionally adequate introitus in the absence of estrogen exposure and mechanical dilation (with dilators or through sexual intercourse), and many patients require reoperation as young adults.

There is a dearth of large longitudinal studies comparing outcomes in patients who have had early genital surgery versus those who have had no surgery or surgery in adolescence. According to self-assessment surveys among sexually active women with CAH who have had genital surgery, most are able to have satisfactory sexual intercourse. As surgical and medical treatment regimens have improved in recent years, more women with CAH have successfully conceived spontaneously, completed pregnancies, and given birth. Most often, delivery is by cesarean section because of an inadequate introitus, but vaginal delivery is possible in some cases.

Hypospadias repair is usually begun in the first year of life, after testosterone treatment (if necessary to increase phallic size). Depending on the degree of hypospadias, more than one surgical procedure may be required.

Removal of Intra-abdominal Testes in 46,XY DSD Patients

Intra-abdominal testes are at increasing risk for malignant transformation over time. In a boy with cryptorchidism who is being reared as male, orchiopexy should be performed as quickly as possible; this also maximizes the possibility of fertility when the underlying condition does not preclude it. Dysgenetic gonads that cannot be brought into the scrotum should be removed soon after diagnosis because the risk of malignant transformation in childhood is relatively high.

There is a lack of consensus regarding nondysgenetic testes in severely undervirilized genetic male infants in whom rearing as female is planned. In patients with complete androgen insensitivity or complete defects in testosterone biosynthesis, no possibility of fertility exists, and so there seems to be no reason to retain the testes. Conversely, the risk of malignant transformation in such gonads is low before puberty, and patients with complete androgen

insensitivity can undergo spontaneous breast development at puberty. At that time, patients themselves can assent or consent to gonadectomy, which can usually be accomplished laparoscopically. This is of particular importance in genetic male patients with partial androgen insensitivity or incomplete defects of testosterone biosynthesis, because such patients may eventually desire a male gender role.

Patients with persistent müllerian duct syndrome have a reduced but still appreciable potential for fertility, and virilization is unaffected. Thus, the testes should be removed only if they cannot be brought into the scrotum. Because the müllerian and wolffian structures are closely approximated in these patients, surgical excision of the uterus and fallopian tubes may result in ischemic and/or traumatic damage to the vas deferens and testes; thus, salpingectomy and hysterectomy are indicated only in patients whose müllerian structures limit intrascrotal placement of the testes.

Prenatal Diagnosis and Treatment

Many conditions causing ambiguous genitalia can be detected by karyotyping of chorionic villus samples (for chromosomal abnormalities) or by direct molecular genetic testing. In most cases, this information is useful only for counseling purposes. In the case of virilizing forms of CAH (particularly 21-hydroxylase deficiency), the mother of an affected female fetus can take dexamethasone (20 µg/kg/day), which can cross the placenta and suppress the fetal adrenal gland, thus reducing the secretion of androgens and ameliorating virilization of the external genitalia. To be most effective, this treatment should be started by the sixth week of gestation, before the sex or genotype of the fetus is known. Thus, seven unaffected or male fetuses must be treated with dexamethasone to avoid genital ambiguity in one affected female, until chorionic villus sampling can be performed. Although effective in reducing prenatal virilization, this dose of dexamethasone can cause Cushing's syndrome in the mother, and the long-term sequelae in the fetus are not known. Therefore, many endocrinologists believe that this treatment should be used only under approved research protocols that allow for case registries and long-term follow-up.

Psychosocial Support

Families of DSD patients should be assessed for emotional health, initially by the pediatrician and/or pediatric endocrinologist. Parents should be offered psychological counseling soon after the diagnosis is made. Intermittent assessment of family functioning may be a useful tool in predicting future problems. As children mature, they should repeatedly be informed about their condition by parents and physicians in a sensitive and age-appropriate manner. When psychotherapy is undertaken, medical and psychiatric caregivers should communicate with each other so both are aware of the patient's and family's status. Unfortunately, many locales lack mental health professionals with experience in counseling patients with DSD and their families.

Although the psychosexual development of individuals with DSD cannot be predicted with confidence, patients' families should receive anticipatory counseling. For example, counseling of parents of girls affected with CAH should address the high likelihood that such girls will exhibit tomboyish behavior, masculine play preferences, and perhaps, when older, a preference for a career over domestic activities. In the contemporary United States, these preferences usually have a high degree of social acceptance. Parents should also be told that most (but not all) girls with CAH function heterosexually, although they may require repeated genital surgical procedures to have satisfactory sexual intercourse. The endocrinologist and/or mental health professional (depending on inclination and experience) caring for the adolescent girl with CAH should address sexual orientation, both fantasized and actual. Health care professionals should accept that some women with CAH may be most comfortable as homosexuals and that such individuals should be helped to come to terms with their situation. Adult patients should also be made aware of relevant patient advocacy groups.

THE TESTIS AND MALE SEXUAL FUNCTION

RONALD S. SWERDLOFF AND CHRISTINA WANG

PHYSIOLOGY

The testis is a bifunctional organ serving as the site of sex steroid (i.e., testosterone) synthesis and sperm production in the male. Androgens and their metabolites (including estrogens) also act on nonreproductive organs and serve essential roles in muscles, adipose tissues, bones, metabolism, and brain functions.

The male reproductive axis consists of six main components: (1) extrahypothalamic central nervous system (CNS), (2) hypothalamus, (3) pituitary, (4) testes, (5) sex steroid–sensitive end organs, and (6) sites of androgen transport and metabolism (Fig. 242-1). The components of this system function in an integrative fashion to control the concentrations of circulating gonadal steroids required for normal male sexual development and function and for androgen- and estrogen-mediated metabolic effects on critical end organs. The reproductive axis is also responsible for normal germ cell development and maturation and sperm transport function necessary to ensure male fertility.

Hypothalamic-Pituitary Function

The hypothalamus is responsible for the normal pulsatile secretion of gonadotropin-releasing hormone (GnRH) (Chapter 231). The pulsatile release of GnRH provides the signals for the timing of the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which occurs every 60 to 90 minutes in men. The secretion of GnRH is regulated by neuronal input from higher cognitive and sensory centers and by circulating levels of sex steroids and peptide hormones such as prolactin and leptin (Chapter 230). Testosterone or its metabolic products (i.e., estradiol and dihydrotestosterone) inhibit the secretion and release of GnRH, LH, and FSH. Prolactin is also a potent inhibitor of GnRH secretion.

Both LH and FSH consist of two subunits (α and β). Both subunits are required for biologic activity; the subunits can be detected in serum and may

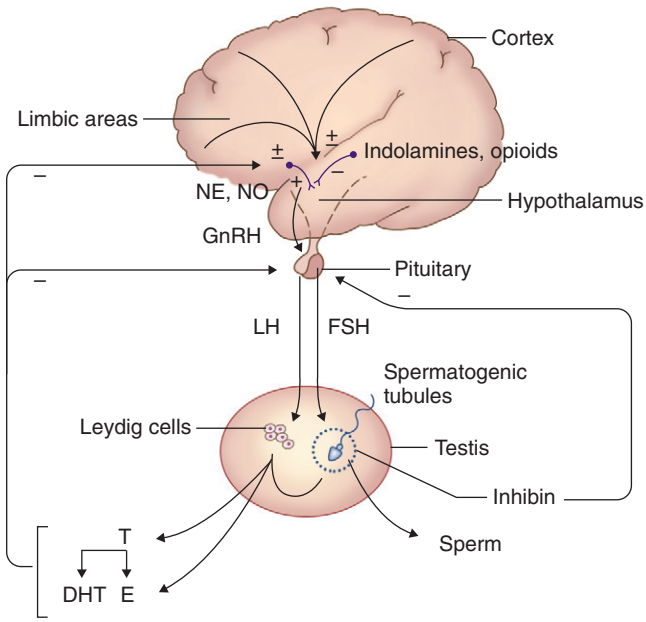

FIGURE 242-1. The hypothalamic-pituitary-gonadal axis in the male. DHT = dihydrotestosterone; E = estrogen; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; NE = norepinephrine; NO = nitric oxide; T = testosterone.

be increased in certain pathologic conditions (e.g., α-subunit elevations in gonadotropin-secreting pituitary adenomas). LH has a shorter half-life than FSH. Feedback regulation of LH and FSH secretion also occurs at the pituitary, with testosterone, dihydrotestosterone (DHT), and estrogens inhibiting the synthesis or release of both gonadotropins. The circulating testicular peptide inhibin, produced by Sertoli cells, also selectively inhibits FSH. LH and FSH act predominantly through specific cell surface receptors on the Leydig and Sertoli cells of the testes, respectively.

Testosterone

The testis is a complex organ consisting of (1) seminiferous tubules containing Sertoli cells and germ cells and (2) the interstitium, which contains the steroid-secreting (Leydig) cells. Leydig cells synthesize steroid hormones under the regulation of LH. The LH receptors on the cell surface of the Leydig cells lead to G protein–, adenyl cyclase–, and cyclic adenosine monophosphate–mediated activation of steroid biosynthesis.

Testosterone is the principal male hormone secreted by the testes; about 5 to 10 mg/day is produced in adult men. Testosterone synthesis occurs in the human testes through either the Δ^4 or the predominant Δ^5 pathway. The enzymatic rate-limiting steps in the process are the LH-inducible steroid acute regulatory (StAR) protein and the conversion of cholesterol to pregnenolone by the cholesterol side-chain cleavage enzyme P450SCC (Fig. 242-2).

Testosterone circulates mainly bound to two plasma proteins: sex hormone–binding globulin (SHBG) and albumin. In young adult men, about 54% of testosterone is bound to albumin, 44% is bound to SHBG, and 2 to 3% is unbound. Bioavailable testosterone refers to the sum of albumin-bound and free testosterone and is measured by separating SHBG-bound testosterone from total testosterone. Serum SHBG levels are increased in hyperestrogenemic states, hyperthyroidism, aging, phenytoin treatment, anorexia nervosa, and prolonged stress. SHBG levels are lowered with androgen treatment, obesity, acromegaly, and hypothyroidism. In most instances, measurement of serum total testosterone provides biochemical support for the diagnosis of androgen deficiency. In conditions with abnormal SHBG levels, however, the total testosterone measurement may be misleading, and direct measurement of free testosterone, measurement of bioavailable testosterone, or calculation of the free testosterone by a formula requiring the serum testosterone and SHBG concentrations may be necessary to separate true testosterone deficiency from binding protein problems.

Testosterone exerts its effects either through direct action or after conversion to DHT by two separate 5α-reductase isozymes (1 and 2) or to estradiol by the aromatase enzyme (Fig. 242-3). Thus, testosterone can act directly on the androgen receptor or as a precursor for DHT which also binds to the androgen receptor. Different tissues have coactivators or coinhibitors that modify the action of the androgen-receptor complex, providing tissue selectivity and amplification. Testosterone can also serve as a precursor for estradiol in some tissues, and after conversion, estrogen binds the estrogen receptors (α or β) to induce its effects. Various end organs differ in their 5α-reductase isoenzyme concentrations and aromatase activity. Congenital and acquired defects in these two enzymes, as well as in the estrogen and androgen receptors, result in distinct syndromes with characteristic phenotypes (Chapter 241).

Spermatogenesis

The spermatogenic compartment of the testis consists of the Sertoli and germ cells that are intimately interactive with the interstitial compartment. The Sertoli cells bridge the entire space between the basement membrane and the lumen of the tubules. They are the target of androgenic and FSH stimulation of spermatogenesis and also the source of a multitude of paracrine regulators of spermatogenesis (e.g., inhibin, activin, growth factors, cytokines).

Germ cell development and maturation are dependent on the proper hormonal (FSH) and paracrine (testosterone) milieu. Not all germ cells reach maturity. Considerable data indicate that a major effect of both testosterone and FSH is to limit the amount of germ cell death (apoptosis).

After spermatogenesis is completed, mature spermatozoa are released into the excretory system and travel through the rete testes and epididymis, where they become functionally mature and acquire fertilizing capacity before traversing the vas deferens. The seminal fluid gains constituents from the seminal vesicles, prostate, and bulbourethral glands before ejaculation.

Normal Sexual Function and Erectile Physiology

Normal sexual function in men requires normal sexual desire (libido) and erectile, ejaculatory, and orgasmic capacity. The process is complex, involving cognitive, sensory, hormonal, autonomic neuronal, and penile vascular integrative actions for normal function. Defects can occur at multiple levels.

The brain is the integrative center of the sexual response system. It processes sensory input and hormonal signals to create the hypothalamic neuronal message that traverses the spinal cord to the T9–12 sympathetic and sacral parasympathetic outflow tracts. The nonadrenergic, noncholinergic autonomic plexus nerves initiate vasodilation of the cavernosal arterial and corpora cavernosal sinusoids of the penis through the release of local vasodilators such as nitric oxide and vasoactive intestinal peptide from the vascular endothelium and the smooth muscle cells of the sinusoids (Fig. 242-4). Nitric oxide produces smooth muscle dilation through the generation of cyclic guanosine monophosphate (cGMP) and the modification of calcium flux. The neurogenic mechanisms leading to vasodilation of the cavernosal arterioles and sinusoids lead to a rapid increase in penile blood flow and expansion of the vascular channels; this, in turn, inhibits venous return through compression of the venous channels against the tunica albuginea and limits venous drainage.

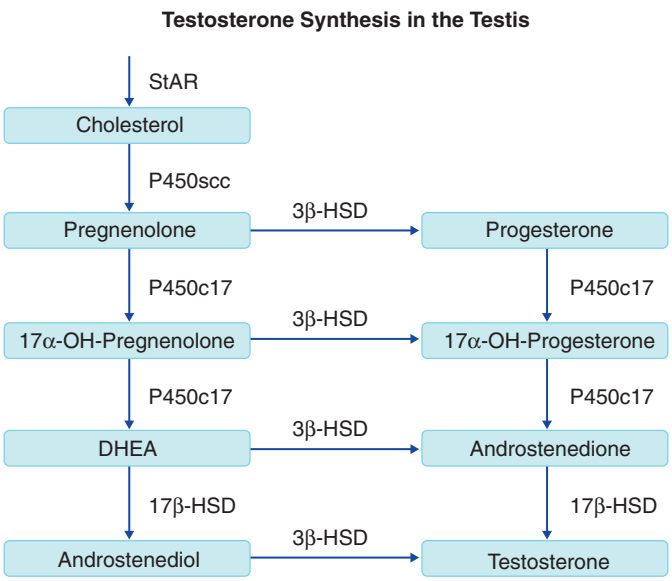

FIGURE 242-2. The steroid acute regulatory (StAR) protein mobilizes cholesterol from cellular stores to the mitochondria. Intratesticular steroidogenic pathways for the synthesis of testosterone. Although both the Δ^5 (left) and Δ^4 (right) pathways exist, the Δ^5 pathway predominates in the testis. DHEA = dehydroepiandrosterone; HSD = hydroxysteroid dehydrogenase.

The interaction among cholinergic, adrenergic, and nonadrenergic, noncholinergic (NANC) neuronal pathways and their contribution to penile smooth muscle contraction and dilation (arrows). NO = nitric oxide; VIP = vasoactive intestinal polypeptide. (From Lue TF. Physiology of penile erection and pathophysiology of erectile dysfunction and priapism. In: Walsh P, Retick A, Vaughn E, Wein A, eds. *Campbell's Urology*, 7th ed. Philadelphia: WB Saunders; 1998:1164.)

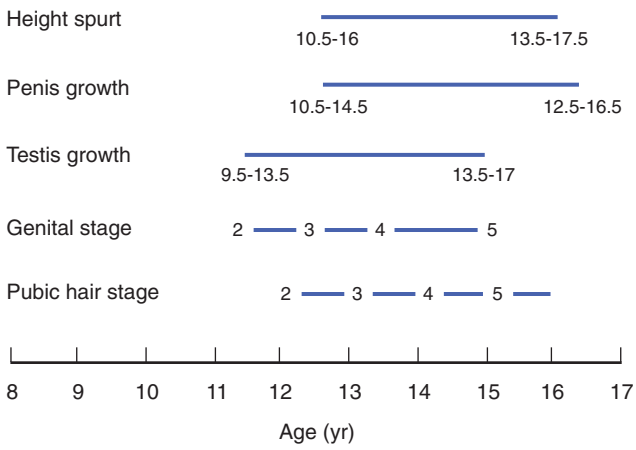

FIGURE 242-5. Diagram of the timing of the various components of puberty. The range of ages at which each parameter begins and is completed is shown for each bar. These data were obtained from European children 40 years ago. Since then, there may be a slight trend for an earlier onset of puberty. (From Marshall WA, Tanner JM. Variations in the pattern of pubertal changes in boys. *Arch Dis Child*. 1970;45:13-23.)

Testosterone's primary effect on erectile function is to enhance libido, with secondary effects on nitric oxide synthase activity. Sexual desire and fantasy are highly sensitive to testosterone, explaining the preservation of erectile capacity in many men with partial androgen deficiency. Erectile dysfunction (see later) is common in older men despite normal serum testosterone levels; this effect appears to be the result of impaired penile vasodilatory capacity probably due to atherosclerosis. Men presenting with erectile dysfunction may also have increased risk for the metabolic syndrome and cardiovascular disease. Erectile dysfunction can be treated by the oral administration of penile-selective phosphodiesterase-5 inhibitors (sildenafil, vardenafil, tadalafil) or through local (intracavernosal or transurethral) administration of potent vasodilators (prostaglandins, papaverine, phentolamine). Combined androgen deficiency with decreased libido and decreased penile responsiveness due to impaired nitric oxide synthase activity may be common in elderly men. With the availability of effective penile vasodilatory medications to ensure erectile capacity, complaints of diminished libido can be effectively treated with androgen supplementation.

Physiology in Development and Aging

Reproductive Axis Development during Childhood and Puberty

Adrenarche and Puberty

Adrenarche occurs at about 7 or 8 years of age when the zona reticularis of the adrenal gland undergoes maturation, leading to increased secretion of androstenedione, dehydroepiandrosterone (DHEA), and DHEA sulfate (DHEA-S). The process is under the control of adrenocorticotropic hormone, not LH or FSH. Androstenedione and DHEA are technically androgenic prehormones, and the prepubertal growth spurt as well as the early development of pubic and axillary hair are mediated by the conversion of these precursors to testosterone and DHT in peripheral tissues.

Initiation of puberty is determined by an increase in the pulsatile pattern of hypothalamic GnRH secretion. This is marked by nocturnal bursts of LH secretion. As puberty progresses, feedback sensitivity of the hypothalamus and pituitary to circulating steroids lessens, thus increasing the secretion of gonadotropins. The increasing concentrations of intratesticular testosterone and circulating FSH stimulate the Sertoli cell to produce factors leading to the maturation of spermatogenesis. The majority of the extratesticular end-organ events of puberty are secondary to the increased testosterone and its metabolic products (DHT and estradiol) (Table 242-1). The penis and scrotum grow and become pigmented. As spermatogenesis advances, the testes increase in size from 1 to 2 mL at the outset of puberty to 15 to 35 mL in adulthood. There is a progressive increase in facial, axillary, chest, abdominal, thigh, and pubic hair; frontal scalp hair regresses, and the voice deepens (Fig. 242-5). Genital and sexual hair development and temporal scalp hair regression require DHT. The increased levels of sex steroids result in closure of the epiphysis and achievement of adult height.

TABLE 242-1 PUBERTAL STAGES IN BOYS

STAGE	PUBIC HAIR	GENITAL
1	Absence of pubic hair	Child-like penis, testes, and scrotum (testes 2 mL)
2	Sparse, lightly pigmented hair mainly at base of penis	Scrotum enlarged with early rugation and pigmentation; testes begin to enlarge (3-5 mL)
3	Hair becomes coarse, darker, more curled, and more extensive	Penis has grown in length and diameter; testes now 8-10 mL; scrotum more rugated
4	Hair adult in quality, but distribution does not include medial aspect of thighs	Penis further enlarged, with development of glans; scrotum and testes (10-13 mL) further enlarged
5	Hair is adult and extends to thighs	Penis and scrotum fully adult; testes ≥15 mL

Modified from Marshall WA, Tanner JM. Variation in pattern of pubertal changes in boys. *Arch Dis Child.* 1970;45:13-23.

Aberrations of Timing of Puberty

Delayed puberty, more common in boys than in girls, is usually defined as a temporary form of hypothalamic hypogonadotropic hypogonadism in which sexual development has not begun by age 13.5 years. Height age (the age representative of 50% of normal children at the patient's height) is delayed with respect to chronologic age, but it is concordant with bone age. Once initiated, puberty is completed within 4.5 years. The majority of boys with delayed development eventually attain full sexual adulthood. There is often a family history of a parent or sibling being a "late bloomer." The *GPR54* gene encodes a kisspeptin-responsive G protein–coupled receptor whose absence results in hypogonadotropic hypogonadism due to impaired secretion of GnRH. Careful documentation of changing physical findings and measurement of serum LH, FSH, and testosterone concentrations may provide valuable clues to the beginning of puberty. An increase in testicular size to more than 3 mL usually heralds other signs of pubertal onset. Inquiring and testing for hyposmia or anosmia and other midline defects may indicate a common variant of congenital hypogonadotropic hypogonadism (Kallmann's syndrome). The decision to institute early treatment depends on the perceived degree of psychological stress associated with the maturational delay. The major concern is early fusion of the epiphyses induced by treatment with

testosterone, which compromises optimal height; however, with proper dosing and monitoring of bone age, this is unusual. In adolescent boys with delayed puberty and low levels of gonadotropins, periodic withdrawal of treatment is used to determine whether spontaneous puberty has occurred. Many adult men diagnosed with and treated for hypogonadotropic hypogonadism achieve normal reproductive function when they discontinue therapy.

Precocious puberty in boys is defined as the onset of pubertal (genital and secondary sexual) development before 9 years of age. Sexual precocity can be subcategorized as true (complete and incomplete) isosexual precocious puberty and pseudo–precocious puberty. The distinction is that true precocious puberty is associated with increases in GnRH-stimulated LH and FSH secretion (hypothalamic-pituitary origin), whereas pseudo–precocious puberty is independent of GnRH stimulation of LH and FSH secretion. True precocious puberty in boys is often associated with CNS disease (two thirds of boys), including hypothalamic tumors, cysts, inflammatory conditions, and seizure disorders. Diagnostic findings include sexual precocity, inappropriately elevated serum LH levels, and associated elevations of testosterone. Magnetic resonance imaging (MRI) can localize most lesions. Another cause of central precocious puberty is human chorionic gonadotropin secretory germinomas (testicular, hepatic, hypothalamic, or pineal tumors). Pseudo–precocious puberty is characterized by increased testosterone with suppressed LH. Causes of pseudo–precocious puberty include congenital virilizing adrenal hyperplasia, testicular testosterone-secreting neoplasms, and constitutively active LH receptor mutations, resulting in uncontrolled testosterone secretion (testotoxicosis). Treatment of true precocious puberty is removal or correction (with surgery or radiation therapy) of the CNS lesion, if possible, and treatment with GnRH analogues to completely suppress LH and FSH secretion. Treatment of pseudo–precocious puberty depends on the cause but includes glucocorticoids for congenital virilizing adrenal hyperplasia and ketoconazole (to suppress steroidogenesis), with or without antiandrogens (e.g., spironolactone, flutamide).

Male Senescence: Decreased Testosterone and Other Anabolic Hormones

Testosterone Deficiency in the Elderly

Blood concentrations of testosterone, other anabolic hormones (e.g., growth hormone), and prehormones (e.g., DHEA, DHEA-S) are significantly lower in older men than in young adult men. There is a gradual decline in the serum testosterone concentration beginning in young adulthood. Both total and bioavailable or free serum testosterone levels progressively decrease with aging (Fig. 242-6). The percentage decline in serum testosterone has been estimated at between 0.8 and 1.6% per year. Many men with low serum testosterone do not have the typical symptoms of hypogonadism seen in younger androgen-deficient men. Serum SHBG levels also rise with age in men, resulting in a higher percentage of circulating testosterone that is tightly bound and less bioavailable. Between 40 and 80% of men older than 70 years have blood levels of bioavailable or free testosterone below the normal range for young adults (Fig. 242-7). Many older men with serum testosterone below the young adult reference range do not complain of symptoms attributable to low testosterone.

The effects of low testosterone levels in aging men are similar to those observed in younger hypogonadal men. These include decreases in muscle mass, muscle strength, bone mass, libido, and erectile function and impaired mood and sense of well-being. Older men have increased body fat, particularly visceral fat. The benefits of testosterone treatment for symptomatic older men with low serum testosterone levels remain controversial because large-scale randomized, controlled international trials have not been performed. Beneficial effects of testosterone replacement have been demonstrated in elderly men with relatively low serum testosterone levels. Testosterone replacement therapy (up to 3 years) decreases fat mass, increases lean body mass, improves strength, and increases bone mineral density.[1–4] In larger, more recent studies of elderly men with borderline low serum testosterone levels, treatment with testosterone did not change functional status in symptomatic individuals in one study,[5] but it improved muscle strength and physical function in another study in frail elderly men.[6] Because erectile dysfunction in the older man is multifactorial (see later), with impaired vasodilatory function in the penis predominating in many cases, testosterone replacement therapy in older men may enhance libido but often does not improve erectile dysfunction. At present, testosterone treatment is not recommended for men known to have or suspected of having prostate cancer, severe and uncorrected sleep apnea, and high red blood cell mass.

A digital rectal examination should be performed, prostate-specific antigen level determined, and symptoms of severe urinary tract obstruction evaluated to ensure that there are no findings suggestive of severe benign prostatic hypertrophy or prostate cancer (nodules, irregularities).

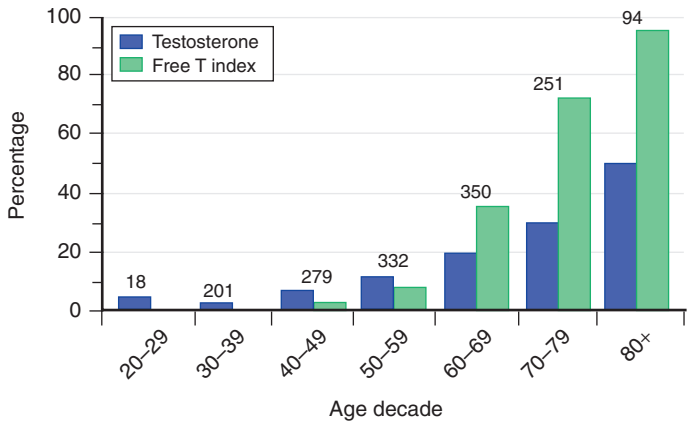

FIGURE 242-7. Hypogonadism in aging men. Bar height indicates the percentage of men in each 10-year interval, from the third to the ninth decades, with at least one testosterone value in the hypogonadal range. The criteria used for these determinations are total testosterone less than 11.3 nmol/L (325 ng/dL) and testosterone and sex hormone–binding globulin (free T index) less than 0.153 nmol/nmol. The numbers above each pair of bars indicate the number of men studied in the corresponding decade. The fraction of men who are hypogonadal increases progressively after age 50 years by either criterion. More men are hypogonadal by free T index than by total testosterone after 50 years, and there seems to be a progressively greater difference, with increasing age, between the two criteria.

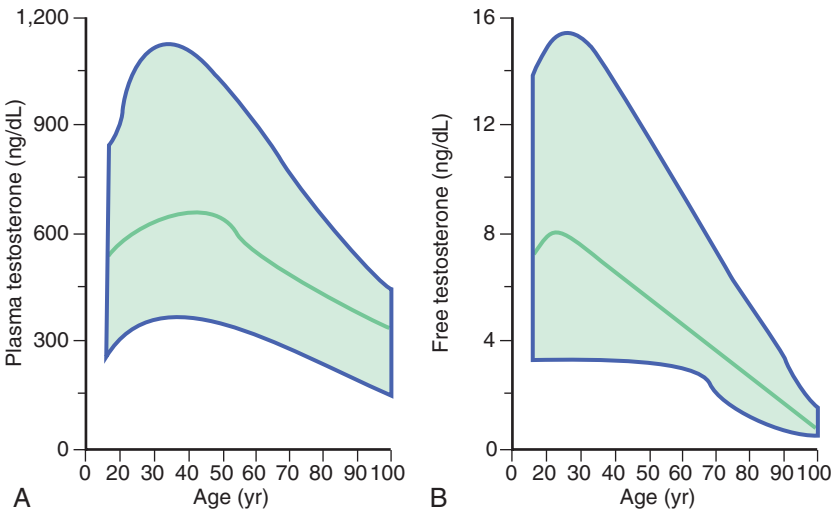

FIGURE 242-6. Relationship between plasma testosterone (**A**) and free testosterone (**B**) levels and age in normal males. (From Baker HWG, Berger HG, DeKretser DM, et al. Changes in the pituitary-testicular system with age. *Clin Endocrinol*. 1996; 5:349-372.)

Deficiency of Adrenal Androgen in Older Men

In recent years, a marked decline in the circulating levels of adrenal androgens, especially DHEA and DHEA-S, has been recognized in elderly men and women (Chapter 242). Serum levels of DHEA and DHEA-S peak at about the third decade of life and then decline at about 2% per year, resulting in levels 10 to 20% of baseline by 80 years of age. DHEA is a precursor to androgens such as testosterone and DHT. Studies have shown that the oral administration of 50 mg of DHEA to older men raises serum DHEA and DHEA-S concentrations to the levels found in young men without changing serum levels of testosterone, with no beneficial effects on quality of life, sexual function, mood, body composition, or exercise capacity.[1,2] In the United States, DHEA is available without prescription as a health supplement and is widely used, making large-scale multicenter, prospective, placebo-controlled trials difficult to perform.

MALE HYPOGONADISM

DEFINITION

Hypogonadism refers to low circulating levels of testosterone. Most androgen-deficient men are infertile. Primary hypogonadism indicates that the abnormality originates in the testis; secondary hypogonadism indicates a defect at the hypothalamus or pituitary, resulting in decreased gonadotropins (LH, FSH, or both). Combined primary and secondary hypogonadism occurs in aging and in a number of systemic diseases, such as alcoholism, liver disease, diabetes mellitus, human immunodeficiency virus (HIV) infection, hemochromatosis, and sickle cell disease. Obesity leads to low total and free testosterone levels. Greater decreases are seen in the total testosterone level because obesity not only decreases testosterone secretion but also lowers SHBG levels. Decreased androgen action with normal or elevated testosterone levels, mimicking androgen deficiency, may occur in patients with androgen receptor defects (androgen resistance), postreceptor signaling abnormalities, and inability to convert testosterone to the active metabolite DHT (5α-reductase abnormalities).

Many of the causes of primary and secondary hypogonadism are listed in Tables 242-2 and 242-3 (see also Chapter 241).

TABLE 242-2 CAUSES OF PRIMARY TESTICULAR FAILURE AND END-ORGAN RESISTANCE

Congenital disorders
Chromosome disorders
Klinefelter's and related syndromes (e.g., XXY, XXY/XY, XYY, XX males)
Testosterone biosynthetic enzyme defects
Myotonic dystrophy
Developmental disorders
Prenatal diethylstilbestrol syndrome
Cryptorchidism
Acquired defects
Orchitis
Mumps and other viruses
Granulomatous disease (e.g., tuberculosis, leprosy)
Human immunodeficiency virus infection
Infiltrative disease (e.g., hemochromatosis, amyloidosis)
Surgical, traumatic injuries, torsion of testis
Irradiation
Toxins (e.g., alcohol, fungicides, insecticides, heavy metals, cottonseed oil, DDT, other environmental "endocrine disruptors")
Drugs
Cytotoxic agents
Inhibitors of testosterone synthesis and antiandrogens (e.g., ketoconazole, cimetidine, flutamide, cyproterone, spironolactone)
Ethanol, opioids, other recreational drugs
Autoimmune testicular failure
Isolated
Associated with other organ-specific disorders (e.g., Addison's disease, Hashimoto's thyroiditis, insulin-dependent diabetes)
Systemic diseases (e.g., cirrhosis, chronic renal failure, sickle cell disease, acquired immunodeficiency syndrome, amyloidosis)
Aging*
Androgen resistance syndromes
5α-Reductase deficiency

*Aging produces a mixed pattern of testicular and hypothalamic-pituitary dysfunction.

CLINICAL MANIFESTATIONS

History

The medical history should focus on testicular descent, pubertal development, shaving frequency, changes in body hair, and present and past systemic illnesses. A complete sexual history includes changes in libido, erectile and ejaculatory functions, frequency of masturbation, coital activity, and fertility (including that of present and previous partners). Information should be obtained on previous orchitis, sinopulmonary complaints, sexually transmitted diseases, HIV status, genitourinary infections, and previous surgical procedures that might affect the reproductive tract (e.g., vasectomy, hernia repair, prostatectomy, varicocele ligation). Social history includes tobacco and alcohol intake. Medication and drug history includes recreational drugs; opioids; anabolic steroids; psychiatric, antihypertensive, antiandrogenic, cytotoxic, and alternative medicine therapies; environmental toxins; and exposure to heat (including saunas and Jacuzzis) and irradiation.

Physical Examination

The general physical examination is supplemented by height and span measurements; assessment of muscle mass and adiposity; characterization of facial, pubic, and body hair distribution; presence of acne and facial wrinkling; breast examination for gynecomastia; measurement of penile length and urethral integrity; digital rectal prostate examination; and visual field assessment. The scrotal examination should include an assessment of midline fusion (e.g., bifid scrotum, hypospadias); testicular size and consistency; presence of intratesticular masses; abnormalities of the epididymis; bilateral presence of vas deferens; and presence of varicoceles, hydroceles, or hernias. Normal testicular size ranges from 3.6 to 5.5 cm in length, 2.1 to 3.2 cm in width, and 15 to 35 mL in volume in white and black men. Asian men have a slightly smaller mean testicular size. A decrease in testicular volume usually implies decreased spermatogenic cells because the seminiferous tubules account for more than 80% of testicular volume.

Laboratory Studies

Because there is a strong diurnal rhythm in testosterone secretion in young men (highest in the morning), testosterone, LH, and FSH are routinely determined from morning blood samples. There is a broad range of reference values due in part to measurement variability. Most laboratories used immunoassay methods to measure serum testosterone, which may lack precision at low serum testosterone levels. Recent studies suggest that methods using

TABLE 242-3 CAUSES OF HYPOGONADOTROPIC HYPOGONADISM

IDIOPATHIC OR CONGENITAL
Isolated deficiency of gonadotropin-releasing hormone
With anosmia (Kallmann's syndrome)
With other abnormalities (Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, basal encephalocele)
Partial deficiency of gonadotropin-releasing hormone (fertile eunuch syndrome)
Multiple hypothalamic and pituitary hormone deficiency
Pituitary hypoplasia or aplasia
ACQUIRED
Trauma, post surgery, post irradiation
Neoplastic
Pituitary adenoma (prolactinoma, other functional and nonfunctional tumors)
Craniopharyngioma, germinoma, glioma, leukemia, lymphoma
Pituitary infarction, carotid aneurysm
Infiltrative and infectious diseases of hypothalamus and pituitary (sarcoidosis, tuberculosis, coccidioidomycosis, histoplasmosis, syphilis, abscess, histiocytosis X, hemochromatosis)
Autoimmune hypophysitis
Aging*
Obesity
Malnutrition and systemic disease
Anorexia nervosa, starvation, renal failure, liver failure
Exogenous hormones and drugs
Antiandrogens, estrogens and antiestrogens, progestogens, glucocorticoids, cimetidine, spironolactone, digoxin, drug-induced hyperprolactinemia (metoclopramide, tranquilizers, antihypertensives)

*Aging produces a mixed pattern of central and testicular dysfunction.

liquid or gas chromatography and mass spectrometry may give more accurate results even at low serum testosterone levels. Elevated LH and FSH levels distinguish primary from secondary hypogonadism (both have low serum testosterone levels), but many older men with low serum testosterone levels have normal LH concentrations. Serum prolactin levels should be measured in all cases of hypogonadotropic hypogonadism, pituitary mass lesions, and galactorrhea. DHT is measured in cases of abnormal differentiation of the genitalia and when DHT deficiency is suspected. Serum estradiol should be measured in cases of gynecomastia. Assessment of other testosterone precursors and products may be required in special circumstances, including suspected congenital enzyme defects. The semen analysis is the "cornerstone" of the laboratory examination for male infertility.

Hypogonadism and Androgen Resistance

PRIMARY TESTICULAR HYPOGONADISM

Primary hypogonadism refers to a condition of androgen deficiency with or without infertility in which the pathologic process lies at the testis level. A list of common causes is given in Table 242-2. Congenital defects are described in Chapter 241.

PATHOBIOLOGY

Acquired Defects

Mumps, Orchitis, Leprosy, HIV Infection, and Hemochromatosis

After puberty, mumps (Chapter 377) is associated with clinical orchitis in 25% of cases, and 60% of those affected become infertile. During acute orchitis, the testes are inflamed, painful, and swollen. This is followed by a gradual decrease in size. The testes may return to normal size and function, or they may atrophy. Spermatogenic defects occur more often and earlier than Leydig cell dysfunction. Thus, patients with postorchitic infertility may have normal testosterone and LH levels with increased serum FSH levels. Over time, elevations in LH and lower serum testosterone levels may appear. Leprosy (Chapter 334) may also cause orchitis and gonadal insufficiency. HIV infection is often associated with hypogonadism, which can be either hypogonadotropic or hypergonadotropic. Hemochromatosis (Chapter 219) may affect the hypothalamus-pituitary as well as act directly on the testis.

Trauma

The exposed position of the testes in the scrotum makes them particularly susceptible to injury. Surgical injury during scrotal surgery for hernia, varicocele, and vasectomy can result in permanent testicular damage.

Irradiation

Accidental exposure of the testes to irradiation for the treatment of an associated malignant disease produces testicular damage.

Drugs and Toxins

Chemotherapy, in particular alkylating agents such as busulfan, frequently leads to irreversible germ cell damage. Heavy metals (lead, cadmium) and cottonseed oil (gossypol) cause damage to the germ cells. Leydig cells are relatively less susceptible to most chemotherapeutic drugs than are Sertoli and germ cells. Some medications may interfere with testosterone biosynthesis (e.g., ketoconazole, spironolactone) or action (e.g., cyproterone, flutamide). Ethanol, independent of its role in causing liver disease, inhibits testosterone biosynthesis. Marijuana, heroin, methadone, medroxyprogesterone acetate, other progestins, and estrogens lower testosterone, mainly by decreasing LH. Medical treatment with androgens such as testosterone, DHT, and synthetic anabolic steroids or their illicit use (e.g., in athletes, bodybuilders) lowers serum LH and FSH and sperm counts. Serum testosterone levels are low after the use of DHT and synthetic anabolic agents. Environmental toxins such as fungicides and insecticides (e.g., DBCP, metabolites of DDT, vinclozolin) and byproducts of the plastics industry (e.g., phthalates, bisphenol A) are called "endocrine disruptors" because these chemicals may have either weak estrogenic or antiandrogenic effects and have been shown to cause testicular dysgenesis in male offspring when administered in large doses to pregnant female rodents.

Autoimmune Testicular Failure

Antibodies against the microsomal fraction of the Leydig cells may occur either as an isolated disorder or as part of a multiglandular disorder (Chapter 239) involving, to variable degrees, the thyroid, pituitary, adrenals, pancreas, and other organs.

Hypogonadism Associated with Systemic Diseases

Abnormalities of the hypothalamic-pituitary-testicular axis occur in a number of systemic diseases, including liver failure, renal failure, severe malnutrition, sickle cell anemia, advanced malignant disease, severe obesity, diabetes, cystic fibrosis, and amyloidosis, as well as in those on chronic hemodialysis. The effects of cirrhosis of the liver on testicular function are complex and may be either independent of or associated with the direct toxic effects of the continued use of alcohol. Gynecomastia, testicular atrophy, and impotence are concomitant signs of cirrhosis. Decreased spermatogenesis with peritubular fibrosis occurs in 50% of cases. Estradiol levels are usually elevated. This results in an increased ratio of serum estradiol to testosterone, often associated with gynecomastia. Boys with sickle cell anemia may have impaired sexual maturation, and men are often infertile. Diabetes and obesity are two major factors in hypogonadism. Emerging data show that type 2 diabetes is associated with low blood testosterone levels mainly due to hypothalamic-pituitary dysfunction; the decrease in serum testosterone correlates with the degree of hyperglycemia.

SECONDARY GONADAL INSUFFICIENCY (HYPOGONADOTROPIC HYPOGONADISM)

Hypogonadotropic hypogonadism represents a deficiency in the secretion of gonadotropins (LH and FSH) due to an intrinsic or functional abnormality in the hypothalamus or pituitary glands (see earlier and Chapter 241). Such disorders result in secondary Leydig cell dysfunction (see Table 242-3). The clinical manifestations depend on the age of the patient at the onset of the disorder.

Acquired Hypogonadotropic Disorders and Functional Disorders

Anorexia Nervosa and Weight Loss

Anorexia nervosa (Chapter 226) and weight loss are examples of functional defects resulting in low serum testosterone levels. Men and women with anorexia nervosa present with manifestations of hypogonadotropic hypogonadism. Starvation may also reduce gonadotropic secretion. Strenuous exercise has minimal effects on testicular function in men.

Stress and Illness

Severe stress (e.g., surgery, trauma) and systemic illness also lower gonadotropin and testosterone levels. Organic hypothalamic-pituitary disorders include neoplastic, granulomatous, infiltrative, and post-traumatic lesions in the region of the hypothalamus and pituitary.

Pituitary Tumors

Prolactinomas present differently in men and women (Chapter 231). In men these tumors are usually large (>1 cm in diameter; macroadenomas) by the time they are detected. Male patients with prolactin-secreting macroadenomas usually present with hypogonadism, erectile dysfunction, and visual manifestations from suprasellar extension. In small tumors, hypogonadotropic hypogonadism may be due to suppressive effects on GnRH described earlier, but in large tumors, it may also be due to a mass effect damaging the non-neoplastic gonadotrophs.

Large non-prolactin-secreting pituitary tumors (growth hormone, adrenocorticotropic hormone, glycopeptide, and null cell) may also produce gonadotropin insufficiency from damage to the adjacent normal pituitary gland (Chapter 231), resulting in decreased serum LH and testosterone levels.

ANDROGEN RESISTANCE (ANDROGEN-SENSITIVE END-ORGAN DEFICIENCY)

Certain conditions have clinical phenotypes mimicking testosterone deficiency in the absence of lowered testosterone levels. These are either drug-induced (antiandrogens) or congenital defects in the androgen receptor, postreceptor defects, or 5α-reductase deficiency (Chapter 241).

DIAGNOSIS

The diagnosis is based on clinical symptoms and signs and a reduced serum testosterone level. The normal range of serum total testosterone in a young adult male population varies for different laboratories but should be in the general range of 300 to 1000 ng/dL (10 to 38 nmol/L). Accurate measurements of testosterone in the severely hypogonadal range are best done by gas

or liquid chromatography followed by tandem mass spectrometry. Total testosterone measurements may be misleading indicators of Leydig cell status in conditions in which SHBG levels are abnormal (see earlier section). In these circumstances, a measurement of free testosterone (by an equilibrium dialysis method), bioavailable testosterone (consisting of free plus albumin bound), or calculated free testosterone (by total testosterone and SHBG measurements) may be useful.

The following rules apply to most young and middle-aged men thought to have hypogonadism. If a morning serum total testosterone level is repeatedly below 250 ng/dL (8.5 nmol/L), the patient is probably hypogonadal, and testosterone replacement is indicated. If the serum testosterone level is between 250 and 300 ng/dL with normal serum LH levels, the patient may not be hypogonadal, and androgen replacement may not improve the symptoms (e.g., sexual dysfunction). Thus, when serum total testosterone is borderline and LH is not increased, one of the measurements of bioactive testosterone is indicated. The guidelines for men older than 60 years are less certain. Because SHBG levels are increased, total testosterone levels may overestimate the biologically active forms. A serum total testosterone level above 400 ng/dL argues strongly against hypogonadism, a serum level below 250 ng/dL is almost always clinically significant, and total testosterone concentrations between 250 and 400 ng/dL deserve further testing with one of the tests of bioactive testosterone.

TREATMENT

Rx

The main medical indication for androgen replacement therapy is male hypogonadism (Table 242-4). In about 10% of men with idiopathic hypogonadism reversed by testosterone therapy, the reversal is sustained after therapy is stopped. This suggests that some patients with low serum testosterone may have a transient cause of the defect. Administration of testosterone to elderly men with low-normal testosterone concentrations increases lean body mass and decreases fat mass but may not improve functional status or cognition.[1-4] Carefully designed studies of the efficacy of testosterone treatment in older men are ongoing.

Absolute contraindications to androgen replacement therapy include carcinoma of the prostate and the male breast. Androgens should be used with caution in older men with enlarged prostates and urinary symptoms, elevated hematocrits, and sleep-related breathing disorders.

Testosterone esters, such as testosterone enanthate (or cypionate) injections, are widely used in the United States and throughout the world (Table 242-5). The recommended dose is 150 to 200 mg administered intramuscularly once every 2 to 3 weeks. Testosterone undecenoate injections administered every 10 to 12 weeks are available in many parts of the world but not yet in the United States.

Modified 17α-alkylated androgens (methyltestosterone and many anabolic steroids), which are available in oral preparations, are not recommended as androgen replacement. These agents may lead to abnormalities in liver function, marked decreases in high-density lipoprotein cholesterol, and increases in total cholesterol levels compared with the testosterone esters. Transbuccal delivery of testosterone by mucoadhesive tablets (30 mg applied twice daily) results in physiologic-range testosterone levels through direct absorption into the systemic circulation, thus avoiding first-pass effects on the liver.

Implants consist of pellets of crystalline testosterone. Serum testosterone levels are maintained in the physiologic range for 4 to 6 months. Implants are not very popular in the United States but are widely used in Australia and the United Kingdom.

Transdermal testosterone delivery through skin patches and hydroalcoholic gels is available. The nonscrotal patches deliver 5 mg/day of testosterone, which is the physiologic production rate. These patches deliver levels of testosterone within the normal range but have a high incidence of skin irritability (redness, swelling, and blisters). Hydroalcoholic testosterone gels have been developed for transdermal application and have become the most widely used testosterone formulations in the United States. The usual dosage is 5 to 10 g of 1% testosterone gel applied daily. This results in a reasonably constant serum concentration and causes little skin irritation. Transfer from the user to others is possible during routine use and may be a concern if there is close skin contact with women and children. Protective clothing or a shower is necessary to avoid transferring testosterone through skin-to-skin contact.

Table 242-6 shows the benefits and potential side effects of androgen treatment. In hypogonadal men, androgen replacement leads to the development and maintenance of secondary sexual characteristics. Testosterone has important anabolic effects on muscle and bone and improves libido and sexual dysfunction. It has less effect on erectile dysfunction. It has no major short-term effects on prostate tissue[5] but appears to increase the risk of cardiovascular events, at least in elderly men.[6]

TABLE 242-4 INDICATIONS FOR ANDROGEN THERAPY

- Androgen deficiency (hypogonadism)
- Microphallus (neonatal)
- Delayed puberty in boys
- Elderly men with low total or bioavailable or free testosterone levels
- Angioneurotic edema
- Other possible uses or under investigation
  - Hormonal male contraception
  - Wasting disease associated with cancer, human immunodeficiency virus infection, chronic infection
  - Postmenopausal women

TABLE 242-5 ANDROGEN PREPARATIONS

ROUTE	PREPARATION	DOSE AND FREQUENCY OF ADMINISTRATION
Oral*	Testosterone undecenoate (not available in United States; available in Canada, Mexico, Europe, Asia)	40-80 mg orally two or three times/day
Buccal	Transbuccal testosterone, mucoadhesive tablets (Striant)	30 mg two times/day
Injection	Testosterone enanthate and cypionate	100 mg/wk intramuscularly or 150-200 mg intramuscularly every 2-3 wk
	Testosterone undecanoate (not available in United States)	750-1000 mg intramuscularly every 10-12 wk
Implant	Testosterone implants	75-mg pellets (in United States), 6-10 inserted once every 4-6 mo
Transdermal	Scrotal patch	One patch delivering 4 or 6 mg testosterone per day
	Nonscrotal patch, Androderm	Two patches, each delivering 2.5 mg testosterone per day; or one patch delivering 5 mg testosterone per day
	Testoderm TTS	One patch delivering 5 mg testosterone per day
Transdermal hydroalcoholic gel	AndroGel or Testogel; Testim	5-10 g containing 50-100 mg testosterone applied once daily

*Oral modified 17α-alkylated androgens such as methyltestosterone, fluoxymesterone, oxymetholone, stanozolol, and oxandrolone are not recommended for the treatment of androgen-deficient states because of potential hepatotoxicity and adverse effects on serum lipids.

TABLE 242-6 ANDROGEN THERAPY: RISKS VERSUS BENEFITS

BENEFITS	RISKS
Development or maintenance of secondary sex characteristics	Fluid retention
Improved libido and sexual function	Gynecomastia
Increased muscle mass and strength	Acne, oily skin
Increased bone mineral density	Increased hematocrit
Decreased body and visceral fat	Decreased high-density lipoprotein cholesterol (oral 17α-alkylated agents produce the greatest effect)
Improved mood	Sleep apnea
Effect on cognition (?)	Aggressive behavior (?)
Effect on vitality and quality of life (?)	Prostate disease
	Benign prostatic hyperplasia (?)
	Carcinoma of prostate (aggravate existing cancer)

MALE INFERTILITY

DEFINITION

Infertility is defined as the failure of a couple to achieve pregnancy after at least 1 year of frequent unprotected intercourse. If a pregnancy has not occurred after 3 years, infertility will most likely persist without medical treatment.

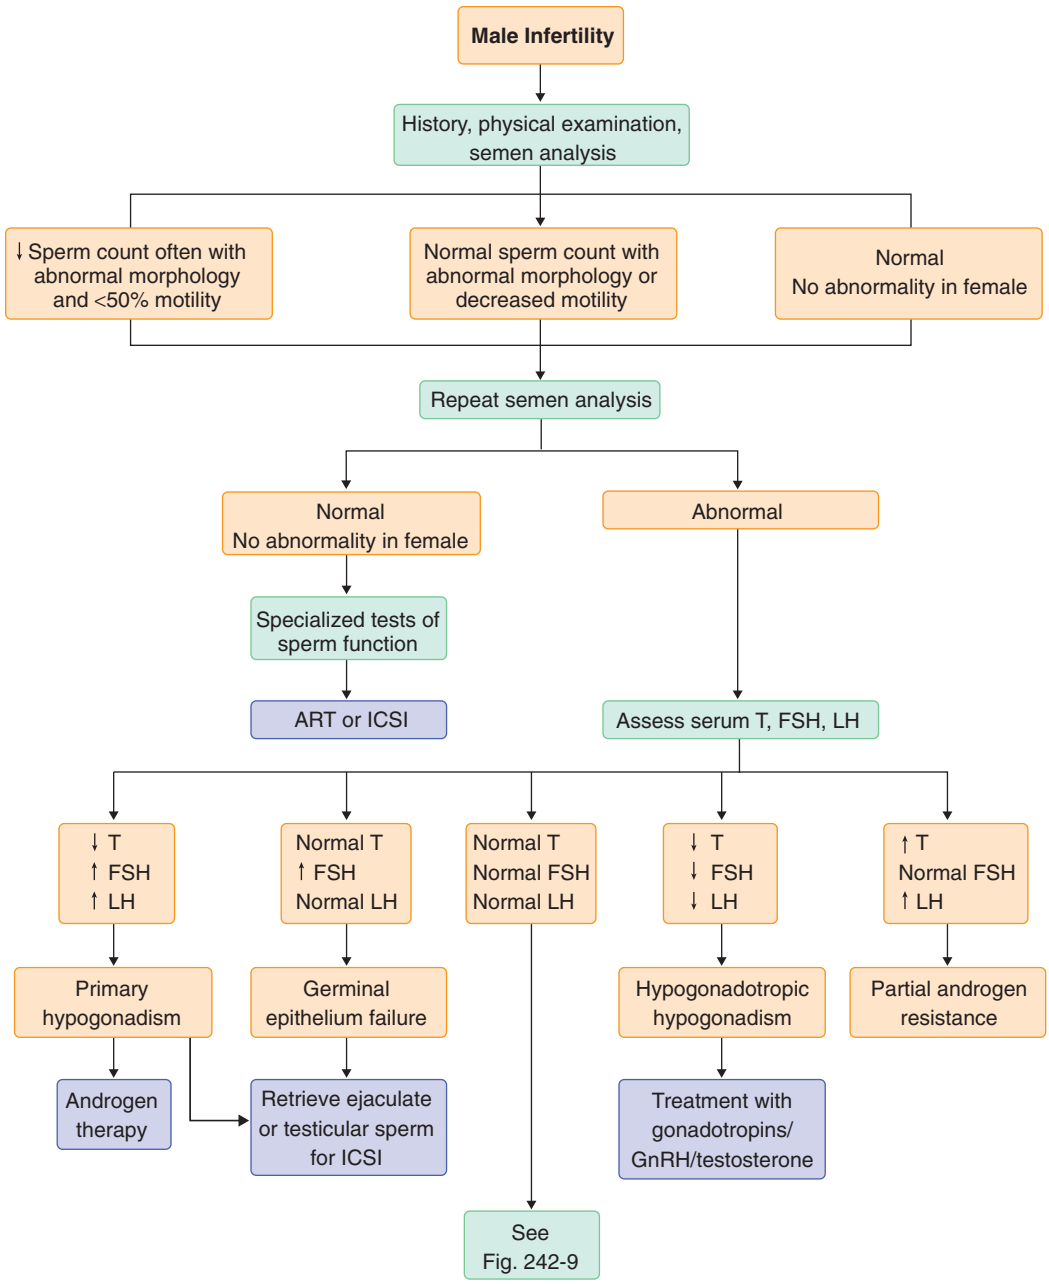

FIGURE 242-8. Algorithmic approach to the diagnosis and treatment of male infertility. ART = assisted reproductive technology; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; ICSI = intracytoplasmic sperm injection; LH = serum luteinizing hormone; T = serum testosterone.

EPIDEMIOLOGY

Studies in the United States and Europe showed a 1-year prevalence of infertility in 15% of couples. The prevalence in developing countries is likely to be higher because of the higher prevalence of genital tract infection. Thirty percent to 35% of subfertility can be attributed to predominantly female factors, 25 to 30% to male factors, and 25 to 30% to problems in both partners.

PATHOBIOLOGY

Hypothalamic-pituitary disorders are infrequent causes of male infertility and are discussed in the section on hypogonadism and androgen deficiency. Testicular disorders are the most frequent identifiable cause of infertility (see Table 242-2). Y chromosome microdeletions are increasingly recognized as a genetic cause of azoospermia and severe oligozoospermia. Up to 20% of infertile men have microdeletions in the long arm of the Y chromosome, many of which map to the Yq11 region of the chromosome, which is called the azoospermic factor (AZF).

DIAGNOSIS

The approach to the diagnosis of an infertile couple includes management of both the male and the female partner (Figs. 242-8 and 242-9).

Examination of the ejaculate is the cornerstone for the investigation of an infertile man (Table 242-7). Semen samples are collected at the physician's office or at home, preferably after 2 to 7 days of abstinence from sexual intercourse. The generally accepted reference values for a semen analysis are given in Table 242-8. A normal sperm concentration is greater than 15 million/mL, with a total sperm number greater than 39 million per ejaculate; however, men with lower sperm counts can be fertile. More than 40% of the spermatozoa should be motile, and more than 32% should demonstrate a progressive motility pattern. Using a strict criterion to assess sperm morphology, the percentage of morphologically normal forms should be above 4%. There is considerable overlap in the semen quality of fertile and subfertile men. There is no definite threshold below which a man is infertile, except when azoospermia is present.

In patients with abnormal semen analyses, measurements of serum FSH, LH, and testosterone are indicated (see Fig. 242-7). Elevated FSH levels usually indicate severe germinal epithelium damage. A decreased serum inhibin β level also reflects poor Sertoli cell function and may indicate spermatogenic dysfunction. Elevated serum LH and FSH concentrations together with a low serum testosterone level indicate pantesticular failure. Low serum FSH, LH, and testosterone concentrations suggest hypothalamic-pituitary dysfunction; serum prolactin should be measured, and additional investigations may be required. A low sperm concentration and suppressed

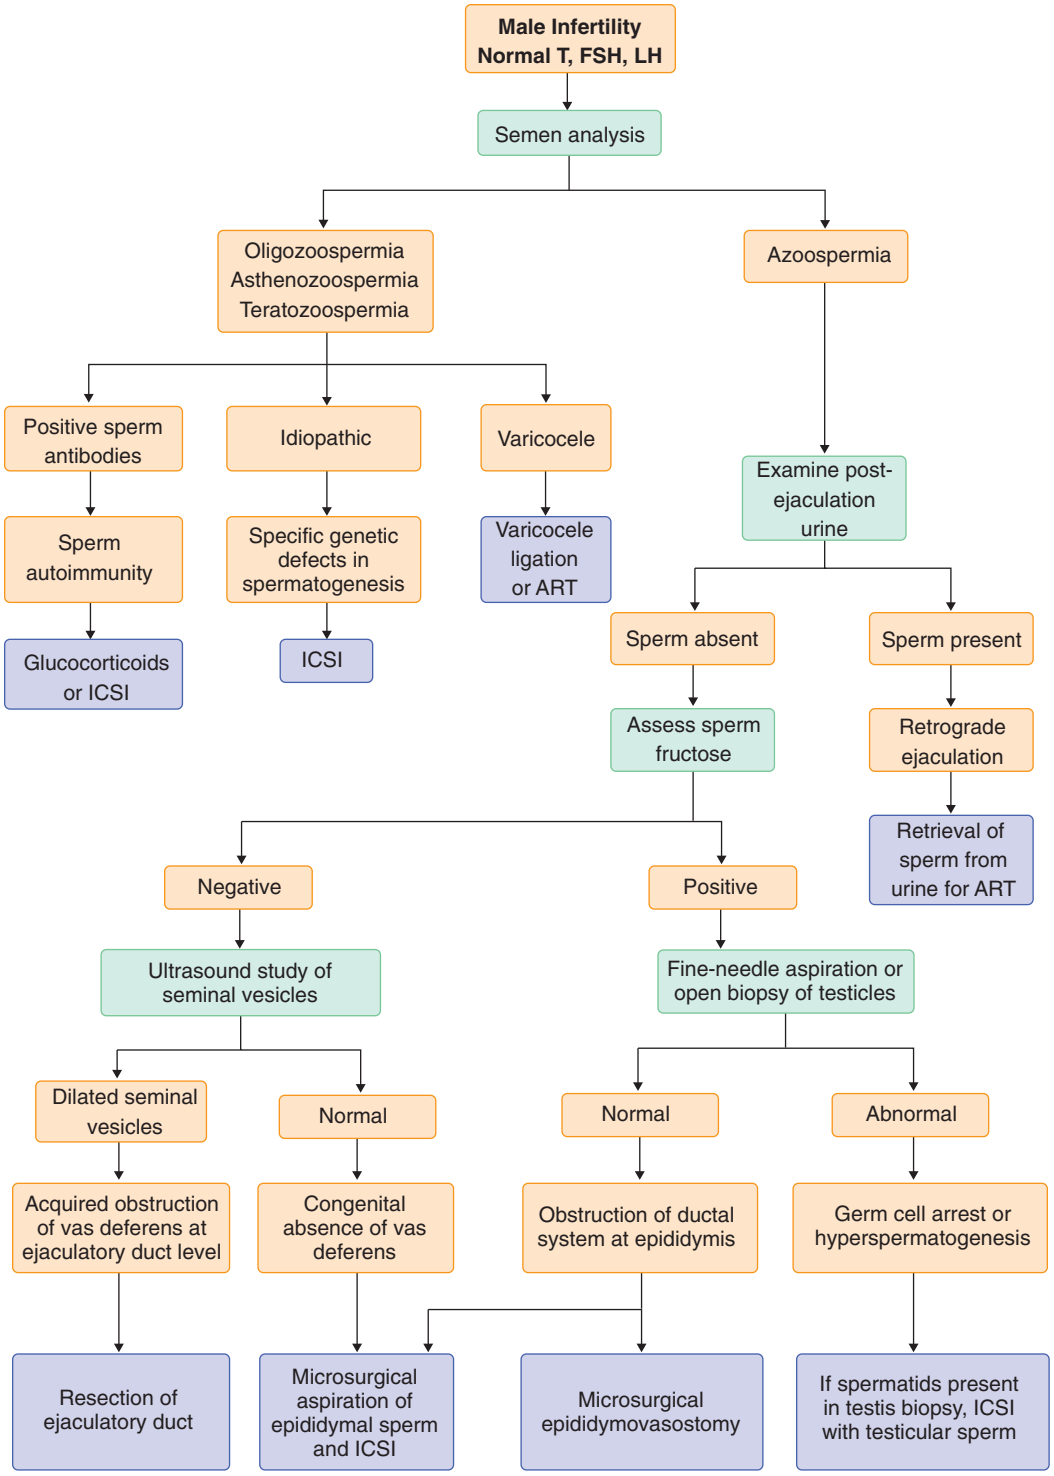

FIGURE 242-9. Algorithmic approach to the diagnosis and treatment of male infertility in patients with normal serum hormone concentrations. ART = assisted reproductive technology; FSH = follicle-stimulating hormone; ICSI = intracytoplasmic sperm injection; LH = serum luteinizing hormone; T = serum testosterone.

TABLE 242-7 MALE INFERTILITY: BASIC LABORATORY TESTS

SEMEN ANALYSES	HORMONE ANALYSES (IN PATIENTS WITH ABNORMAL SEMEN ANALYSES)
Volume, pH	Serum luteinizing hormone and follicle-stimulating hormone
Microscopy: agglutination, debris	Serum testosterone
Sperm: concentration, motility, morphology, vitality	If luteinizing hormone and testosterone levels are low, serum prolactin
Leukocytes	
Immature germ cells	
Sperm autoantibodies (sperm and semen biochemistry, sperm function tests)	

TABLE 242-8 SEMEN ANALYSIS: REFERENCE RANGE FROM FERTILE MEN*

PARAMETER	REFERENCE RANGE
Semen volume	>1.5 mL
Sperm	
Concentration	>15 million/mL
Total count	>39 million/ejaculate
Motility	>40% motile
	>32% progressively motile
Morphology	>4% normal†
Vitality (live)	>58%
Leukocytes	<1 million/mL

*Men whose partners had a time-to-pregnancy of ≤12 months were chosen to provide reference distributions for semen parameters.
†This value is based on the strict criteria for assessing sperm morphology in studies using in vitro fertilization as an end point. This value will likely be adjusted to a lower level based on recent studies in fertile men.

LH level with an increased, normal, or low serum testosterone level (without clinical manifestations of androgen deficiency) may suggest exogenous androgen use. The hormonal pattern in androgen insensitivity (an uncommon cause of male infertility) is elevated LH, normal FSH, and high-normal to increased serum testosterone levels. Normal hormonal parameters in azoospermic (no sperm in the ejaculate) men with normal-sized testes may suggest congenital or acquired obstruction in the epididymis or vas deferens.

TREATMENT Rx

An algorithmic approach to the treatment of male infertility is illustrated in Figures 242-8 and 242-9. The principles of managing male infertility can be summarized as follows: (1) Men with mild to moderate oligozoospermia, with or without decreased sperm motility and some impairment of motility, are subfertile rather than infertile. Spontaneous pregnancies can occur in this group. (2) Reliable medical treatment is limited to the 1 to 2% of infertile men with gonadotropin insufficiency. (3) Assisted reproductive technologies, including in vitro fertilization and intracytoplasmic sperm injection, have dramatically improved pregnancy rates. (4) Azoospermia (absence of sperm in the ejaculate) may occur in men with obstruction of the ejaculatory system. In these patients, in vitro fertilization and intracytoplasmic sperm injection after either percutaneous epididymal sperm extraction or microsurgical epididymal sperm extraction are highly successful. (5) Azoospermia due to impaired spermatogenesis may not be a sterile state, because sperm may be present within the testes. These sperm can be extracted, and intracytoplasmic sperm injection can be performed with good success, even in patients with Klinefelter's syndrome.

SEXUAL DYSFUNCTION

Sexual dysfunction can be divided into four main categories: (1) loss of desire (libido), (2) erectile dysfunction, (3) ejaculatory insufficiency, and (4) anorgasmic states.

Decreased Libido

Loss of libido refers to a reduction in sexual interest, initiative, and frequency and intensity of responses to internal or external erotic stimuli. Causal factors include psychogenic factors, CNS disease, androgen deficiency and resistance, and side effects from medications (e.g., antihypertensives, psychotropics, alcohol, narcotics, dopamine blockers, antiandrogens). Treatment is directed toward the causal mechanism.

Ejaculatory Failure and Impaired Orgasm

Ejaculatory insufficiency refers to absent or reduced seminal emission or impaired ejaculatory contraction. It is usually associated with neurologic conditions and medication therapy. An anorgasmic state is a distressing but relatively uncommon condition in men in which the normal process of erection and ejaculation occurs in the absence of the subjective sensation of pleasure initiated at the time of emission and ejaculation. Premature ejaculation is the most common form of male sexual dysfunction. Estimates of prevalence vary, but 25 to 30% seems to be a reasonable estimate. The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* defines the diagnostic criteria for premature ejaculation as follows: persistent or recurrent ejaculation with minimal sexual stimulation that (1) occurs before, upon, or shortly after penetration and before the person wishes, (2) is associated with marked distress or interpersonal difficulty, and (3) is not a direct effect of substance abuse such as opiate withdrawal.

Erectile Dysfunction

Erectile dysfunction can be defined as a man's inability to obtain rigidity sufficient to permit coitus of adequate duration to satisfy himself and his partner.

Current estimates suggest that 10 to 15% of all American men suffer from erectile dysfunction, with the incidence progressively increased as men become older. Data from the Massachusetts Aging Study report that 52% of men 40 to 70 years of age experience some degree of erectile dysfunction.

The causes of erectile dysfunction are many, but they can generally be categorized as follows: psychological, endocrine, systemic illness, neurologic, iatrogenic, drug related, and aging.

TREATMENT Rx

Medical Therapy

Oral Medications

Oral and selective inhibitors of cGMP phosphodiesterase-5 (the primary phosphodiesterase in the penile cavernosal tissue) are effective for at least 50% of men. Inhibition of phosphodiesterase-5 causes persistence of normally (sexually) stimulated cGMP in the corpora cavernosa, resulting in protracted cavernosal tumescence and rigidity. Patients with diabetes mellitus, spinal cord injuries, prostatic surgery, and pelvic irradiation also benefit, but with a somewhat lower response rate. The usual starting dose of sildenafil is 50 mg, increasing in 25-mg increments up to 100 mg. The most serious side effect is cardiovascular collapse, particularly in patients taking long-acting nitrate or nitroglycerin preparations. Because of its mechanism of action, sildenafil is used on demand; it is administered 20 to 60 minutes before intercourse. Two additional phosphodiesterase-5 inhibitors (vardenafil and tadalafil) are widely used for the treatment of erectile dysfunction and appear to be equally effective. Vardenafil has a relatively longer duration of action (4 to 6 hours), and tadalafil has a much longer duration of action (17.5 hours). Hypogonadal men with erectile dysfunction and low libido may benefit from combined treatment with testosterone and phosphodiesterase-5 inhibitors.

Apomorphine is a selective dopamine receptor agonist that stimulates the CNS, generating an arousal response that includes a penile erection. Apomorphine has not been approved by the Food and Drug Administration and appears to be inferior to phosphodiesterase-5 inhibitors. Yohimbine is an indolalquinolonic alkaloid with central-acting effects, including α_2-adrenergic blockade and cholinergic and dopaminergic stimulation. Despite its widespread use, placebo-controlled studies have shown variable degrees of success, and yohimbine seems to be most useful in conditions in which there is organic disease. Trazodone, an antidepressant, possesses both serotonin and α_2-adrenergic antagonistic properties. It appears to be moderately effective in one third of patients; the main side effect is sedation.

Intracavernosal Injection

The intraurethral prostaglandin E_1 suppository alprostadil is believed to work locally on the corpora cavernosa as a vasodilatory agent. The suppository is apparently successful in improving erectile function in one third to two thirds of cases. Until the recent availability of oral phosphodiesterase-5 inhibitors, intracavernosal injection with prostaglandin E_1 and other vasodilators (papaverine, phentolamine) was the mainstay of pharmacologic therapy for erectile dysfunction. The medications are injected with a 27- to 30-gauge needle and may be useful in men who are refractory to oral agents.

243 OVARIES AND DEVELOPMENT

ROBERT W. REBAR AND GREGORY F. ERICKSON

DEFINITION

The ovaries or female gonads episodically release female gametes (oocytes or eggs) and secrete sex steroid hormones, principally androstenedione, estradiol, and progesterone. Oocytes are released only during the adult reproductive years, when sex steroid secretion is also greatest, but the ovaries are physiologically active throughout life.

Sex steroids affect the growth, differentiation, and function of a variety of tissues and organs throughout the body; therefore, abnormalities of the ovaries and of sex steroid secretion should be recognized by all physicians. A rational approach to the diagnosis and treatment of reproductive disorders in women requires an understanding of the functions of the ovaries and of their most important unit, the follicle, throughout life.

PHYSIOLOGY

Embryology

Embryogenesis and Differentiation

Organogenesis of the ovaries occurs during fetal life. Ovarian cells are derived from two different sources: (1) primordial germ cells (PGCs) originate at a site outside the prospective gonads, and (2) somatic cells differentiate from the coelomic epithelium and gonadal mesenchyme. In females, PGCs become oocytes, whereas somatic cells differentiate into a variety of cell types, including granulosa, theca, and vascular cells.

PGCs in the human embryo can be distinguished at the gastrula stage (Fig. 243-1). Shortly after formation, PGCs migrate through the dorsal mesentery to the genital ridges. Chemotaxis plays a role in directing PGCs to the gonads. During migration, PGCs proliferate in response to growth factors, most notably Kit ligand. The importance of Kit is demonstrated by the finding that loss-of-function mutations result in a paucity of PGCs, which in turn results in premature ovarian failure.

The genital ridges are characterized by a thickening of the coelomic epithelium and underlying primary mesenchyme. Initially, the gonads are sexually indifferent. Male gonadal differentiation is triggered by the Y chromosome–encoded testis-determining factor SRY. SRY expression results in the differentiation of Sertoli cells and the secretion of müllerian-inhibiting substance, which induces regression of the müllerian ducts. Testicular interstitial cells differentiate into Leydig cells, which secrete testosterone, which in turn stimulates wolffian duct development. In the female, the absence of müllerian-inhibiting substance and testosterone leads to the degeneration of the wolffian ducts and the development of the müllerian ducts. Thus, the development of the ovaries and female reproductive system is considered a "default" pathway.

When PGCs enter the genital ridges, they begin gametogenesis (see Fig. 243-1). In females, this process is termed *oogenesis* and involves the differentiation of PGCs into oogonia and oocytes. When sex-specific differentiation of the ovary commences, the inactive X chromosome in the PGCs becomes active. This denotes the formation of mitotically active oogonia. The importance of two functional X chromosomes during oogenesis is emphasized by the fact that 45,X females lack oocytes and undergo premature menopause.

After repeated mitosis, oogonia initiate meiosis and become oocytes (see Fig. 243-1). At approximately the same time, granulosa cells differentiate within the gonadal mesenchyme and establish intimate associations with oocytes. Oocytes that become surrounded by granulosa cells stop meiosis after diplotene, and the bivalents enter an interphase state known as dictyotene. If an oocyte is not surrounded by granulosa cells, meiosis continues to diakinesis, and the oocyte dies by apoptosis. Granulosa cells, therefore, are critical for oocyte survival. The majority of oocytes die during fetal ovary development (Fig. 243-2), apparently from a lack of contact with granulosa cells.

With further development, the oocyte–granulosa cell complex becomes a primordial follicle. This occurs between the sixth and ninth months of gestation (Fig. 243-3). A primordial follicle consists of a single layer of squamous granulosa cells, a small (about 15 μm in diameter) dictyotene oocyte, and a thin basal lamina (see Fig. 243-3). In the human female, all potential future eggs have entered diplotene of meiosis at the time of birth, and no reserve oogonia remain.

Anatomy

The Adult Ovary

The ovaries, which normally measure 2.5 to 5.0 cm long, 1.5 to 3.0 cm wide, and 0.6 to 1.5 cm thick in adults, are organized into two principal parts. A central zone, the medulla, is surrounded by a prominent peripheral zone, the cortex (Fig. 243-4). Growing follicles at different stages of development are

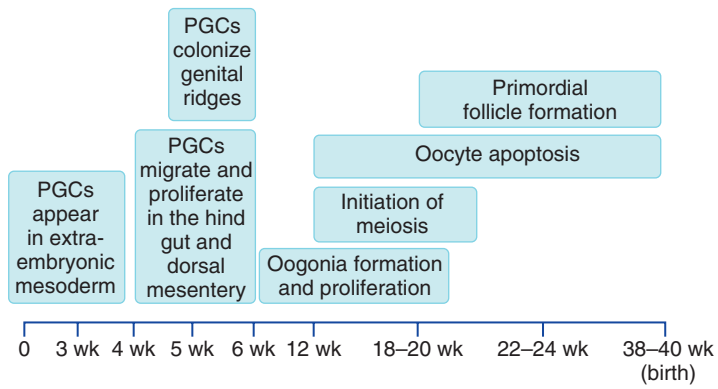

FIGURE 243-1. Diagram illustrating the developmental timetable of the major events that ultimately lead to the formation of primordial follicles during the process of human ovary organogenesis. PGC = primordial germ cell.

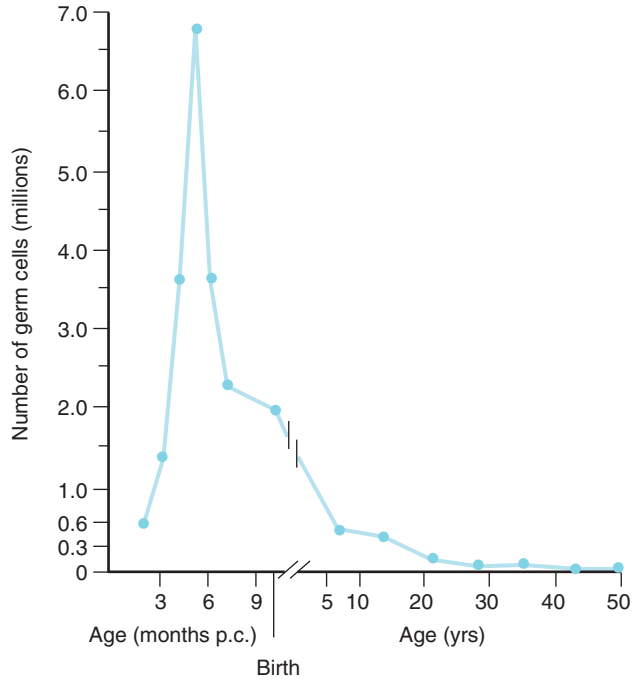

FIGURE 243-2. Changes in the total number of germ cells in the human ovaries during aging. At early to mid-gestation, the number of germ cells increases to almost 7 million; shortly thereafter, the number declines rapidly to about 2 million at birth. The number continues to decline until no oocytes are detected at 50 years of age. p.c. = post conception. (From Baker TG. Radiosensitivity of mammalian oocytes with particular reference to the human female. *Am J Obstet Gynecol*. 1971;110:746-761.)

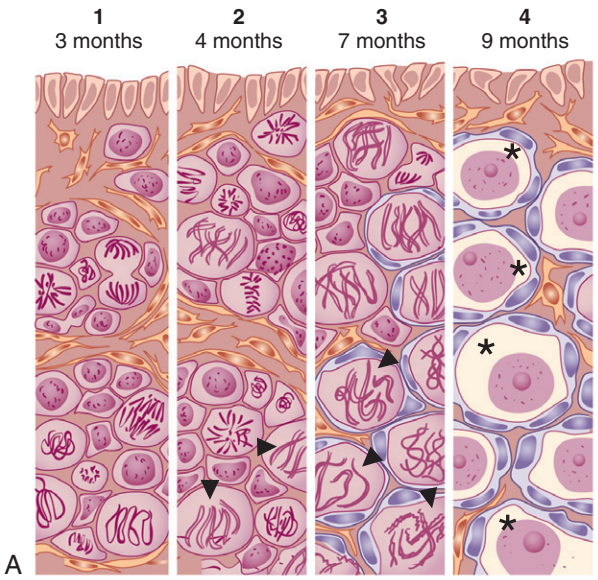

FIGURE 243-3. **A,** Drawing showing gametogenesis in the human fetal ovary leading to the formation of primordial follicles. At 3 months (1), oogonia divide mitotically. At 4 months (2), some oogonia deep within the cortical cords enter meiosis (arrowheads). At 7 months (3), the cords are no longer distinct, and all germ cells are in meiotic prophase I. At 9 months (4), some oocytes become associated with granulosa cells and appear as primordial follicles (asterisks). **B,** Electron micrograph of human primordial follicle. Granulosa cells (arrowheads), oocyte nucleus (N), and Balbiani's body (asterisk) are shown. (From Erickson GF. The ovary: basic principles and concepts. In: Felig P, Baxter JD, Broadus AE, et al, eds. *Endocrinology and Metabolism*, 3rd ed. New York: McGraw-Hill; 1995.)

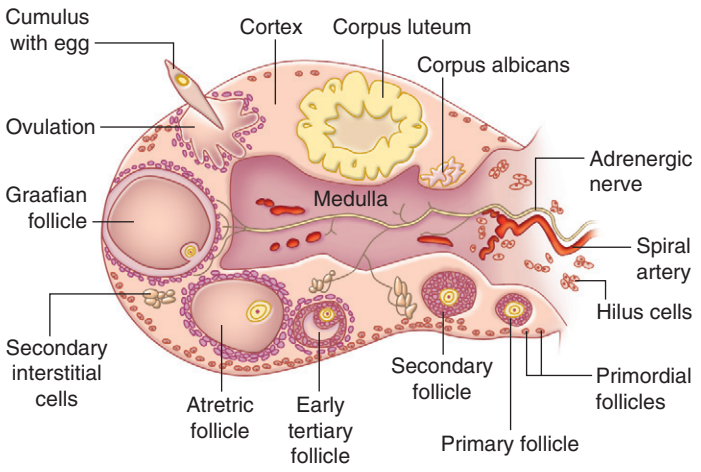

FIGURE 243-4. **Diagram showing the anatomy of the human ovary during the reproductive years.** Developing follicles and the corpus luteum are located in the cortex; the hilus cells, autonomic nerves, and spiral arteries are present in the medulla. (From Erickson GF. The ovary: basic principles and concepts. In: Felig P, Baxter JD, Broadus AE, et al, eds. *Endocrinology and Metabolism*, 3rd ed. New York: McGraw-Hill; 1995.)

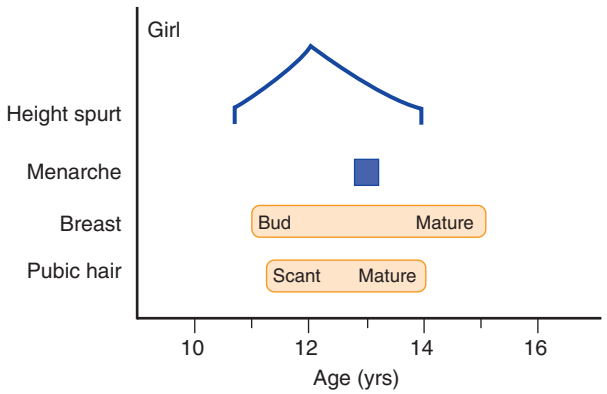

FIGURE 243-5. **Temporal sequence of events for the "average" girl during puberty.** (From Rebar RW. Practical evaluation of hormonal status. In: Yen SSC, Jaffe RB, Barbieri RL, eds. *Reproductive Endocrinology: Physiology, Pathophysiology, and Clinical Management*, 4th ed. Philadelphia: WB Saunders; 1999:710.)

present in the cortex. Typically, one follicle per cycle reaches maturity and ovulates its ovum. After ovulation, the follicle transforms into a corpus luteum. The corpus luteum of the cycle lasts for about 14 days, after which it dies and becomes a nodule of dense connective tissue, the corpus albicans (see Fig. 243-4).

The medulla is composed of loose connective tissue with numerous blood vessels and associated nerves. The arterial supply to the ovary originates from two principal sources: the ovarian artery and the uterine artery. These two vessels, which enter the medulla from opposite directions, form an anastomotic trunk and become a common vessel called the ramus ovaricus artery. This artery gives rise to a series of primary branches (spiral arteries) that enter the hilum. In the hilum, numerous secondary and tertiary branches are given off to supply the medulla and the follicles and luteal tissue in the cortex (see Fig. 243-4). The hilum also contains the hilus cells (see Fig. 243-4), which, like the testicular Leydig cells, contain Reinke crystals and secrete testosterone. The physiologic role of the hilus cells is still unknown.

Ovarian Function in Childhood and Puberty

Physical Changes at Puberty

Puberty extends from the earliest signs of sexual maturation until the attainment of physical, mental, and emotional maturity. Pubertal changes in girls result directly or indirectly from maturation of the hypothalamic-pituitary-ovarian unit. Human puberty is characterized hormonally by a resetting of the negative gonadal steroid feedback loop, the establishment of new circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the female of a positive estrogen feedback loop controlling the menstrual cycle as interdependent expressions of the gonadotropins and ovarian steroids. In girls, pubertal development generally occurs between 7 and 14 years of age. The age at onset and the rate of progress through puberty are variable and depend on genetic, socioeconomic, nutritional, physical, and psychological factors. It appears that there are racial differences in the onset of pubertal development. In the United States, development begins earlier in African American than in white girls.

Physical changes occur in an orderly sequence during a definite time frame in puberty (Fig. 243-5). Breast budding in girls is usually the first pubertal change, followed shortly by the appearance of pubic hair, with menarche occurring late in pubertal development. The time from breast budding (mean age of 10.0 years in white girls and 8.9 years in African Americans) to menarche is 2 years. Breast development results from increasing ovarian estrogen production, and pubic and axillary hair results from increasing ovarian androgen production. Estrogens are required for the growth of pubic hair as well.

The ovarian sex steroids join with growth hormone and adrenal androgens to produce the adolescent growth spurt. Peak growth velocity is achieved relatively early, with little growth observed after menarche. It has been estimated that more than 50 genes play roles in determining final adult height. It is now clear that estrogen, and not testosterone, is the primary hormone mediating pubertal bone growth in both males and females. Lean body mass,

skeletal mass, and body fat are equal in prepubertal boys and girls, but by maturity, women have twice as much body fat as men and less lean body mass and skeletal mass as a result of differences in sex steroid secretion. Estrogens are necessary for the normal formation, mineralization, and maturation of bones. Well-established standards exist for determining whether bone age is appropriate for chronologic age, typically by examining radiographs of the bones of the wrist. Estrogen deficiencies retard, and excesses advance, bone age in relation to chronologic age.

Hormonal Changes

The ovaries function even in early childhood. Low levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are normally present, and these levels increase if the ovaries are removed before puberty, just as they do later in life, indicating the exquisite sensitivity of the hypothalamic-pituitary unit to extremely low circulating sex steroid levels. As puberty nears, there is a progressive decrease in sensitivity of the hypothalamic-pituitary unit to sex steroids, leading to the increased secretion of pituitary gonadotropins, stimulation of sex steroid output, and development of secondary sex characteristics. Increased secretion of both LH and FSH initially occurs at night with sleep and is associated with increased estradiol secretion the next morning (Fig. 243-6). As is true for most hormones, LH and FSH are secreted in an episodic or pulsatile rather than a continuous fashion. Later in puberty, secretion of LH and FSH is increased throughout the 24-hour period, except during the early follicular phase, when nighttime increases still occur. Basal levels of estradiol, the major estrogen secreted by the ovaries, increase throughout puberty. A "critical body mass" may be required for positive estrogen feedback and ovulation. During the first 2 years after menarche, up to 90% of menstrual cycles may be anovulatory because of a delay in synchronization of the hypothalamic-pituitary-ovarian axis.

ABERRATIONS IN PUBERTAL DEVELOPMENT

Abnormalities of pubertal development can be divided into four major categories (Table 243-1):

1. *Precocious puberty* represents any pubertal changes before age 9 years in white girls and before age 8 years in African-American girls. This remains controversial. Some clinicians believe evaluation is warranted only if pubertal development begins before age 7 years in white girls and 6 years in African-American girls. A compromise may involve careful screening by history and physical examination of girls with early-onset puberty, looking for central nervous system (CNS) symptoms, behavioral concerns, and any other abnormal findings that might warrant further evaluation. The nearer pubertal development begins to the mean age of puberty onset, the less likely it is to have a pathologic basis. Precocious development is *isosexual* when it is common to the phenotypic sex of the individual and *heterosexual* when the development is characteristic of the opposite sex. *True* or *central precocious puberty* is due to premature maturation of the hypothalamic-pituitary axis. In the absence of increased hypothalamic-pituitary activity, *precocious pseudopuberty* exists.
2. *Delayed* (or *interrupted*) *puberty* is defined as the absence of any secondary sex characteristics by age 13 years, the absence of menarche by age 16 years, or the passage of 5 years or more from breast budding to menarche.
3. *Asynchronous pubertal development* occurs when there is deviation from the normal pattern of pubertal development.
4. *Heterosexual pubertal development* occurs at the appropriate time but has some features characteristic of the opposite sex.

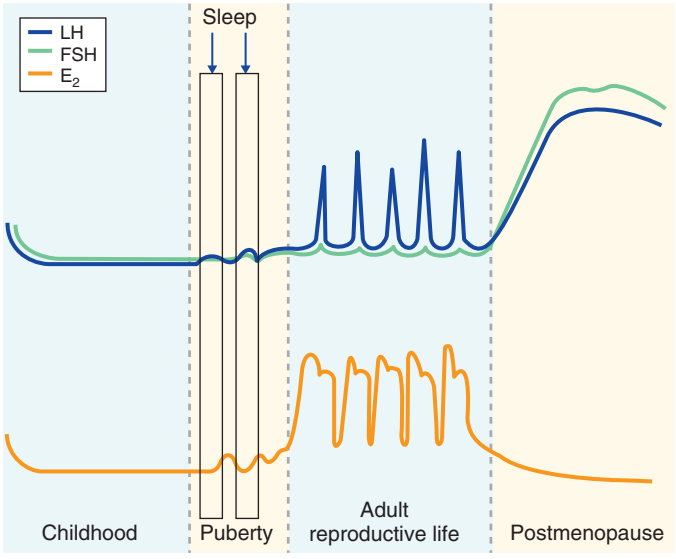

FIGURE 243-6. The changing patterns of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol (E_2) concentrations in peripheral blood throughout the life of a woman. Not shown is the fact that both LH and FSH are secreted in a pulsatile fashion. The pubertal period has been expanded to illustrate the sleep-associated increases in LH and FSH followed by morning increases in E_2 that are observed during puberty. (Reprinted with permission from Endocrine and Metabolism Continuing Education Quality Control Program, 1982. Copyright American Association for Clinical Chemistry Inc.)

Precocious Puberty

DIAGNOSIS

The overall incidence of precocious puberty has been estimated at 1 in 5000 to 10,000 children. About 10 times as many girls as boys are affected.

Differential Diagnosis

The temporal sequence in which the signs and symptoms of sex steroid hormone excess appear is most important. *Incomplete isosexual precocious puberty* indicates premature development of only a single pubertal feature. If breast budding occurs before age 8 years in the absence of any other development, the diagnosis may be *premature thelarche.* Premature thelarche is believed to be due to transient increases in estrogen secretion or increased breast sensitivity to the small quantities of circulating estrogens present before puberty. Simple ovarian cysts may be present in some girls with this disorder and may be due in some cases to the same genetic abnormality found in girls with McCune-Albright syndrome (Chapters 239 and 256). If pubic or axillary hair develops alone and persists, *premature pubarche* and *adrenarche* must be considered. These abnormalities are associated with slight increases in adrenal androgen secretion but not with clitorimegaly or other signs of virilization. These syndromes require no treatment, and affected girls typically begin true puberty at the usual age. Careful follow-up is required to distinguish these disorders from true precocious puberty.

When precocious development is isosexual, the purpose of the evaluation is to determine whether the cause is central (true precocious puberty) or peripheral, in which case it is considered gonadotropin-releasing hormone (GnRH)–independent precocious puberty or precocious pseudopuberty. Careful questioning of the patient and her parents may indicate the inadvertent ingestion or absorption of sex steroids (iatrogenic or factitious). As many as 20% of individuals with true precocious puberty have one of several organic brain diseases, including any of several neoplasms, tuberous sclerosis, neurofibromatosis, encephalitis, meningitis, vascular malformations, and hydrocephalus. Because of the seriousness of intracranial lesions, girls with precocious puberty must have radiographic evaluation of the CNS, most effectively by magnetic resonance imaging (MRI). In at least 75% of girls with true precocious puberty, however, no cause is identified (idiopathic or constitutional).

The physical examination may also provide critical information about the cause of the precocious development. Cutaneous café au lait spots, facial asymmetry, polyostotic fibrous dysplasia and other skeletal abnormalities, cranial nerve deficits, and multiple ovarian follicular cysts suggest McCune-Albright syndrome (Chapters 239 and 256) in a girl with precocious development. It is now known that various clones of cells in the endocrine glands of girls with this disorder function autonomously with respect to cyclic adenosine monophosphate production as a consequence of a mutation within exon 8 of the G protein α–subunit. This same mutation probably accounts for the bone lesions and café au lait hyperpigmentation. Other endocrine cells may be similarly affected and lead to pituitary adenomas (usually secreting growth hormone), hyperthyroidism, and, rarely, adrenal hyperplasia.

Precocious development associated with short stature, congenital body asymmetry, triangular facies, and clinodactyly suggests Silver-Russell syndrome. Characteristic signs and symptoms may suggest the coexistence of primary hypothyroidism and precocious puberty, especially if galactorrhea is also present. In these patients, thyroid hormone replacement therapy halts the progression of pubertal development until the expected age of puberty (enigmatically, primary hyperthyroidism may also lead to delayed pubertal development).

TABLE 243-1 ABERRATIONS OF PUBERTAL DEVELOPMENT

PRECOCIOUS DEVELOPMENT

- Isosexual precocity
  - Incomplete sexual precocity
    - Premature thelarche
    - Premature pubarche
    - Premature adrenarche
  - True (central) precocious puberty
    - Idiopathic (constitutional)
    - Due to central nervous system lesions
    - Primary hypothyroidism
    - Silver-Russell syndrome
  - Precocious pseudopuberty (of peripheral origin)
    - Ovarian neoplasms
    - Adrenal neoplasms
    - Iatrogenic (estrogen-containing preparations)
    - Human chorionic gonadotropin–secreting neoplasms distinct from central nervous system and ovarian tumors
    - McCune-Albright syndrome
- Heterosexual precocity
  - Ovarian neoplasms
  - Adrenal neoplasms
  - Congenital adrenal hyperplasia
  - Other rare disorders of sexual differentiation

DELAYED PUBERTAL DEVELOPMENT*

- Anatomic abnormalities
  - Müllerian agenesis or dysgenesis (Rokitansky-Küster-Hauser syndrome)
  - Distal genital tract obstruction
    - Transverse vaginal septum
    - Imperforate hymen
    - Vaginal agenesis
- Hypergonadotropic hypogonadism (FSH >30-40 mIU/mL)
  - Gonadal dysgenesis
    - With stigmata of Turner's syndrome
    - Pure (46,XX or 46,XY)
    - Mixed
  - Ovarian failure with normal ovarian development
    - Genetic disorders
    - Autoimmune disorders
    - Gonadotropin receptor or postreceptor defects (resistant ovary or Savage's syndrome?)
    - Enzymatic defects (17α-hydroxylase deficiency, galactosemia)
    - Physical causes
      - Irradiation
      - Chemotherapeutic agents
      - Viral agents
    - Idiopathic
- Hypogonadotropic or normogonadotropic hypogonadism (LH and FSH <10 mIU/mL, or LH and FSH 6-25 mIU/mL with at least one being >10 mIU/mL)
  - Isolated gonadotropin deficiency
    - In association with midline defects (Kallmann's syndrome)
    - Independent of associated disorders
  - Neoplasms of the hypothalamic-pituitary axis
    - Craniopharyngiomas
    - Pituitary tumors
    - Others
  - Infiltrative processes (Langerhans-type histiocytosis)
  - Idiopathic hypopituitarism
  - "Hypothalamic" forms of amenorrhea
    - Psychogenic
    - Exercise associated
    - Associated with malnutrition
    - Anorexia nervosa
  - Miscellaneous disorders
    - Prader-Labhart-Willi syndrome
    - Laurence-Moon-Bardet-Biedl syndrome
    - Primary hypothyroidism
  - Constitutional delayed puberty

ASYNCHRONOUS PUBERTAL DEVELOPMENT

- Incomplete forms of androgen insensitivity
- Complete forms of androgen insensitivity

HETEROSEXUAL PUBERTAL DEVELOPMENT

- Polycystic ovary syndrome
- Congenital adrenal hyperplasia (female pseudohermaphroditism)
  - 21-Hydroxylase deficiency
  - 11β-Hydroxylase deficiency

*No development by age 13 yr, absence of menarche by age 15 yr, or passage of ≥5 yr from breast budding without menarche.
FSH = follicle-stimulating hormone; LH = luteinizing hormone.

Abdominal and rectal examination may reveal a mass, suggesting an adrenal or ovarian tumor. Because palpable ovarian cysts may rarely develop before ovulation in true precocious puberty, the presence of a mass does not confirm the diagnosis of precocious pseudopuberty.

When vaginal bleeding is the only sign of development, the diagnosis of sexual precocity should be suspect. Common causes of bleeding in this age group include irritation from a vaginal infection or foreign body, sexual assault, prolapse of the urethral meatus, and ingestion of estrogen-containing medications (most commonly, oral contraceptive preparations). A vaginal or cervical neoplasm is also a rare possibility. Thus, vaginal bleeding requires a vaginal examination, which is often best performed with the patient under anesthesia, before further evaluation is undertaken.

Heterosexual precocity in an apparent prepubertal female is almost always due to congenital adrenal hyperplasia or to an androgen-secreting adrenal or ovarian neoplasm. Only rarely must another disorder of sexual differentiation be considered (Chapter 241). It is important to examine the external genitalia carefully, because congenital adrenal hyperplasia is usually associated with some degree of sexual ambiguity.

Excessive androgens produced endogenously by abnormal fetal adrenal glands in utero or diffusing across the placenta to the fetus from the mother can virilize the external genitalia and result in female pseudohermaphroditism. The extent of virilization varies from only an enlarged clitoris to sexual ambiguity sufficient to make gender assignment difficult.

Excessive maternal androgen secretion, typically from an ovarian or adrenal neoplasm, can lead to virilization of a female fetus. This occurs very rarely because of the great capacity of the placenta to aromatize naturally occurring androgens to estrogens. Virilization of a female fetus is much more likely to occur if a pregnant woman has ingested a synthetic steroid preparation with androgenic properties, because synthetic compounds generally cannot be aromatized.

Excessive androgen secretion beginning in utero is usually associated with defective cortisol synthesis. As a consequence, pituitary corticotropin secretion is increased, resulting in congenital adrenal hyperplasia and excessive androgen secretion. The three different enzyme defects in the steroidogenic pathway that can lead to virilization of the female fetus are described in Chapter 241. The most common form of congenital adrenal hyperplasia is 21-hydroxylase deficiency, accounting for the disorder in more than 90% of affected individuals. The defect may vary from partial to complete deficiency of the enzyme.

Diagnostic Tests

Measurement of Peptide and Steroid Hormones

Increased levels of immunoreactive human chorionic gonadotropin (HCG) may suggest an HCG-secreting neoplasm, most commonly an ovarian teratoma or dysgerminoma. In such cases, the HCG, which is antigenically and

biologically similar to LH, stimulates ovarian steroid secretion and pseudopubertal development. Because even specific LH immunoassays show some cross-reactivity with HCG, values for serum LH may be elevated in individuals with HCG-secreting tumors. Immunoreactive HCG is always elevated in the presence of such tumors. Levels and ratios of FSH and LH typical of pubertal as opposed to prepubertal girls help in the diagnosis of true precocious puberty. Timed urine collections rather than blood samples can be used to measure gonadotropin secretion if necessary. The use of exogenous GnRH to stimulate endogenous LH and FSH secretion can help differentiate gonadotropin-dependent from gonadotropin-independent precocious puberty and is regarded as the "gold standard" in the diagnosis of central precocious puberty. If GnRH is not available, a GnRH analogue can be substituted. Excessively high circulating levels of estrogen (>100 pg estradiol) suggest an estrogen-producing neoplasm or a functioning ovarian cyst. High levels of serum testosterone suggest an ovarian source of excess androgen in girls with heterosexual development, whereas increased levels of dehydroepiandrosterone or its sulfate (the principal precursors of 17-ketosteroids) suggest an adrenal source. High levels of serum 17-hydroxyprogesterone imply congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency, whereas high levels of serum 11-deoxycortisol imply an 11β-hydroxylase deficiency (Chapter 241). In congenital adrenal hyperplasia, these hormone levels should decrease promptly after the oral administration of suppressive doses of dexamethasone. Suppression in response to exogenous corticoids occurs much less consistently in individuals with adrenal cortical adenomas and carcinomas (Chapter 234) and rarely in those with ovarian androgen-secreting neoplasms.

Additional Studies

Imaging of the CNS is the most important test if true precocious puberty is present or if there are any neurologic deficits. Ultrasonography of the adrenals and ovaries or computed tomography (CT) of the adrenals may be indicated to confirm clinical suspicions. In girls with ovarian or adrenal neoplasms, the tumor can almost always be localized radiographically. Catheterization of the ovarian and adrenal veins and measurements of the effluent steroids from each gland should be pursued only when CT, ultrasonography, or MRI fails to identify a suspected neoplasm. Radiographic estimation of bone age is also indicated and serves as a useful tool to follow the results of treatment.

TREATMENT Rx

Treatment of precocious puberty should be initiated promptly so that the patient's ultimate height is not compromised as a result of sex steroid–induced premature epiphyseal closure and to prevent or attenuate emotional disturbances in the patient and her parents.

GnRH analogues are now the preferred therapy for suppressing gonadotropin secretion, and they also may prevent early bone maturation. No randomized trials have been conducted, but there is universal acknowledgment that GnRH analogues increase ultimate adult height in girls presenting before 6 years of age. Two unresolved issues are whether to initiate treatment with GnRH analogues in girls between 6 and 8 years of age and at what age to stop treatment. The analogues are not effective in children with McCune-Albright syndrome, and ketoconazole and testolactone have been only marginally successful. Aqueous depot medroxyprogesterone acetate (100 to 200 mg intramuscularly every 2 to 4 weeks) also may be used to suppress gonadotropin secretion; however, it does not always prevent premature epiphyseal closure and the resultant short stature.

Individuals with CNS or steroid-secreting neoplasms must undergo therapy appropriate for the particular lesion. Girls with congenital adrenal hyperplasia are appropriately managed with glucocorticoids (plus mineralocorticoids when indicated), as outlined in Chapter 241.

Delayed Puberty

Girls who have no evidence of thelarche by age 13 or who fail to undergo menarche by age 15 have delayed puberty and should be evaluated. Ovarian failure, congenital absence of the uterus and vagina, and constitutional delay constitute about two thirds of cases in large series. Because of the anxiety generated by delayed puberty, some evaluation is always indicated regardless of the age of the patient.

When pubertal development progresses normally but menstruation does not begin, an abnormality in the genital tract should be considered. Congenital malformations of the müllerian ducts are uncommon, occurring in 0.02% of all women. Most do not cause amenorrhea, and many do not impair reproduction. The anomalies associated with amenorrhea vary in severity from an imperforate hymen to complete aplasia of all müllerian duct derivatives, with vaginal atresia. Although aplasia generally involves all the müllerian duct derivatives, defects may involve only a single part of the distal genital tract. Family aggregates of the most common disorders of müllerian differentiation in females—müllerian aplasia and incomplete müllerian fusion—do occur and are best explained by polygenic or multifactorial inheritance. It is clear that the *HOX* genes, a family of regulatory genes that encode transcription factors, are essential for proper development of the müllerian tract.

A müllerian duct anomaly is suggested by (1) normal levels of serum gonadotropins and steroids, (2) an abnormal outflow tract, (3) a history of cyclic abdominal pain with or without a palpable mass, and (4) normal development of secondary sex characteristics. Normal ovarian function still induces endometrial growth and shedding after menarche if the uterus is normal. In the absence of a normal outflow tract, however, the menstrual effluent is retained and may or may not be able to escape into the abdominal cavity. Free in the abdominal cavity, the effluent may cause endometriosis. Constrained to the uterine cavity, the effluent causes hematometra and a large abdominal mass. In the absence of a mass or cyclic pain, karyotyping is indicated in girls with evidence of an abnormal genital tract to rule out disorders of sexual differentiation (Chapter 241). Such disorders, however, almost never occur together with completely normal pubertal development. In girls with a normal karyotype and a genital tract anomaly, examination under anesthesia and diagnostic laparoscopy should be undertaken to delineate the extent of the defect. When the abnormality consists of an imperforate hymen or transverse vaginal septum only, surgical restoration can be accomplished relatively simply. Attempts to provide an outflow tract for the uterus should not be undertaken if there is no cervix because of the high risk of recurrent pelvic infection. Even with a functional cervix, the construction of an outflow tract that permits successful pregnancy is unlikely. A functional vagina can be constructed surgically or by the daily use of ever-larger dilators. To prevent shrinkage and scarring, surgery should be deferred until the patient is willing to use dilators on a daily basis or she is about to become sexually active.

Other causes of delayed puberty and primary amenorrhea are the same as those that cause amenorrhea in older women (Chapter 244). When no apparent cause of delayed development is found, constitutional delayed puberty must be entertained as a diagnosis of exclusion. A strong family history of delayed maturation supports this presumption. Small doses of estrogen can be administered to induce some pubertal development, but this may obscure a pathologic cause of the delay and may compromise linear growth and ultimate height.

Asynchronous Pubertal Development

Asynchronous pubertal development is characteristic of male pseudohermaphroditism due to androgen insensitivity, especially complete testicular feminization. This syndrome of androgen insensitivity is inherited as either an X-linked recessive trait or a sex-limited autosomal dominant trait. Despite the presence of intra-abdominal or inguinal testes, there is complete failure of virilization. Affected individuals develop breasts (but only to Tanner stage 3) and a typical female habitus with unambiguous female external genitalia, but with the absence of internal female structures and generally only a foreshortened, blind-ending vagina. Little or no pubic and axillary hair develops. The karyotype is 46,XY in these individuals. Circulating testosterone levels are equivalent to or higher than those found in normal men, LH levels are elevated, and FSH levels are normal compared with those in menstruating women. For a more detailed description, see Chapter 241.

Heterosexual Pubertal Development

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS), by far the most common cause of heterosexual pubertal development, is associated with the development of some secondary sex features characteristic of males at the normal age of puberty. Feminization occurs in affected girls, and they develop normal breasts and a typical female habitus, but masculinization also occurs (in contrast, girls with congenital adrenal hyperplasia generally show little if any female development at puberty). A heterogeneous syndrome, PCOS typically begins at or near puberty with hirsutism and irregular menses from the time of menarche. Many girls who develop PCOS are overweight in childhood, and obesity is clearly a risk factor. It now appears that many girls who develop PCOS were growth restricted in utero. Menarche may be delayed in a few cases, so young

women may present with primary amenorrhea. Basal LH levels tend to be somewhat elevated in perhaps two thirds of cases, and circulating levels of all androgens are moderately elevated. Some degree of insulin resistance is almost invariably present as well, and hypercholesterolemia may predispose to cardiovascular disease later in life. This is discussed more completely in Chapter 244.

CONGENITAL ADRENAL HYPERPLASIA

Congenital adrenal hyperplasia is generally diagnosed before puberty, and heterosexual precocious pseudopuberty is typical. However, if the defect is mild and changes to the external genitalia are minimal, masculinization may occur at the expected age of puberty. This attenuated or nonclassic form of 21-hydroxylase deficiency seems to occur in families with a strong history of hirsutism. Affected girls generally have some defeminization, with flattening of the breasts, severe hirsutism, relatively short stature, and obesity. For a more detailed description, see Chapter 241.

MIXED GONADAL DYSGENESIS

Mixed gonadal dysgenesis designates asymmetrical gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other. The extent of genital virilization before puberty is variable in this rare disorder. Most individuals are reared as girls, in whom virilization occurs at puberty; some may note breast development as well. Affected individuals generally have a mosaic karyotype, with 45,X/46,XY being most common. Short stature and other stigmata associated with a 45,X karyotype in Turner's syndrome are less common in patients with tumors than in patients with testes. Gonadectomy is indicated in all individuals with a Y chromosome to eliminate the increased neoplastic potential of such dysgenetic gonads and in all patients in whom virilization occurs at puberty to remove the source of androgen. Estrogen replacement therapy is warranted after gonadectomy. Other causes of male pseudohermaphroditism associated with heterosexual pubertal development are described in Chapter 241.

OTHER CAUSES

An androgen-producing adrenal neoplasm or Cushing's syndrome may occur rarely during the pubertal years and lead to heterosexual development (Chapter 234).

244 REPRODUCTIVE ENDOCRINOLOGY AND INFERTILITY

ROBERT W. REBAR AND GREGORY F. ERICKSON

THE NORMAL MENSTRUAL CYCLE

Between menarche and menopause, the reproductive organs of normal women undergo a series of closely coordinated changes at monthly intervals that constitute the normal menstrual cycle. The menstrual cycle is the expression of the coordinated interactions of the hypothalamic-pituitary-ovarian axis, with associated changes in the target tissues (endometrium, cervix, vagina) of the reproductive tract.

A menstrual cycle begins with the first day of genital bleeding (day 1; menses) and ends just before the next menstrual period. The median menstrual cycle length is 28 days but ranges from 21 to 35 days. Menstrual cycles vary most in the years immediately after menarche and preceding menopause, partly because of an increase in anovulatory cycles. Irregularities in menstrual cycle length may be caused by changes in diet, exercise, emotional disturbances, parturition, or abortion. The menstrual cycle has three distinct phases: follicular, ovulatory, and luteal.

Follicular (Preovulatory) Phase

The follicular phase begins with the first day of bleeding and extends to the day before the preovulatory luteinizing hormone (LH) surge. A rise in serum follicle-stimulating hormone (FSH) begins in the late luteal phase of the previous menstrual cycle and continues into the early follicular phase. This initiates development of a group of follicles (Fig. 244-1). The preovulatory follicle destined for ovulation is selected from this cohort. After the early follicular phase, FSH levels fall, and LH levels rise slowly. About 7 days before the preovulatory LH surge, estradiol and estrone increase until the day before the LH surge. The divergence in LH and FSH levels may be related to secretion of inhibin B, which inhibits the release of FSH. Several days before the LH surge, plasma androgens and some progestins begin to increase. They peak on the day of the LH surge. Progesterone does not increase until just before the LH surge onset.

Ovulatory Phase

During this phase, the ovum is released from the mature graafian follicle about 32 to 34 hours after the preovulatory LH surge. The ovulatory phase extends from 1 day before the LH surge to 1 day after the LH surge (see Fig. 244-1). Some women experience unilateral pelvic pain near the time of ovulation, termed *mittelschmerz,* which occurs before or after ovulation. During the ovulatory phase, a rapid rise in plasma LH in response to positive estrogen feedback leads to ovulation. As peak LH levels are reached, estradiol levels drop, but progesterone levels increase.

Luteal (Postovulatory) Phase

The luteal phase is about 14 days in length and ends with the onset of menses (see Fig. 244-1). This phase includes the functional lifespan of the corpus luteum, which supports the released ovum by secreting progesterone. Progesterone secretion increases up to 8 days after the LH surge. Smaller increases in 17α-hydroxyprogesterone, estradiol, and estrone occur. Progesterone decreases before menses unless the ovum is fertilized and pregnancy results. A serum progesterone level higher than 10 ng/mL 1 week before menses is probably diagnostic of normal ovulation. Progestins increase basal morning body temperature so that a "thermogenic shift" of more than 0.3° C occurring after a nadir is a presumptive sign of ovulation. Unfortunately, taking basal temperatures on a daily basis is tedious, subject to error, and not very reliable.

CYCLIC CHANGES IN TARGET ORGANS

Endometrium

The endometrium undergoes histologic and cytologic changes that culminate with menstrual bleeding when the corpus luteum ceases to secrete progesterone (see Fig. 244-1). The basal layer of the endometrium then regenerates the superficial layer of compact epithelial cells lining the uterine cavity and an intermediate layer of spongiosa. Both layers are shed at menstruation. Endometrial glands proliferate under the influence of estrogen, and the mucosa thickens. In the luteal phase, the glands become coiled and secretory, with increased vascularity and edema of the stroma. When estradiol and progesterone decline, the stroma becomes edematous, endometrial and blood vessel necrosis occurs, and bleeding ensues. Local release of prostaglandins may initiate vasospasm with ischemic necrosis and uterine contractions that accompany menstrual flow. Prostaglandin synthetase inhibitors can relieve menstrual cramping. Fibrinolytic activity peaks at the time of menstruation, accounting for the noncoagulability of menstrual blood. The histologic changes are characteristic; therefore, endometrial biopsies can be used to characterize the stage of the cycle and to assess the tissue response to gonadal steroids.

Cervix and Cervical Mucus

During the follicular phase, cervical vascularity, congestion, and edema increase as a result of estrogen. The external cervical os opens to a diameter of 3 mm at ovulation and then decreases to 1 mm. Cervical mucus increases in quantity (10- to 30-fold) and in elasticity. So-called ferning becomes prominent. Progesterone stimulates cervical mucus thickening and loss of elasticity and ability to fern. These characteristics are useful in evaluating the stage of the cycle and the amount of estrogen present.

Vagina

Low estrogen is associated with pale, thin vaginal epithelium. As estrogens rise, the number of cornified epithelial cells increases. Subsequently, progesterone decreases the percentage of cornified cells and increases the number of precornified intermediate cells. There is also increased cellular debris and clumping of shed desquamated cells. Histologic changes in the vaginal epithelium are sensitive indicators of estrogen status. The reliability of vaginal smears depends on the absence of infection or exogenously administered steroids that have antiestrogenic effects. Steroid hormones also facilitate progression of spermatozoa toward the ovaries and of ova toward the uterine cavity through effects on the fallopian tubes.

Ovary

The ovaries produce a single dominant graafian follicle that grows and develops to the preovulatory stage during the follicular phase. This process is brought about by combined action of FSH and LH on the follicle wall to increase estradiol biosynthesis. The LH surge acts on the preovulatory follicle to cause the secretion of the mature fertilizable oocyte. After ovulation, the follicle wall transforms into the corpus luteum, which produces progesterone and estradiol. If implantation does not occur, the corpus luteum undergoes luteolysis and stops hormone production. In the late luteal phase, another dominant follicle develops, and a new menstrual cycle begins. The potential to produce a dominant follicle stops at menopause.

Chronology of Folliculogenesis

The preovulatory follicle begins its development when a primordial follicle is recruited into the pool of growing follicles. As a consequence of successive primordial follicle recruitments, the ovaries contain a pool of small graafian follicles with the potential to develop into the preovulatory follicle. Folliculogenesis is a long process. The preovulatory follicle arises from a primordial follicle that was recruited to grow about 1 year earlier. There are two major phases of folliculogenesis: the preantral (gonadotropin-independent) and the antral (gonadotropin-dependent) periods. The first phase is characterized by growth of the oocyte and granulosa proliferation. Preantral folliculogenesis proceeds slowly, requiring at least 300 days. During the second phase, granulosa and theca cells proliferate, and the antrum enlarges. The graafian follicle increases relatively rapidly as it develops. The mature graafian follicle that will ovulate requires 40 to 50 days to complete the antral phase. The follicles that do not participate in ovulation undergo atresia and die by apoptosis.

Selection

The dominant follicle is selected from a cohort at the end of the luteal phase of the previous menstrual cycle. The selected follicle requires 20 days to develop to the ovulatory stage.

Shortly after the midluteal phase of the cycle, the granulosa cells show a sharp increase in the rate of mitosis. The first indication of selection is that the granulosa cells continue dividing at a high rate. As a consequence of the high sustained mitotic rate and the progressive accumulation of follicular

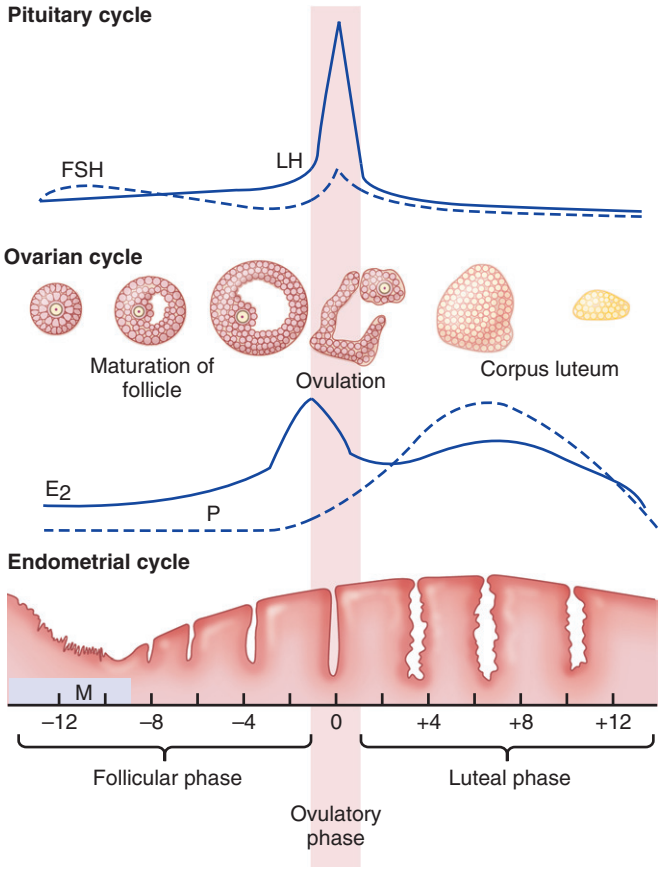

FIGURE 244-1. The idealized cyclic changes observed in gonadotropins, estradiol (E_2), progesterone (P), and uterine endometrium during the normal menstrual cycle. The data are centered on the day of the luteinizing hormone (LH) surge (day 0). Days of menstrual bleeding are indicated by M. FSH = follicle-stimulating hormone; LH = luteinizing hormone. (From Endocrine and Metabolism Continuing Education Quality Control Program, 1982. Copyright American Association for Clinical Chemistry, Inc.)

fluid, the dominant follicle undergoes remarkable growth, reaching 6.9 ± 0.5 mm in diameter at days 1 to 5, 13.7 ± 1.2 mm at days 6 to 10, and 18.8 ± 0.5 mm at days 11 to 14. The increase in plasma FSH levels that begins at the end of luteal phase and continues through the early follicular phase evokes follicle selection. The concentration of FSH in the follicular fluid of the healthy (dominant) follicle increases but does not increase in the nondominant atretic follicles. The manner in which this selective increase in FSH is controlled is unknown. More than 99.9% of all follicles are not selected and undergo atresia.

Mechanism of Follicle-Stimulating Hormone Action

FSH exerts its influence on follicle growth and development by stimulating granulosa cell mitosis and cytodifferentiation. FSH activates high-affinity receptors on the granulosa cell. The binding event is transduced into an intracellular signal through the cyclic adenosine monophosphate (cAMP)-dependent protein kinase A signal transduction pathway (E-Fig. 244-1). This leads to an increase in cell number and cytodifferentiation.

The granulosa cells in the chosen follicle continue to divide at a relatively rapid rate throughout the follicular phase of the cycle, increasing from 1×10^6 cells to 50×10^6 cells at ovulation. FSH induces granulosa cytodifferentiation in the dominant follicle. Expression of cytochrome P-450 aromatase (P450arom) is induced by FSH (see E-Fig. 244-1). The temporal pattern of expression of P450arom determines when and how much estradiol is produced. FSH also induces the expression of LH receptors. This is delayed until the dominant follicle is fully differentiated at day 12. The large number of LH receptors in the granulosa cells is essential for the LH surge to trigger ovulation. There is compelling evidence in laboratory animals that oocyte-derived inhibitors inhibit FSH-induced LH receptors in granulosa cells, leading to the interpretation that the oocyte plays a role in controlling the onset of the preovulatory LH surge. The terminal differentiation of the granulosa cells is characterized by the accumulation of other FSH-regulated gene products, including inhibin B, activin, and follistatin.

Mechanism of Luteinizing Hormone Action

The primary function of LH in follicle development is to stimulate androgen production by the theca interstitial cells (see E-Fig. 244-1). LH binds to LH human chorionic gonadotropin (hCG) receptors located on theca cells, which interact with G proteins and activate adenylate cyclase, leading to the synthesis of cAMP, which stimulates gene expression through protein kinase A. LH signaling elicits increases in a variety of genes, including steroidogenic acute regulatory (StAR) protein, P450c22, 3β-hydroxysteroid dehydrogenase, and P450c17. This leads to increased conversion of cholesterol to androstenedione. Theca cells express insulin receptors, and insulin stimulates theca androgen production. The crosstalk between the insulin and LH receptor signaling is clinically relevant because of the relationship between hyperinsulinemia and hyperandrogenism in women.

One of the most important consequences of FSH and LH action on the dominant follicle is the production of estradiol. This physiologically important process is called the *two-gonadotropin, two-cell concept* of follicular estrogen production (see E-Fig. 244-1).

Ovulation

At midpoint in the menstrual cycle, the preovulatory surges of LH and FSH act on the preovulatory follicle to initiate the events leading to ovulation (E-Fig. 244-2). The LH surge induces meiotic maturation, a process that converts the oocyte into a fertilizable egg arrested at the second meiotic metaphase. During meiotic maturation, the granulosa cells next to the oocyte are stimulated by FSH to undergo cumulus expansion. This is a prerequisite for the egg's pickup and transport by the oviduct. The LH surge also stimulates production of proteolytic enzymes in the vicinity of the presumptive stigma. This process requires the LH stimulation of progesterone and prostaglandins, which are obligatory for stigma formation. After 36 hours, the fertilizable egg and surrounding cumulus cells are secreted through the stigma (see E-Fig. 244-2).

Luteogenesis

Ovulation leads to changes in the granulosa and theca cells of the ovulated follicle that result in increased production of progesterone and estradiol during the first week of the luteal phase. This event, termed *luteinization*, is important for the formation and development of a secretory endometrium. Three major physiologic mechanisms are responsible for luteinization: removal of luteinization inhibitors; secretion of LH by the pituitary; and delivery of high levels of cholesterol. The induction of StAR, P450c22, and 3β-hydroxysteroid dehydrogenase in the granulosa lutein cells leads to progesterone production by the corpus luteum. The two-cell, two-gonadotropin mechanism is responsible for estradiol production. If implantation does not occur, the corpus luteum initiates luteolysis, leading to decreases in progesterone, estradiol, and apoptosis. When luteolysis occurs, another dominant follicle is selected, and a new menstrual cycle begins.

The Autocrine-Paracrine Concept

An important concept to emerge recently is that the follicle and luteal cells produce regulatory molecules that can modulate—either amplify or attenuate—FSH and LH action. This is the autocrine-paracrine concept. In experimental animals, early folliculogenesis and female fertility are critically dependent on two oocyte-derived factors, growth differentiation factor 9 and bone morphogenetic protein 15, but their importance for ovarian function is unknown.

The data indicate that FSH is required only for early folliculogenesis. It appears that inhibin-A, inhibin-B, and activin, peptides produced by granulosa cells and belonging to the transforming growth factor-β family, are critical for follicular development. In immature granulosa cells, activin augments all FSH actions, especially aromatase activity. In the follicular phase, granulosa cell production of inhibin-B is under the control of FSH; but in the late follicular phase, a shift occurs such that LH controls luteal synthesis of inhibin-A. Together, inhibin and activin regulate androgen synthesis in human theca cells; inhibin enhances and activin suppresses the stimulatory action of LH. Synthesis of insulin-like growth factor II (IGF-II) by granulosa cells is dependent on FSH and enhanced by estradiol. Both binding proteins for IGF-II and receptors are also present in the ovary. IGF-II enhances all the actions of FSH and LH within the ovary and may be critically important to follicular development. A variety of other growth factors may also play important roles; for example, transforming growth factor-β may be critical in the atresia of follicles. The current challenges are to understand how the autocrine-paracrine

activities are integrated into the overall pathways that govern human ovarian physiology and pathophysiology.

Neuroendocrine Regulation of the Ovaries

Neurons containing various peptide hormones that can release or inhibit secretion of the gonadotropins are found in the hypothalamus (Chapter 230). Cells containing gonadotropin-releasing hormone (GnRH) occur in the arcuate nucleus, median eminence, and preoptic area. Axons from these neurons run in the tuberoinfundibular tract and terminate on capillaries within the median eminence, allowing delivery of their products to the anterior pituitary gland. Neurotransmitters, including norepinephrine, dopamine, and serotonin, as well as neuromodulators, such as endogenous opiates and prostaglandins, influence secretion of GnRH. Estrogens and androgens bind to cells in the hypothalamus and the anterior pituitary, and progestins bind to cells in the hypothalamus, to influence hypothalamic-pituitary regulation of ovarian function.

GnRH is secreted in a pulsatile fashion and is responsible for pulsatile release of gonadotropins. Pulsatile gonadotropin release accounts for the pulsatile secretion of sex steroids from the ovaries. The ovarian sex steroids feed back on the hypothalamic-pituitary unit to modulate both the frequency and amplitude of the gonadotropin pulse (Fig. 244-2). Gonadotropin pulses vary throughout the menstrual cycle. Pulses occur at approximately 60- to 90-minute intervals in the follicular phase and at intervals of 180 minutes in the luteal phase.

Gonadal steroids can exert both negative and positive feedback effects on gonadotropin secretion. 17β-Estradiol is the most potent inhibitor of gonadotropin secretion. For women to ovulate, estradiol must also elicit a positive feedback effect on gonadotropin release. The feedback effects are both time and dose dependent. In the normal menstrual cycle, the positive feedback action of estradiol leading to the LH surge is preceded by a period when lower estradiol levels are present.

It appears that the ovary is the "clock" for the timing of ovulation, with the hypothalamus stimulating pulsatile release of the gonadotropins. The follicle complex and corpus luteum develop in response to gonadotropin stimulation. For appropriate ovarian regulation of reproductive function in women, three biologic characteristics are necessary: an appropriate balance and sequence of negative and positive feedback actions; differential feedback effects on the release of LH and FSH; and local intraovarian controls on follicular growth and maturation.

ABNORMALITIES OF THE REPRODUCTIVE YEARS

Dysmenorrhea and Endometriosis

DEFINITION

Dysmenorrhea, defined as painful menstruation, affects about 50% of postpubertal women and can be classified as primary or secondary. *Endometriosis,* which may result in dysmenorrhea, infertility, and dyspareunia (i.e., painful intercourse), is the ectopic occurrence of endometrial tissue, most commonly within the abdominal cavity but sometimes in surgical scars, on the vulva, in the umbilicus, and elsewhere.

PATHOBIOLOGY

Primary dysmenorrhea occurs only in ovulatory cycles. Prostaglandins produce dysmenorrhea by initiating painful, exaggerated uterine contractions and myometrial ischemia. Associated systemic symptoms include nausea, diarrhea, headache, and emotional changes. In secondary dysmenorrhea, there is a pathologic cause, with endometriosis being the most common. Other causes include pelvic inflammatory disease; congenital abnormalities, such as atresia of a portion of the distal genital tract and cystic duplication of the paramesonephric ducts; and cervical stenosis. Recent studies suggest the possibility that the pain of endometriosis is caused by the presence of nerve fibers within ectopic endometrium.

TREATMENT

Rx

Prostaglandin synthetase inhibitors (Chapter 36), such as naproxen, ibuprofen, mefenamic acid, and indomethacin, are used to treat primary dysmenorrhea. If the dysmenorrhea persists, addition of an oral contraceptive to inhibit ovulation and limit prostaglandin release is generally effective. In cases in which the pelvic pain remains intractable, additional evaluation is warranted. If thorough evaluation of the gastrointestinal and urinary tracts fails to reveal a definitive cause, examination under anesthesia and diagnostic laparoscopy may be indicated.

If endometriosis is diagnosed at laparoscopy, treatment varies according to the severity of the disease and the goals of the patient regarding fertility. It may be possible to fulgurate implants or to lyse adhesions. Available data support ablation at the time of initial diagnosis as the preferred approach to controlling symptoms. From this point onward, efforts should be directed toward treating endometriosis medically, with additional surgery deferred until infertility (if present) becomes manifest. Medical therapy can consist of continuous suppression with oral contraceptives, progestins (oral, injectable, or implantable), or GnRH analogues or danazol for 3 to 6 months (with so-called add-back therapy with a progestin or oral contraceptive to prevent accelerated bone loss). Selective estrogen and progesterone receptor modulators and aromatase inhibitors are now in various stages of testing for the treatment of endometriosis. Future therapies being evaluated include estrogen receptor-β (ERB) inhibitors, various antiangiogenic agents, and tumor necrosis factor-α inhibitors.

GnRH analogues are currently the most frequently used form of medical suppressive therapy. After a course of treatment, use of oral contraceptive agents should probably be continued until fertility is desired. Conservative surgical resection of endometriotic tissue should almost always be deferred until it is established as the cause of infertility. Surgery may be required, however, for continuing severe pain, severe endometriosis, or large ovarian cysts containing endometriosis (endometriomas). If symptoms continue despite adequate treatment or if psychological overlay is suspected, psychiatric evaluation may be indicated. Medical causes of dysmenorrhea, however, should be eliminated first.

TABLE 244-1 COMMON SYMPTOMS OF CYCLIC PREMENSTRUAL SYNDROME

SOMATIC SYMPTOMS	
Abdominal bloating	Constipation or diarrhea
Acne	Headache
Alcohol intolerance	Peripheral edema
Breast engorgement and tenderness	Weight gain
Clumsiness	
EMOTIONAL AND MENTAL SYMPTOMS	
Anxiety	Insomnia
Change in libido	Irritability
Depression	Lethargy
Fatigue	Mood swings
Food cravings (especially salt and sugar)	Panic attacks
Hostility	Paranoia
Inability to concentrate	Violence toward self and others
Increased appetite	Withdrawal from others

Premenstrual Syndrome

DEFINITION

Premenstrual syndrome (PMS), also known as *premenstrual tension*, is a complex of physical and emotional symptoms that occur repetitively in a cyclic fashion before menstruation and that diminish or disappear with menstruation.

DIAGNOSIS

The cyclic symptoms typically are sufficiently severe to interfere with some aspects of life. Women with established psychiatric disturbances probably should not be included among those with PMS. More than 150 different symptoms are now thought to vary with the menstrual cycle (Table 244-1). Estimates of the prevalence of PMS range from 25 to 100%. The *Diagnostic and Statistical Manual of Mental Disorders* classifies severe PMS as premenstrual dysphoric disorder (PMDD). Certain specific symptoms must be present for diagnosis of PMDD. For most women, PMS is merely annoying; severe PMS (or PMDD) causes serious difficulties for 3 to 5% of women of reproductive age. The diagnosis of both PMS and PMDD is best established by requiring patients to keep prospective daily records of symptoms during a 2- to 3-month period. Less than 50% of women complaining of PMS are found to have the syndrome when such records are examined.

Most women seek help for PMS in their 30s after 10 or more years of symptoms. Many report that their symptoms began at menarche; approximately half state that symptoms followed childbirth. Severity and duration of symptoms are often reported to increase after each successive pregnancy and to become more severe with advancing age. Women with severe long-standing PMS almost always describe associated psychological reactions, including social difficulties, such as marital discord, difficulty relating to their children, difficulty maintaining friendships, and withdrawal from social activities.

TREATMENT Rx

General Measures

The cause of PMS is unknown, and patients should be informed that no one therapy has been effective in all women. Women with mild premenstrual symptoms often benefit from simple changes in lifestyle, including daily mild aerobic exercise; reduction in intake of xanthine-containing beverages, salt, and refined sugar, particularly in the luteal phase; stress reduction; and adequate rest.

Medical Therapy

Women with more severe PMS may benefit from symptomatic treatment. Bromocriptine (generally 2.5 mg twice a day) or danazol (100 to 400 mg/day in two divided doses) may be given continuously for relief of mastalgia (breast pain), although this use is not listed in the manufacturer's directive or approved by the U.S. Food and Drug Administration (FDA). Prostaglandin synthetase inhibitors may help reduce dysmenorrhea and may alleviate headaches. Mild sedatives and tranquilizers may help reduce insomnia and anxiety. Low doses of fluoxetine (20 mg) and other selective serotonin reuptake inhibitors, administered either daily or for the last 2 weeks of each menstrual cycle, are highly effective in reducing the emotional symptoms associated with PMS. Mild diuretics (especially spironolactone at doses up to 100 mg each morning) may benefit cyclic edema.

Natural progesterone, given in the form of vaginal suppositories, has been used, but results of double-blind placebo-controlled trials show no efficacy. Likewise, the value of large quantities of multiple vitamins or of oil of evening primrose, containing the essential fatty acid γ-linolenic acid, a precursor of prostaglandins, is unsubstantiated.

Surgical Therapy

Because PMS requires the occurrence of cyclic ovulation, oophorectomy is occasionally considered for patients with particularly intractable symptoms. However, oophorectomy may create new problems related to estrogen deficiency for women with PMS treated in this permanent fashion. Several trials employing a GnRH agonist together with exogenous steroids have been described as reducing PMS. Whether such therapy can be used in the long term remains to be determined.

Abnormal Uterine Bleeding

DIAGNOSIS

Differential Diagnosis

Because there is considerable confusion about terminology of abnormal uterine bleeding, it is important to determine just what is being included in any term used other than *abnormal uterine bleeding*. Postmenarchal bleeding in adolescents secondary to immaturity of the hypothalamic-pituitary-ovarian axis (resulting in anovulation) accounts for about 20% of cases, and perimenopausal bleeding consequent to incipient ovarian failure constitutes more than half.

The causes of abnormal uterine bleeding in the reproductive years include complications from the use of oral contraceptives; complications of pregnancy, especially threatened, incomplete, or missed miscarriages and ectopic pregnancy; coagulation disorders, most commonly idiopathic thrombocytopenic purpura and von Willebrand's disease; and pelvic disease, such as intrauterine polyps, leiomyomas, and tumors of the vagina and cervix. Clear cell adenocarcinoma of the vagina or cervix may occur in women exposed to diethylstilbestrol during fetal life. Affected women may also have congenital abnormalities of the upper vagina, cervix, and uterus. Women with a history of diethylstilbestrol exposure should be reassured that the incidence of malignant change is extremely low. Trauma (coital or otherwise), foreign bodies, systemic illnesses including various endocrinopathies (such as diabetes mellitus, hypothyroidism and hyperthyroidism, Cushing's syndrome, and Addison's disease), leukemia, and renal disease may also be associated with abnormal bleeding as the presenting manifestation.

Abnormal uterine bleeding with no demonstrable organic genital or extragenital cause (75% of cases) is most frequently associated with anovulation and is appropriately termed *anovulatory* (sometimes termed *dysfunctional*) *bleeding*. Most anovulatory bleeding is due to either estrogen withdrawal or estrogen breakthrough bleeding. In anovulatory women, estrogen stimulates the endometrium unopposed by progesterone. The endometrium proliferates, becomes thicker, and may shed irregularly. Anovulatory bleeding tends to occur at less frequent intervals, and organic lesions tend to cause bleeding more frequently than cyclic menses.

CLINICAL EVALUATION

All cases of abnormal bleeding should be evaluated, beginning with a thorough history emphasizing the amount and duration of blood loss. Prospective charting of the days on which bleeding occurs may be required to evaluate the bleeding pattern. Complications of pregnancy or a bleeding diathesis must always be ruled out.

The findings on physical examination (including the Papanicolaou smear) are normal in anovulatory bleeding except for signs of anemia in the more severe cases. Laboratory tests should include a complete blood count, platelet count, coagulation studies, thyroid function tests, and fasting blood glucose concentration. Anovulatory bleeding must be a diagnosis of exclusion, with management depending on the age of the patient and the extent of the bleeding. A sample of the endometrium should be obtained by biopsy or by dilation and curettage from all women older than 35 years and from those at increased risk for endometrial carcinoma because of prolonged anovulatory bleeding.

TREATMENT

Even profuse bleeding in anovulatory women can almost always be successfully treated by the administration of one combination oral contraceptive pill every 6 hours for 5 to 7 days, although this use is not listed in the manufacturer's directive or approved by the FDA. Bleeding should cease within 24 hours, but patients should be warned to expect heavy bleeding 2 to 4 days after therapy is stopped. If anemia is profound, blood transfusion may be necessary. If the bleeding continues despite therapy, curettage can be carried out. Recurrence can be prevented by giving the patient combination oral contraceptive agents cyclically. If spontaneous cyclic menses do not resume and pregnancy is not desired, the patient can be treated with cyclic progestin (medroxyprogesterone acetate, 5 to 10 mg for 10 to 14 days each month) or oral contraceptive agents. If pregnancy is desired, ovulation can be induced.

Acute episodes of anovulatory bleeding can also be treated with conjugated estrogens administered intravenously (25 mg every 4 hours for up to three doses) until bleeding ceases, although this use is not listed in the manufacturer's directive or approved by the FDA. Progestin therapy (medroxyprogesterone acetate, 5 to 10 mg orally for 10 days) should be started simultaneously. Withdrawal bleeding occurs after cessation of therapy, and the patient can then be treated with oral contraceptive agents for at least three cycles.

For individuals with anovulatory bleeding without an episode of profuse bleeding, treatment with cyclic oral contraceptive agents or progestin can be provided unless pregnancy is desired, in which case ovulation must be induced.

Endometrial ablation by any of several methods is being used increasingly to treat persistent bleeding. However, ablation is not 100% effective, and medical management remains the first line of therapy for most women. Hysterectomy may be an appropriate choice for a small number of women.

TABLE 244-2 CRITERIA FOR DISTINGUISHING TANNER STAGES 1 TO 5 DURING PUBERTAL MATURATION

TANNER STAGE	BREAST	PUBIC HAIR
1 (Prepubertal)	No palpable glandular tissue or pigmentation of areola; elevation of areola only	No pubic hair; short, fine vellus hair only
2	Glandular tissue palpable with elevation of breast and areola together as a small mound; areolar diameter increased	Sparse, long, pigmented terminal hair chiefly along the labia majora
3	Further enlargement without separation of breast and areola; although more darkly pigmented, areola still pale and immature; nipple generally at or above midplane of breast tissue when individual is seated upright	Dark, coarse, curly hair, extending sparsely over mons
4	Secondary mound of areola and papilla above breast	Adult-type hair, abundant but limited to mons and labia
5 (Adult)	Recession of areola to contour of breast; development of Montgomery's glands and ducts on areola; further pigmentation of areola; nipple generally below midplane of breast tissue when individual is seated upright; maturation independent of breast size	Adult-type hair in quantity and distribution; spread to inner aspects of the thighs in most racial groups

Data from Ross GT. Disorders of the ovary and female reproductive tract. In: Wilson JD, Foster DW, eds. *Textbook of Endocrinology*, 7th ed. Philadelphia: WB Saunders; 1985:206; Speroff L, Glass RH, Kase N. *Clinical Gynecologic Endocrinology and Infertility*, 3rd ed. Baltimore: Williams & Wilkins; 1983:377; and Kustin J, Rebar RW. Menstrual disorders in the adolescent age group. *Primary Care*. 1987;14:139-166.

Amenorrhea

DEFINITION

Amenorrhea is the absence of menstruation for 3 months or more in women with past menses (secondary amenorrhea) or the absence of menarche by the age of 15 years regardless of the absence or presence of secondary sex characteristics (primary amenorrhea).

PATHOBIOLOGY

If an intact genital outflow tract exists and there is no primary disease of the uterus, amenorrhea is a sign of failure of the hypothalamic-pituitary-ovarian axis to produce cyclically the hormones necessary for menses. Amenorrhea is physiologic in the prepubertal girl, during pregnancy and early in lactation, and after menopause. At any other time, it is pathologic and demands evaluation. Use of the term *postpill amenorrhea* to refer to failure to resume menses within 3 months of discontinuation of oral contraceptives is inappropriate. Women so affected should be evaluated in the same manner as any woman with amenorrhea. Similarly, individuals with menses occurring at infrequent intervals of more than 40 days or having fewer than nine menses per year, termed *oligomenorrhea*, should be evaluated identically to women with amenorrhea.

DIAGNOSIS

Clinical Evaluation

In patients with amenorrhea, even subtle hormonal abnormalities may lead to signs and symptoms. Breast development indicates exposure to estrogens, and the presence of pubic and axillary hair indicates androgenic stimulation.

Patients should be questioned especially closely for evidence of psychological disturbances, dietary and exercise habits, lifestyle, environmental stresses, family history of genetic anomalies, abnormal growth and development, and signs of hyperandrogenism, including hirsutism, temporal balding, deepening of the voice, increased muscle mass, clitorimegaly, and increased libido, and signs of defeminization, including decreasing breast size and vaginal atrophy. Any history of galactorrhea should be determined. A history of symptoms related to thyroid and adrenal dysfunction should also be sought (Chapters 231, 233, and 234).

The physical examination should focus on the evaluation of body dimensions and habitus, extent and distribution of body hair, breast development and secretions, and genitalia. In normal adult women, the arm span is similar to the height; in hypogonadal women, the span is generally more than 5 cm greater than the height. The general appearance of the patient should be evaluated to determine whether the habitus is that of an adult female. The distribution and quantity of body hair should be considered in view of the family history. The extent of any hirsutism should be recorded, preferably by photographs. Other signs of virilization should be sought carefully. Breast development should be graded according to the method of Tanner (Table 244-2). Breast secretion should be sought by applying pressure to the breasts while the patient is seated. Any secretion should be examined microscopically for the presence of perfectly round fat globules of varying size, which indicate galactorrhea. Finally, the female genitalia should be examined carefully because they are such sensitive indicators of the hormonal milieu. The Tanner stage of pubic hair development should be noted (see Table 244-2).

Because the sensitivity of the genitalia to androgens decreases onward from early in fetal development, the extent of any virilization is important. Fusion of the labia and enlargement of the clitoris with or without formation of a penile urethra are observed in women exposed to androgens during the first 3 months of fetal development (Chapter 241). Significant clitorimegaly in the absence of other signs of sexual ambiguity and in the presence of other signs of virilization requires marked androgenic stimulation and strongly implicates an androgen-secreting neoplasm. The development of the labia minora in postpubertal women indicates the influence of estrogens. Overt anomalies of the distal genital tract and any evidence of obstruction to the escape of menstrual blood should be sought. Under the influence of estrogen, the vaginal mucosa changes during sexual maturation from a tissue with a shiny, bright red appearance with sparse, thin secretions to a dull, gray-pink rugated surface with copious, thick secretions.

The history and physical examination quickly differentiate among several causes of amenorrhea (Table 244-3). The various disorders of sexual differentiation and the other anatomic causes are often apparent on inspection. Distal genital tract obstruction should be identified at the time of pelvic examination even if the specific abnormality is not obvious. The physical stigmata of Turner's syndrome, discussed subsequently, generally make the diagnosis simple. Any sexual ambiguity indicates the need for chromosomal analysis and the measurement of 17α-hydroxyprogesterone to rule out congenital adrenal hyperplasia. Pregnancy and gestational trophoblastic disease may be confirmed by measurement of hCG. The possibility of intrauterine

synechiae or adhesions (Asherman's syndrome) must be considered in individuals in whom amenorrhea develops after curettage or endometritis. Tuberculous endometritis, especially in younger women, may also lead to this disorder. Without hormonal measurements, it may be impossible to distinguish between individuals with chronic anovulation, in whom hypothalamic-pituitary-ovarian function is insufficiently coordinated to produce cyclic ovulation, and those with ovarian failure. However, it is generally possible to form a clinical impression about the cause of the amenorrhea. It can be noted whether the patient has absence of, incomplete, or complete development of secondary sex characteristics. The presence of excess body hair or galactorrhea may provide clinical evidence of the pathogenesis of the amenorrhea. Signs and symptoms of adrenal or thyroid dysfunction may be important as well. Administration of a progestin (typically medroxyprogesterone acetate, 5 to 10 mg given orally for 5 to 10 days, or progesterone in oil, 100 mg given intramuscularly) has been advocated to assess the level of endogenous estrogen. This test is of limited value, however, because almost half the young women with premature ovarian failure experience withdrawal bleeding in response to progestin.

To ascertain whether the outflow tract is intact, an orally active estrogen, such as 2.5 mg of conjugated estrogen daily for 21 days, with 5 to 10 mg of oral medroxyprogesterone acetate for the last 5 to 10 days, is administered. Withdrawal bleeding should occur if the endometrium is normal. Still, hysterosalpingography and hysteroscopy may be required for the diagnosis of Asherman's syndrome because some patients continue to have some withdrawal bleeding.

TABLE 244-3 CAUSES OF AMENORRHEA

ANATOMIC CAUSES
Pregnancy
Various disorders of sexual differentiation
Distal genital tract obstruction (müllerian agenesis or dysgenesis)
Gonadal dysgenesis*
Ambiguity of external genitalia (male and female pseudohermaphroditism)
Intrauterine adhesions (Asherman's syndrome)
Gestational trophoblastic disease
CHRONIC ANOVULATION
Due to CNS-hypothalamic-pituitary dysfunction
With inappropriate steroid feedback (e.g., polycystic ovary syndrome)
Due to thyroid or adrenal disorders
OVARIAN "FAILURE"
Menopause
Genetic abnormalities
Physical and environmental causes (e.g., chemotherapeutic agents, irradiation)
Autoimmune disorders
Idiopathic

*Gonadal dysgenesis may be viewed as both a disorder of sexual differentiation and a form of gonadal "failure."
CNS = central nervous system.

Laboratory Findings

Basal levels of FSH, prolactin, and thyroid-stimulating hormone (TSH) should be measured in all amenorrheic and oligomenorrheic women to confirm the clinical impression (Fig. 244-3).

Increased TSH levels with or without increased levels of prolactin imply primary hypothyroidism, and further evaluation for this disorder is indicated (Chapter 233). Although hypothyroidism commonly results in anovulation, amenorrhea occurs in only some hypothyroid women. Menorrhagia and oligomenorrhea may occur as well. The sensitive immunoassays for TSH permit identification of women with hyperthyroidism as well because TSH levels are suppressed in those individuals.

If the prolactin concentration is minimally increased and the TSH level is normal, measurement of the prolactin concentration should be repeated before more extensive evaluation is undertaken because prolactin levels are increased by nonspecific stressful stimuli, sleep, and food ingestion. Prolactin levels may be elevated in as many as one third of women with amenorrhea.

Increased FSH levels (generally above 30 mIU/mL) imply ovarian failure and require further evaluation. Incipient ovarian failure should be considered in any woman with basal FSH levels of 15 mIU/mL or higher other than during the midcycle LH surge. Many clinicians believe that chromosomal evaluation is indicated in all individuals with elevated FSH levels before age 40 years, and it is certainly indicated if hypergonadotropic amenorrhea begins before age 30 years.

If FSH levels are low or normal, the measurement of total testosterone levels may be helpful whether or not there is any evidence of hirsutism or virilization. Hyperandrogenic women need not be hirsute because some have relative insensitivity of the hair follicles to androgens. Mildly increased levels of testosterone (and perhaps dehydroepiandrosterone sulfate as well) suggest polycystic ovary syndrome (PCOS). However, total circulating androgen levels need not be elevated because of the alterations in metabolic clearance rate and sex hormone–binding globulin that are present in PCOS.

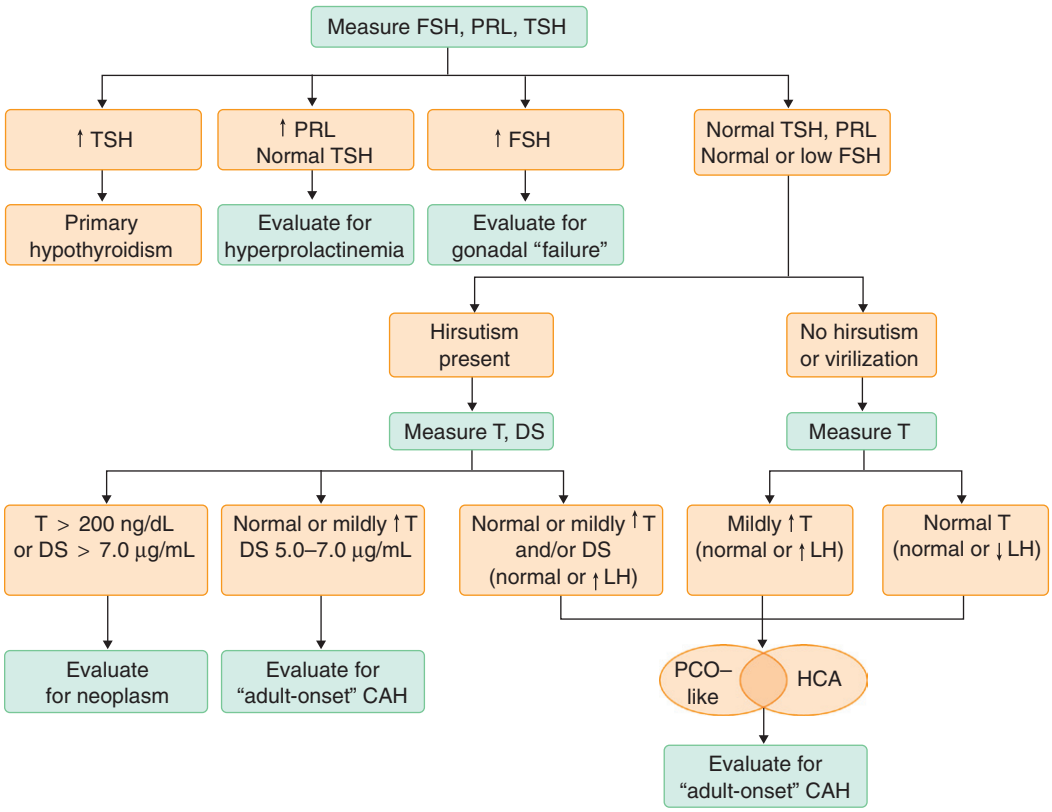

FIGURE 244-3. Biochemical evaluation of amenorrhea. This schema must be considered an adjunct to the clinical evaluation of the patient. See text for details. CAH = congenital adrenal hyperplasia; DS = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; HCA = hypothalamic chronic anovulation; LH = luteinizing hormone; PCO-like = polycystic ovarian syndrome–like; PRL = prolactin; T = testosterone; TSH = thyroid-stimulating hormone.

Consequently, some clinicians prefer to measure circulating free testosterone levels.

Circulating levels of LH and FSH may aid in differentiation of PCOS from hypothalamic-pituitary dysfunction. LH levels are often elevated in PCOS so that the ratio of LH to FSH is increased; however, LH levels may be identical to those observed in normal women in the follicular phase. In contrast, levels of LH and FSH are normal or slightly reduced in hypothalamic-pituitary dysfunction. There is some overlap between women with "polycystic ovarian–like" disorders and those with hypothalamic-pituitary dysfunction. Radiographic assessment of the sella turcica is indicated in all amenorrheic women in whom both LH and FSH levels are consistently low (both below 10 mIU/mL) to exclude a pituitary or parapituitary neoplasm (Chapter 231). Other pituitary functions should be evaluated in any individual with significantly impaired LH and FSH secretion. Both total testosterone and dehydroepiandrosterone sulfate levels should be measured in hirsute or virilized women. Testosterone levels greater than 200 ng/dL should lead to investigation for an androgen-producing neoplasm, most likely of ovarian origin. Dehydroepiandrosterone sulfate levels greater than 7.0 μg/mL should lead to evaluation for an adrenal neoplasm, and levels between 5.0 and 7.0 μg/mL should lead to evaluation for adult-onset congenital adrenal hyperplasia (Chapter 241).

HYPERGONADOTROPIC AMENORRHEA (PRESUMPTIVE OVARIAN FAILURE, PRIMARY HYPOGONADISM, PRIMARY OVARIAN INSUFFICIENCY)

DIAGNOSIS

Differential Diagnosis

Gonadal failure may begin at any time during embryonic or postnatal development and may result from many causes. Normally, the ovaries fail at menopause, when virtually no functioning follicles remain. However, premature loss of oocytes before the age of 40 years may occur and lead to premature ovarian failure. Most causes of premature ovarian failure involve FSH secretion or action. Circulating gonadotropin levels increase whenever ovarian failure occurs because of decreased negative estrogen feedback to the hypothalamic-pituitary unit.

PATHOBIOLOGY

There are several causes for premature ovarian failure, including genetic causes (a growing list that includes karyotypic abnormalities, single gene mutations, and complex multifactorial polygenic inheritance), physical and environmental causes, and autoimmune disturbances. In addition, there may be families in which menopause begins earlier than the expected age without any further pathologic cause.

Genetic Abnormalities

Several pathologic conditions with dysgenetic gonads involve elevated gonadotropin levels and amenorrhea as well as abnormalities of the X chromosome. The term *gonadal dysgenesis* refers to individuals with undifferentiated streak gonads without any association with either extragonadal stigmata or sex chromosome aberrations. Because individuals with gonadal dysgenesis have the normal complement of oocytes at 20 weeks of fetal age but virtually none by birth, this disorder is a form of premature ovarian failure.

Turner's Syndrome

Turner's syndrome (also see Chapter 241) describes patients with streak gonads composed of fibrous stroma and four cardinal features: a female phenotype; sexual infantilism; short stature; and several physical abnormalities, sometimes including webbed neck, low-set ears, multiple pigmented nevi, double eyelashes, micrognathia, epicanthal folds, shieldlike chest with microthelia, short fourth metacarpals, increased carrying angle of the arms, and certain renal and cardiovascular defects (most commonly coarctation of the aorta and aortic stenosis). The diagnosis can sometimes be made at birth because of unexplained lymphedema of the hands and feet. The syndrome is associated with an abnormality of sex chromosome number, morphology, or both. Most commonly, the second sex chromosome is absent (45,X). This is the single most common chromosome disorder in humans, but more than 95% of such fetuses are aborted, and the incidence in newborns is approximately 1 in 3000 to 5000. Chromosome breakage and mosaicism occur as well. In mosaic individuals with a normal 46,XX cell line, sufficient follicles may persist postnatally to initiate pubertal changes and to cause ovulation so that pregnancy is possible. Deletions of the X-chromosome-linked *SHOX* gene explain many of the dysmorphic skeletal features that are present, including the short stature. It is believed that the number of phenotypic findings may be related to the percentage of cells that are 45,X. There may be an effect of imprinting with the variation in phenotype partly explained by the parental origin of the one remaining X chromosome.

Pure Gonadal Dysgenesis

Pure gonadal dysgenesis is the term given to phenotypically female individuals with streak gonads who are of normal stature and have none of the physical stigmata associated with Turner's syndrome. Such individuals have either a 46,XX or 46,XY karyotype. The 46,XX defect may be inherited as an autosomal recessive, with 10% having associated nerve deafness. The 46,XY defect may be inherited as an X-linked recessive, with clitorimegaly occurring in 10 to 15% and gonadal tumors developing in 25% if the gonads are not removed.

Mutations in the X Chromosome Associated with Premature Ovarian Failure

Several regions of the X chromosome are now recognized to contain mutations in genes that may result in premature ovarian failure. Of particular note is the fragile X mental retardation *(FMR1)* gene. More than 5% of women with 46,XX spontaneous premature ovarian failure have mutations of the *FMR1* gene. This risk is increased if there is a family history of premature ovarian failure. A family history of fragile X syndrome, unexplained mental retardation, dementia, developmental delay of a child, or tremor-ataxia syndrome is reason for genetic counseling. Mutations in the *FMR1* gene are known to be associated with a neurodegenerative disorder. Women with mutations in the *FMR1* gene are at risk of having a child with mental retardation, should they be one of the 6 to 8% of women with premature ovarian failure who conceive spontaneously. For *FMR1*, a CGG repeat sequence occurs, with up to 60 repeats being normal. Expansion to more than 200 repeats leads to the fragile X syndrome, with the high level of repeats causing hypermethylation of the gene promoter and silencing of the gene. Female carriers of the permutation have an unstable intermediate number of repeats (i.e., 60 to 199) and the predisposition for premature ovarian failure.

Trisomy X

Trisomy X (46,XXX karyotype) is also associated with premature menopause, although many such individuals have normal reproductive lives. Premature menopause can also occur in mosaic individuals with cell lines with excess X chromosomes. When gonadal abnormalities occur in women with excess X chromosomes, they seem to occur after ovarian differentiation so that some ovarian function is possible. Only later in life do such women develop secondary amenorrhea and premature ovarian failure.

Known Genetic Alterations of Specific Genes

In girls with the rare syndrome of 17α-hydroxylase deficiency involving *p450c17* who survive until the expected age of puberty, sexual infantilism and primary amenorrhea occur together with elevated levels of gonadotropins (also see Chapter 241). Increased synthesis of desoxycorticosterone leads to hypertension with hypokalemic alkalosis; serum progesterone levels are elevated as well. As with other causes of congenital adrenal hyperplasia, the hypertension is controlled by replacement therapy with glucocorticoids (Chapter 241). Defects in the 20,22-lyase *(p450scc)* or aromatase *(p450arom)* enzymes may also lead to ovarian failure. Women with galactosemia also experience ovarian failure early in life, even when a galactose-restricted diet is introduced early in infancy.

Mutations of several autosomal genes result in premature ovarian failure. Included in this growing list are mutations involving *FSHR* (the FSH receptor gene), *FOXL2* (a forkhead transcription factor associated with the blepharophimosis-ptosis-epicanthus inversus syndrome), *INHA* (the inhibin-α gene), *E1F2B* (a family of genes associated with central nervous system leukodystrophy and ovarian failure), *PMM2* (the gene for phosphomannomutase), *GALT* (the gene for galactose-1-phosphate uridyltransferase), and *AIRE* (leading to the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome). Myotonic dystrophy (Chapter 429) is caused by an autosomal triple repeat mutation, like the fragile X syndrome, that is similarly associated with premature loss of germ cells from the ovary.

Mutations Involving Reproductive Hormones, Their Receptors, and Action

The resistant ovary (Savage's) syndrome occurs in young amenorrheic women who have elevated peripheral gonadotropin concentrations, normal

(although immature) follicles present on ovarian biopsy, 46,XX karyotype with no evidence of mosaicism, fully developed secondary sex characteristics, and ovarian resistance to stimulation with human menopausal or pituitary gonadotropins.

At least one form of premature ovarian failure is caused by mutations in the FSH receptor. Affected individuals present with primary or secondary amenorrhea and elevated levels of FSH and may still have ovarian follicles detectable on transvaginal ultrasonography. One specific mutation on chromosome 2p (C566T:alanine to valine) in exon 7 of the FSH receptor has been identified in several Finnish families, but the mutation has not been detected in any other populations.

Other Causes

Physical and Environmental

Irradiation and chemotherapeutic agents used to treat various malignant diseases may also cause premature ovarian failure. Ovulation and cyclic menses return in some of these patients even after prolonged intervals of hypergonadotropic amenorrhea associated with signs and symptoms of profound hypoestrogenism. Rarely, mumps affects the ovaries and causes ovarian failure.

Autoimmune Disorders

Premature ovarian failure may occur in conjunction with a variety of autoimmune disorders. The most well-known syndrome (autoimmune polyglandular syndrome type 1) involves hypoadrenalism, hypoparathyroidism, and mucocutaneous candidiasis together with ovarian failure (Chapter 239). Testing for adrenal antibodies by indirect immunofluorescence will identify the 4% of women with spontaneous premature ovarian failure who have steroidogenic cell autoimmunity and are at risk for adrenal insufficiency. Thyroiditis is the most commonly associated abnormality. Antibodies to the FSH receptor have been identified in a few cases. These associations make it mandatory to rule out other potentially life-threatening endocrinopathies in young women with hypergonadotropic amenorrhea.

TREATMENT Rx

Women with hypergonadotropic amenorrhea and ovarian failure should be treated identically whether or not they have signs of hypoestrogenism or desire pregnancy. Counseling and psychological support are indicated in women in whom the diagnosis of premature ovarian failure is made. Ovarian biopsy is not indicated to document the existence of follicles because only a small portion of each ovary can be sampled and because pregnancies have resulted in patients who had biopsy samples devoid of follicles. Estrogen replacement is warranted to prevent the accelerated bone loss known to occur in affected women (Chapter 251). The estrogen should be given sequentially with a progestin to prevent endometrial hyperplasia. Young women with ovarian failure may require twice as much estrogen as postmenopausal women for relief of signs and symptoms of hypoestrogenism. Inexplicably, women with premature ovarian failure may conceive while taking exogenous estrogen, even in the form of oral contraceptive agents, at the same rate as those not taking estrogen, so barrier contraception should be discussed if pregnancy is not desired.

Women with hypergonadotropic amenorrhea are rarely able to become pregnant. It is not clear why pregnancy may rarely occur in such women, but the spontaneous pregnancy rate is 6 to 8%. Infertility treatment of young women with hypergonadotropic amenorrhea involves hormone replacement to mimic the normal menstrual cycle and embryo transfer by use of donor oocytes. Pregnancy rates are higher than in other women undergoing in vitro fertilization and exceed 30% per cycle. Whether women with gonadal dysgenesis should be offered pregnancy by use of donor oocytes is now the subject of debate because a markedly increased incidence of aortic rupture during pregnancy secondary to medial necrosis has been documented. Women with Turner's syndrome contemplating pregnancy should be counseled regarding the risks.

CHRONIC ANOVULATION

Chronic anovulation, the most frequent form of amenorrhea encountered in women of reproductive age, implies that functional ovarian follicles remain and that cyclic ovulation can be induced with appropriate therapy (Table 244-4). The cause of the anovulation should be determined. The pathophysiologic bases for several forms of anovulation are unknown, but the anovulation can be interrupted transiently by nonspecific induction of ovulation in most affected women. Anovulation can result in either amenorrhea or irregular (generally less frequent) menses.

TABLE 244-4 CAUSES OF CHRONIC ANOVULATION

- Chronic anovulation of hypothalamic-pituitary origin
  - Hypothalamic chronic anovulation
    - Psychogenic
    - Exercise associated
    - Associated with diet, weight loss, or malnutrition
    - Anorexia nervosa and bulimia
    - Pseudocyesis
  - Forms of isolated (idiopathic) hypogonadotropic hypogonadism (including Kallmann's syndrome)
  - Due to hypothalamic-pituitary damage
    - Pituitary and parapituitary tumors
    - Empty sella syndrome
    - Following surgery
    - Following irradiation
    - Following trauma
    - Following infection
    - Following infarction
  - Idiopathic hypopituitarism
  - Hypothalamic-pituitary dysfunction or failure with hyperprolactinemia (multiple causes)
  - Due to systemic diseases
- Chronic anovulation due to inappropriate feedback (i.e., polycystic ovary syndrome)
  - Excessive extraglandular estrogen production (i.e., obesity)
  - Abnormal buffering involving sex hormone–binding globulin (including liver disease)
  - Functional androgen excess (adrenal or ovarian)
  - Neoplasms producing androgens or estrogens
  - Neoplasms producing chorionic gonadotropin
- Chronic anovulation due to other endocrine and metabolic disorders
  - Adrenal hyperfunction
    - Cushing's syndrome
    - Congenital adrenal hyperplasia (female pseudohermaphroditism)
  - Thyroid dysfunction
    - Hyperthyroidism
    - Hypothyroidism
  - Prolactin or growth hormone excess
    - Hypothalamic dysfunction
    - Pituitary dysfunction (microadenomas and macroadenomas)
    - Drug induced
  - Malnutrition

Hypothalamic Chronic Anovulation

DEFINITION

Hypothalamic chronic anovulation (HCA) represents a heterogeneous group of disorders with similar manifestations. Emotional and physical stress, excessive exercise, nutritional deficiencies, weight loss, reduced body fat, and other unrecognized factors may contribute in varying proportions to the anovulation. Women with HCA have normal neuroanatomic findings.

Anorexia Nervosa

Individuals with amenorrhea and significant weight loss should be examined for the possibility of anorexia nervosa (Chapter 226).

Isolated Hypogonadotropic Hypogonadism

Affected individuals have absence of spontaneous pubertal development. Most have functional GnRH deficiency, but some have abnormalities of gonadotropin deficiency localized to the pituitary gland.

Kallmann's syndrome is a familial disorder consisting of gonadotropin deficiency, anosmia or hyposmia, and color blindness in men or, more rarely, in women (Chapter 230). Other midline defects, such as cleft lip and palate, can occur in the affected individual or in family members. The trait is transmitted as an X-linked recessive or a male-limited autosomal dominant trait, but genetic heterogeneity may occur. Partial or complete agenesis of the olfactory bulb is present on autopsy, accounting for use of the term *olfactogenital dysplasia.* The disorder affects only gonadotropin secretion, and all other pituitary hormones are secreted normally. Isolated gonadotropin deficiency in the absence of anosmia occurs as well. Sexual infantilism with a eunuchoid habitus is the clinical hallmark of this disorder, but moderate breast development may occur. Circulating LH and FSH levels are low but almost always detectable. Ovulation induction requires use of exogenous gonadotropins and hCG or pulsatile GnRH. Estrogen replacement therapy

is indicated in these women until pregnancy is desired. It may not be possible to distinguish between partial isolated gonadotropin deficiency and functional HCA in all cases.

There are normosmic individuals with isolated hypogonadotropic hypogonadism as well; the molecular abnormalities identified explain why some individuals are anosmic and others normosmic. The first mutations found in Kallmann's syndrome involve a cell surface adhesive gene, *KAL1*, which prevent normal development of the olfactory bulb and the neurologic tract responsible for transport of GnRH to the median eminence of the hypothalamus. Mutations in several other genes involved in the development of the olfactory bulb and the neurologic tract required for GnRH transport have since been identified. Gene defects in individuals with normal smell include defects in the GnRH receptor gene and the genes responsible for GnRH production *(GNRH1)*, GnRH processing *(PCSK1)*, and GnRH secretion *(GPR54)*.

Gene mutations localized to the pituitary that result in isolated hypogonadotropic hypogonadism include those associated with the GnRH receptor *(GNRHR)* and production of the β-subunit of gonadotropin. Mutations within leptin, the leptin receptor, and *DAX1* genes appear to cause hypogonadotropic hypogonadism within both the hypothalamus and pituitary. These mutations appear to be associated with extreme obesity. There are also a number of mutations associated with both hypogonadotropic hypogonadism and other pituitary or endocrine deficiencies.

Hypopituitarism

Hypopituitarism may be obvious on cursory inspection or sufficiently subtle to require endocrine testing (Chapter 231). The clinical presentation depends on the age at onset, the cause, and the nutritional status of the individual. Failure of development of secondary sex characteristics must always raise the question of hypopituitarism. Ovulation can be induced successfully with exogenous gonadotropins when pregnancy is desired and after the hypopituitarism is treated appropriately. Replacement therapy with estrogen is indicated.

Hyperprolactinemia

Galactorrhea associated with hyperprolactinemia, whatever the cause, almost always occurs together with amenorrhea caused by hypothalamic-pituitary dysfunction or failure. Many conditions can cause excess prolactin secretion (Chapter 231). A prolactinoma must be excluded. Hirsutism may be observed occasionally in association with amenorrhea-galactorrhea and hyperprolactinemia. Elevated levels of the adrenal androgens dehydroepiandrosterone and dehydroepiandrosterone sulfate may be observed and may account for the polycystic-type ovaries present in some hyperprolactinemic women.

Failure of the Hypothalamic-Pituitary Unit

The hypothalamic-pituitary unit may also fail to function normally in a number of stressful, debilitating, systemic illnesses that interfere with somatic growth and development. Chronic renal failure, liver disease, and diabetes mellitus are the most prominent examples.

DIAGNOSIS

Abrupt cessation of menses in women younger than 30 years who have no anatomic abnormalities of the hypothalamic-pituitary-ovarian axis and no other endocrine disturbances suggests a diagnosis of HCA. Affected individuals tend to be bright, educated, and engaged in intellectual occupations and may well give a history of psychosexual problems and socioenvironmental trauma. HCA is characterized by low to normal levels of gonadotropins and relative hypoestrogenism. Rarely, however, do affected women present with signs and symptoms of estrogen deficiency. It is important to rule out a central lesion as the cause of the hypogonadotropic hypogonadism in women who appear to have HCA.

TREATMENT

Rx

Psychological counseling or a change in lifestyle, especially for women engaged in strenuous exercise programs, may be effective in inducing cyclic ovulation and menses in women with functional HCA. Cognitive behavior therapy is effective in a proportion of women with functional HCA. For women desiring pregnancy, ovulation can also be induced with clomiphene citrate (50 to 100 mg/day for 5 days beginning on the third to fifth day of withdrawal bleeding). Treatment with exogenous gonadotropins to induce follicular maturation followed by hCG to induce follicular rupture may be effective in women who do not ovulate in response to clomiphene. Because women with HCA have low circulating levels of leptin, investigators have given recombinant leptin and documented that ovulation may resume in some affected women. Given the heterogeneous nature of the disorder, it is not surprising that exogenous leptin is not effective in all women.

Most physicians advocate the use of exogenous gonadal steroids to prevent osteoporosis. A regimen can consist of daily oral conjugated or esterified estrogens (0.625 to 1.25 mg), ethinyl estradiol (20 μg), or micronized estradiol-17β (1 to 2 mg) or transdermal estradiol-17β (0.05 to 0.10 mg) daily, with oral medroxyprogesterone acetate (5 to 10 mg) added for the first 12 to 14 days of each month. Sexually active women can be given oral contraceptive agents as an alternative. If steroid therapy is administered, patients must be informed that the amenorrhea will probably be present when therapy is discontinued. Other physicians believe that only periodic observation is indicated, with barrier methods of contraception recommended for fertility control. Adequate ingestion of calcium should be ensured regardless of therapy. Contraception is needed for sexually active women with HCA because the functional defect is mild in these disorders and may resolve spontaneously at any time, with ovulation occurring before any episode of menstruation.

Chronic Anovulation Related to Inappropriate Feedback

DEFINITION

PCOS is a heterogeneous disorder in which there is considerable clinical and biochemical variability among affected individuals. PCOS is currently considered to exist in women with any two of the following: (1) oligo-ovulation or anovulation, (2) hyperandrogenism, or (3) polycystic ovaries on ultrasound, and in whom other etiologies have been eliminated.

PATHOBIOLOGY

Current evidence suggests that the hypothalamic-pituitary unit is intact and that a functional derangement, perhaps involving insulin-like growth factors such as IGF-I within the ovary, results in abnormal gonadotropin secretion. PCOS is characterized by insulin resistance and compensatory hyperinsulinemia. The insulin resistance has been found in affected women of many racial and ethnic groups, implying that it is a universal characteristic and that a common defect may be present. There is increasing evidence of specific genetic abnormalities in some women with PCOS.

CLINICAL MANIFESTATIONS

Although patients usually present with amenorrhea, hirsutism, and obesity, affected women may instead complain of irregular and profuse uterine bleeding, may not have hirsutism, and may be of normal weight. Excess androgen from any source or increased extraglandular conversion of androgens to estrogens can lead to the typical findings of PCOS. Included are such diverse disorders as Cushing's syndrome, mild congenital adrenal hyperplasia, virilizing tumors of adrenal or ovarian origin, hyperthyroidism and hypothyroidism, obesity, and primary PCOS with no other recognizable cause.

In the primary syndrome, the irregular menses, mild obesity, and hirsutism begin during puberty and typically become more severe with time. Obesity alone can lead to a polycystic ovarian–like syndrome, with the degree of obesity required to cause anovulation varying widely. The increase in the prevalence of obesity is leading to an increased prevalence of PCOS. All such patients are well estrogenized regardless of whether they present with primary or secondary amenorrhea or dysfunctional bleeding. LH concentrations tend to be elevated, with relatively low and constant FSH levels, but both may be in the normal range for the follicular phase of the menstrual cycle. Levels of most circulating androgens, especially testosterone, tend to be mildly elevated.

DIAGNOSIS

A consensus conference in Rotterdam in 2003 concluded that after exclusion of other etiologies, two of the following three are required for diagnosis of PCOS: (1) hyperandrogenism (clinical or biochemical); (2) oligo-ovulation or anovulation; (3) polycystic ovaries on ultrasound examination or at surgery.

This definition is confusing to clinicians because it implies that hirsute women with polycystic ovaries on ultrasound examination who ovulate regularly should be considered to have PCOS. Moreover, it is clear that polycystic ovaries may be identified on ultrasound examination in normal women. In any case, the aim of the diagnostic evaluation is to rule out any causes (such as neoplasms) that require definitive therapy. Hirsutism should be evaluated as detailed in Chapter 444.

A particularly severely affected subset of women present with marked obesity, anovulation, mild glucose intolerance with high levels of circulating insulin, acanthosis nigricans, hyperuricemia, severe hirsutism, and elevated circulating androgen levels. These women have hyperthecosis of the ovaries, in which the androgen-producing cells in the stromal, hilar, and thecal regions are increased greatly in number. Hyperthecosis should probably be viewed as a part of the spectrum of disorders constituting PCOS.

TREATMENT

Rx

Patients generally require therapy for hirsutism, for induction of ovulation if pregnancy is desired, and for prevention of estrogen-induced endometrial hyperplasia and cancer. No ideal therapy exists; the therapeutic approach must be individualized. The risks for metabolic syndrome, cardiovascular disease, and diabetes mellitus are increased in women with PCOS, presumably at least in part because of the increased androgens and insulin resistance. Moreover, many women have elevated cholesterol levels.

Medical Therapy

In the anovulatory woman not desiring pregnancy who is not hirsute, therapy with intermittent progestin administration (such as medroxyprogesterone acetate, 5 to 10 mg orally for 10 to 14 days each month) or oral contraceptives can be provided to reduce the increased risk for endometrial carcinoma that is present in such a woman with unopposed estrogen. All women using intermittent progestin administration should be cautioned about the need for effective contraception if they are sexually active because these agents do not inhibit ovulation when they are administered intermittently.

Improvements in insulin sensitivity in women with polycystic ovaries, either through lifestyle changes (i.e., exercise and diet) or through pharmacologic intervention, consistently result in improvements in the reproductive and metabolic abnormalities. Resumption of ovulation may occur in up to 60 to 70% of affected women.

The longest and largest published experiences with any agent that improves insulin sensitivity in PCOS is with metformin, a biguanide that functions primarily by suppressing hepatic gluconeogenesis and also improves insulin sensitivity. Its use in PCOS leads to reductions in insulin and androgen levels and resumption of menses in some women. Divided doses of 1500 to 2000 mg/day have proved effective.

Some clinicians advocate giving metformin to all women with polycystic ovaries, whereas others would administer such an agent only to those with documented insulin resistance. Some clinicians also advocate giving metformin first to women who desire pregnancy and then adding an agent to induce ovulation if the metformin proves ineffective. These agents are not approved for use in pregnant women or for the induction of ovulation.

Treatment Considering Pregnancy

Oral contraceptive agents are the first line of therapy for hirsute anovulatory woman not desiring pregnancy and offer protection from endometrial hyperplasia. In women with PCOS desiring pregnancy, clomiphene citrate can be used to induce ovulation. About 75 to 80% conceive with such therapy. In addition to insulin-sensitizing agents, other possible methods of inducing ovulation include use of exogenous gonadotropins and hCG, and laparoscopic ovarian surgery with multiple punctures of the ovary by diathermy or laser. A large clinical trial documented that clomiphene citrate is more effective than metformin in inducing ovulation and resulting in pregnancy; there was no further improvement when the two agents were used concurrently.[1]

Surgical Treatment

Laparoscopic ovarian surgery can achieve unifollicular ovulation or make it easier for medical ovulation induction, but increases the risk for development of ovarian adhesions (themselves leading to infertility). Its use should be restricted to women desiring fertility who do not have funds for ovulation induction or who are unable to undergo the extensive monitoring required for medical ovulation.

Chronic Anovulation Related to Other Endocrine and Metabolic Disorders

Adrenal hyperfunction appears to cause chronic anovulation by inducing a polycystic ovarian-like syndrome secondary to increased adrenal androgen secretion. Both hyperthyroidism and hypothyroidism are associated with a variety of menstrual disturbances, including dysfunctional uterine bleeding and amenorrhea as a result of alterations in the metabolism of androgens and estrogens. These metabolic changes in turn result in inappropriate steroid feedback and chronic anovulation.

Disorders of Folliculogenesis

The luteinized unruptured follicle syndrome and luteal phase dysfunction are believed to arise from disorders of folliculogenesis.

LUTEINIZED UNRUPTURED FOLLICLE SYNDROME

The luteinized unruptured follicle syndrome refers to the development of a dominant follicle without its subsequent disruption and release of the ovum. The abnormality can be diagnosed by ultrasonography or by the absence of evidence of ovulation when the ovary is viewed at laparoscopy. The disorder occurs infrequently and is not a significant cause of infertility. Menstrual cycles in which no ovum is released are characterized by presumptive evidence of ovulation, including biphasic basal body temperatures, secretory endometrium, normal LH surge, and normal progesterone production in the luteal phase.

LUTEAL PHASE DYSFUNCTION

PATHOBIOLOGY

Progesterone secretion in the luteal phase may be reduced in duration (termed *luteal phase insufficiency*) or in amount (termed *luteal phase inadequacy*). More rarely, the endometrium may be unable to respond to secreted progesterone because of the absence of progesterone receptors. These disorders represent causes of infertility (because of inability of fertilized ova to implant) in less than 5% of infertile couples. Abnormalities of the follicular phase, especially in the frequency of gonadotropin pulses, may account for most luteal phase defects. Luteal phase defects may also occur sporadically in normally ovulating women.

DIAGNOSIS

Luteal phase dysfunction may be associated with several clinical entities, including mild or intermittent hyperprolactinemia, strenuous physical exercise, inadequately treated 21-hydroxylase deficiency, and habitual abortion. Luteal dysfunction occurs more commonly at the extremes of reproductive life and in the first menstrual cycles after full-term delivery, abortion, or discontinuation of oral contraceptives. It may also occur during ovulatory cycles induced with clomiphene citrate or exogenous gonadotropins and hCG.

Although it is clear that this disorder exists in rare circumstances, just how and if the diagnosis of luteal phase dysfunction can be made with accuracy has been challenged because it is clear that endometrial biopsy is much more inaccurate than previously believed. The absolute concentration that progesterone must achieve and the length of time progesterone must be increased in the luteal phase to exclude luteal dysfunction are unclear. Luteal dysfunction is extremely rare in women with menstrual cycles longer than 25 days in whom a single random progesterone determination is greater than 15 ng/mL.

TREATMENT

Rx

Treatment of luteal dysfunction is controversial. Any underlying defect should be treated. If subsequent luteal function depends on prior follicular development, modification of follicular development with either clomiphene citrate (25 to 100 mg daily by mouth for 5 days beginning on cycle day 3 to 5) or FSH (75 to 300 IU intramuscularly for 3 to 5 days beginning on cycle day 3 to 5) can be used; hCG (2500 to 5000 IU intramuscularly at 2- to 3-day intervals beginning with the shift in basal body temperature), or progesterone (12.5 mg intramuscularly in oil daily or 25 mg twice a day as rectal or vaginal suppositories) can be used as well. Bromocriptine may correct the abnormality in individuals with hyperprolactinemia. Synthetic progestational agents should not be used to treat luteal phase defects because of their possible association with congenital anomalies. Furthermore, the synthetic progestins produce an abnormal endometrium. None of these agents has been shown to increase the pregnancy rate.

Infertility

DEFINITION

The World Health Organization (WHO) has defined *infertility* as "a disease of the reproductive system defined by the failure to achieve a clinical pregnancy after 12 months or more of regular unprotected sexual intercourse."

Sterility is total inability to reproduce. More than 10% of couples in the United States seek medical assistance for infertility.

The requirements for pregnancy to occur are several:

- The male must produce adequate numbers of normal, motile spermatozoa.
- The male must be capable of ejaculating the sperm through a patent ductal system.
- The sperm must be able to traverse an unobstructed female reproductive tract.
- The female must ovulate and release an ovum.
- The sperm must be able to fertilize the ovum.
- The fertilized ovum must be capable of developing and implanting in appropriately prepared endometrium.

In approximately 40% of cases, infertility is caused by the male (Table 244-5). In one third of couples, more than one cause contributes to the infertility.

Peak age for fertility in the female is 25 years. For nulliparous women of this age, the average time during which unprotected intercourse occurs until conception is 5.3 months. For parous women, the average duration of intercourse until conception is 2.7 months. The reproductive performance of couples is influenced by the ages of the female and male partners, the frequency of intercourse, and the length of time the couple has been attempting to conceive. There is a decline in both female and male reproductive performance after the age of 25 years.

TABLE 244-5 CAUSES OF INFERTILITY AND THEIR APPROXIMATE INCIDENCE

- Male factors (40%)
  - Decreased production of spermatozoa
    - Varicocele
    - Testicular failure
    - Endocrine disorders
    - Cryptorchidism
    - Stress, smoking, caffeine, nicotine, recreational drugs
  - Ductal obstruction
    - Epididymal (after infection)
    - Congenital absence of vas deferens
    - Ejaculatory duct (after infection)
    - After vasectomy
  - Inability to deliver sperm into vagina
    - Ejaculatory disturbances
    - Hypospadias
    - Sexual problems (i.e., impotence), medical or psychological
  - Abnormal semen
    - Infection
    - Abnormal volume
    - Abnormal viscosity
  - Immunologic factors
    - Sperm-immobilizing antibodies
    - Sperm-agglutinating antibodies
- Female factors
  - Fallopian tube disease (20-30%)
    - Pelvic inflammatory disease or puerperal infection
    - Congenital anomalies
    - Endometriosis
    - Secondary to past peritonitis of nongenital origin
  - Amenorrhea and anovulation (15%)
  - Minor ovulatory disturbances (<5%?)
  - Cervical and uterine factors (10%)
    - Leiomyomas and polyps
    - Uterine anomalies
    - Intrauterine synechiae (Asherman's syndrome)
    - Destroyed endocervical glands (after surgery or after infection)
  - Vaginal factors (<5%)
    - Congenital absence of vagina
    - Imperforate hymen
    - Vaginismus
    - Vaginitis
  - Immunologic factors (<5%)
    - Sperm-immobilizing antibodies
    - Sperm-agglutinating antibodies
  - Nutritional and metabolic factors (5%)
    - Thyroid disorders
    - Diabetes mellitus
    - Severe nutritional disturbances
- Idiopathic or unexplained (<10%)

DIAGNOSIS

Couples who complain of infertility merit evaluation regardless of the length of infertility. Evaluation is warranted in all women after 12 months and in women 35 years of age or older after 6 months of regular unprotected intercourse.

The evaluation begins with a detailed history obtained from both partners and physical examinations of both individuals. If possible, the couple should be seen together. Each couple should be questioned together and separately because separate interviews may uncover information that would not be imparted in the presence of the partner.

Initial evaluation for infertility includes assessment of semen; documentation of ovulation by basal body temperature, serum progesterone determination 6 to 8 days before menses, serum thyroid hormone, or (rarely) endometrial biopsy less than 3 days before onset of menses; and evaluation of the female genital tract by hysterosalpingography or sonohysterography. Diagnostic laparoscopy with tubal dye instillation may be performed if results of all previous tests are normal because 30 to 50% of women are found to have endometriosis or tubal disease on surgical evaluation; alternatively, patients with initial normal findings may be merely treated as having idiopathic infertility.

TREATMENT Rx

Treatment must be predicated on the findings of the infertility evaluation. Abnormalities of sperm are difficult disorders to treat. Low sperm count or poor motility is best treated either by donor insemination or in vitro fertilization with intracytoplasmic injection of a single viable sperm into each oocyte. Obstruction of the fallopian tubes may be amenable to surgical intervention, but success rates are often greater with in vitro fertilization. Endometriosis causing infertility may be treated by surgery or various suppressive drugs as indicated; however, here, too, in vitro fertilization may be indicated.

Induction of ovulation is one of the most successful therapies when used in anovulatory women.

Induction of Ovulation in Anovulatory Women and "Controlled Ovarian Hyperstimulation" in Unexplained Infertility

Induction of ovulation should never be attempted until serious disorders precluding pregnancy are ruled out or treated. Furthermore, ovulation induction should not be used in women with ovarian failure because they are unresponsive to any form of ovulation induction.

Clomiphene citrate is the agent that usually induces ovulation most easily. Clomiphene should be used in individuals without hyperprolactinemia who have the ability to release LH and FSH. A typical course of clomiphene therapy is begun on the third to fifth days after either spontaneous or induced uterine bleeding. The initial dosage is 50 mg daily for 5 days. Clomiphene appears to act as an antiestrogen and stimulates gonadotropin secretion by the pituitary gland to initiate follicular development. If ovulation is not achieved in the first cycle of treatment, the daily dosage is increased to 100 mg. If ovulation is still not achieved, dosage is increased in a stepwise fashion in 50-mg increments to a maximum of 200 to 250 mg daily for 5 days. The highest dose should be continued for 3 to 6 months before the patient is regarded as unresponsive to clomiphene. The quantity of drug and the length of time that it can be used, as suggested here, are greater than those recommended by the manufacturers and the FDA but conform to published series.

The ovulatory surge of LH may occur 5 to 12 days (average, 7 days) after the completion of the last day of clomiphene treatment. Couples are advised to have intercourse every other day during this interval. Ovulation can be documented by monitoring changes in basal body temperature or preferably by measuring serum progesterone 14 days after the last clomiphene dose. Menses should occur after 3 weeks. Withdrawal bleeding with progestin can be induced if the patient fails to bleed within 4 weeks of therapy and if a serum hCG level documents that the patient is not pregnant. Testing the urine for an LH surge may also be useful in timing ovulation.

Some clinicians give 5000 to 10,000 IU of hCG intramuscularly 7 days after the last day of clomiphene therapy to trigger ovulation, but this approach has not been established to increase effectiveness. The administration of hCG, however, does serve to time ovulation and may be helpful in selected couples. Ovulation can be expected to occur approximately 36 hours after hCG administration.

Of appropriately selected patients, 75 to 80% ovulate, and 40 to 50% can be expected to become pregnant. About 15% of pregnancies can be expected with each ovulatory cycle. The multiple pregnancy rate is about 8%, with almost all being twins. The incidence of congenital anomalies is not increased.

Side effects of clomiphene are uncommon and rarely serious. The most serious ones include vasomotor flushes (10%), abdominal discomfort (5%), breast tenderness (2%), nausea and vomiting (2%), visual symptoms (1.5%),

and headache (1%). Ovarian enlargement may occur but is rare (5%). Concern has been raised about the potential for clomiphene to increase the risk for epithelial ovarian cancer. The bulk of the evidence now indicates that clomiphene does not increase this risk.

The addition of dexamethasone, 0.5 mg orally at bedtime, to blunt the nighttime secretion of adrenocorticotropic hormone may be useful in hyperandrogenic women who fail to ovulate in response to clomiphene. Other individuals who do not respond to clomiphene typically require exogenous gonadotropins and hCG or perhaps pulsatile GnRH to induce ovulation.

Several studies have documented that aromatase inhibitors appear to be as effective as clomiphene in inducing ovulation, but their used is not approved and should still be considered experimental.

Both bromocriptine and cabergoline are effective in inducing ovulation in hyperprolactinemic women. The drug should be stopped when pregnancy is confirmed. Ovulatory menses and pregnancy are achieved in about 80% of patients with galactorrhea and hyperprolactinemia. Most women with prolactin-secreting pituitary tumors remain asymptomatic during pregnancy. It is rare for a patient with either a microadenoma or a macroadenoma to develop a problem related to the tumor that affects either the mother or the fetus during pregnancy. Monitoring during pregnancy need consist only of questioning the patient about the development of visual symptoms and headaches. Formal assessment of visual fields and computed tomography or magnetic resonance imaging should be carried out in any patient experiencing suggestive symptoms. Symptoms generally abate with institution of therapy with a dopamine agonist. No adverse effects of dopamine agonists on fetuses or pregnancies have been reported. Concerns have been raised that ergot-derived dopamine agonists, in the large doses used in the treatment of Parkinson's disease, may increase the risk for cardiac valve regurgitation. Although there is no evidence of risk in women treated with much lower doses for hyperprolactinemia, they should be counseled about this potential side effect.

Several preparations of purified and synthetic biochemically engineered gonadotropins for use for induction of ovulation now exist. Synthetic preparations consist entirely of FSH, whereas most purified preparations contain some LH as well. Each vial typically contains 75 IU of gonadotropin. Individuals with gonadotropin deficiency require a preparation containing some LH. Exogenous gonadotropins are typically administered at doses of two to four vials (intramuscularly or subcutaneously, depending on the preparation) for 5 to 12 days to achieve follicular development as monitored by ultrasonography and serum or urinary estradiol concentrations; hCG, 5000 to 10,000 IU, is administered as a single intramuscular dose when follicular maturation is apparent. The hCG should be withheld if more than three follicles mature together. GnRH analogues are now being used to suppress endogenous follicular activity before initiation of therapy with exogenous gonadotropins and continued until hCG is given in older women and those with poor responses to exogenous gonadotropins. Use of the analogues necessitates administration of larger doses of exogenous gonadotropins. Success rates, however, appear to be somewhat improved with this combined therapy. Because of the expense and the complication rate, thorough evaluation should be carried out to exclude other causes of infertility before exogenous gonadotropins and hCG are used. Ovulation can be induced in almost 100% of patients, but pregnancy occurs in only 50 to 70%. There is no increased risk for congenital anomalies with exogenous gonadotropins and hCG. The rate of multiple pregnancies with exogenous gonadotropins and hCG may approach 30%, with 5% being triplets or more.

Ovarian hyperstimulation (*ovarian hyperstimulation syndrome*, or OHSS) is the major side effect and may be life-threatening. The ovaries enlarge remarkably, and multiple follicle cysts, stromal edema, and multiple corpora lutea are present. There is a shift of fluid from the intravascular space into the abdominal cavity with resultant hypovolemia and hemoconcentration. The cause of the ascites is unknown. The most serious complications of OHSS may include thromboembolism, renal failure, adult respiratory distress syndrome, and hemorrhage from ovarian rupture. Treatment is conservative, with monitoring of fluid and electrolyte status. Pelvic examinations should not be performed for fear of rupturing the ovaries. The hyperstimulation generally resolves slowly during about 7 days but lasts longer if the cycle results in pregnancy.

GnRH, administered intravenously or, less effectively, subcutaneously at doses of 5 to 20 µg every 60 to 120 minutes, can also be used to induce ovulation in women with an intact pituitary gland. It is most effective in individuals with HCA; hCG can be administered to support the corpus luteum after ovulation at a dose of 1500 IU intramuscularly every 3 days for three or four doses. The advantage of GnRH rests in the fact that hyperstimulation is extremely unlikely. However, reported pregnancy rates have been no greater than those achieved with exogenous gonadotropins and hCG. Furthermore, some patients do not tolerate wearing the infusion pump that must be used. GnRH is not now marketed for this use in the United States.

Use of clomiphene citrate or exogenous gonadotropins together with intrauterine insemination of spermatozoa is increasing in women with unexplained infertility as so-called controlled ovarian hyperstimulation (COH). The intent is to stimulate several oocytes to be ovulated, but multiple (sometimes high-order) gestations are a significant risk. A randomized trial has noted that the risk for multiple gestation and the costs are reduced if COH with gonadotropins is not used and patients are advanced immediately to treatment by in vitro fertilization.[2]

Assisted Reproductive Technologies

The assisted reproductive technologies, in which by definition both eggs and sperm are handled outside of the body, are being used with increasing frequency to treat infertile couples with tubal disease, endometriosis, oligospermia and azoospermia, sperm antibodies, and unexplained infertility. The procedure consists of in vitro fertilization and several variants. In vitro fertilization involves ovarian hyperstimulation, oocyte retrieval, fertilization, embryo culture, and embryo transfer. Ovarian hyperstimulation with clomiphene citrate and exogenous gonadotropins, gonadotropins alone, or a GnRH agonist or antagonist plus gonadotropins typically causes 1 to 20 oocytes to mature, depending on the patient's age and ovarian "reserve." After follicular growth is judged sufficient by ultrasound examination, hCG is given to induce final follicular maturation. About 34 hours after hCG administration, the oocytes are retrieved by direct needle puncture of each follicle, usually transvaginally with ultrasound guidance. The oocytes are then inseminated in vitro with washed sperm, or a single sperm is injected directly into a single egg (so-called intracytoplasmic sperm injection). The embryos are cultured for about 40 to 120 hours, after which one or more embryos are transferred to the uterine cavity. Embryos may be cultured to the blastocyst stage (at 120 hours) before transfer. Additional embryos can be frozen in liquid nitrogen for transfer in a subsequent natural cycle. The success rate is most dependent on the age of the woman. In the United States, the percentage of cycles resulting in live births ranges from 40% in women younger than 35 years to 11.5% in women aged 41 to 42 years. Approximately 30% are twins and 3% are triplets or higher-order multiples. Thus, the greatest current problem with in vitro fertilization involves the number of high-order (three or more) multiples resulting.

It is now possible to test the early embryo for genetic abnormalities by removal of either a single cell (i.e., blastomere) or a polar body from the embryo in vitro and testing it with probes by fluorescent in situ hybridization, with the assistance of polymerase chain reaction, or most recently by comparative genomic hybridization. Identification of normal and abnormal embryos allows only normal embryos to be transferred in families with recognized and testable genetic abnormalities.

SEXUAL FUNCTION AND DYSFUNCTION

Sexual Function

DEFINITION

Sexual responses historically have been divided into four phases: excitement, plateau, orgasm, and resolution. With sexual arousal and excitement, vasocongestion and muscle tension increase progressively, primarily in the genital region, manifested by vaginal lubrication in the female. The lubrication is due to formation of a transudate in the vagina. Sexual excitement is initiated by any of a variety of psychogenic or somatogenic sexual stimuli and must be reinforced to result in orgasm. With continued stimulation, the excitement phase increases in intensity into a plateau phase during which a high state of sexual interest is maintained. The plateau phase may be short or long, and it is from this phase that an individual can shift to orgasm. The orgasmic phase tends to be brief and is characterized by rapid release from the developed vasocongestion and muscle tension. The orgasmic release is also known as the climax because peak psychological and physical intensity is achieved and there is an attendant feeling of satisfaction. Copious secretions and transudate may flow during orgasm in women. Characteristic genital and extragenital responses occur during these phases. Estrogens magnify the sexual responses, but responses may occur in estrogen-deficient women. For women, these changes occur in the breasts and in the pudendal region and are variable from one response cycle to another. For some women, excitement proceeds quickly through plateau to orgasm, and orgasm is explosive and accompanied by vocalization and involuntary contractions of the pelvic skeletal muscles. For other women, the responses are slow in building, controlled in amplitude, and long lasting. For a few women, orgasm never occurs; for many, it is intermittently absent.

The somatic sensate focus enabling orgasmic release is variable and may include stimulation of the breasts, vagina, or clitoris. The psychological aspect of coitus may involve concentration on the current partner or act or fantasies about other times and persons. Although orgasms may vary in physiologic intensity, what is important is psychological satisfaction. Satisfaction for both men and women may be had without orgasm.

Many clinicians have noted several limitations of this traditional human sex response cycle. More and more clinicians and researchers see the cycle as

circular with stimuli of different types leading to arousal. Clinicians in this field now have extended this theory to include desire and arousal. Women seek sexual experiences for intimacy as well as for sexual gratification. Women may be receptive to or seek out sexual stimuli to enhance intimacy. Biologic and psychological factors contribute to the processing of these stimuli and can enhance arousal and desire simultaneously.

Sexual Dysfunction

Women may seek consultation because of disturbances in normal sexual arousal or orgasm. Such sexual dysfunction may be due to either organic or functional disturbances.

A variety of diseases affecting neurologic function, including diabetes mellitus and multiple sclerosis, may prevent sexual arousal. So, too, may local pelvic disorders, such as endometriosis and vaginitis, which cause dyspareunia and lead to sexual avoidance. Estrogen deficiency causing vaginal atrophy and dyspareunia is a relatively common cause of sexual dysfunction. Debilitating systemic diseases such as malignant disease may also affect sexual function indirectly.

In most cases, the cause of sexual dysfunction is psychological. For instance, vaginismus involves involuntary contractions of the muscles surrounding the introitus and leads to dyspareunia. It is a conditioned response engendered by a previous imagined or real traumatic sexual experience. Feelings of guilt (caused by incest or rape, as examples), of inadequacy (caused by hysterectomy or mastectomy), or of depression or anxiety may lead to failure to be aroused. Failure to achieve orgasm may be viewed as a dysfunction if the woman is frustrated or dissatisfied.

TREATMENT

Rx

Treatment of sexual dysfunction should eliminate functional causes and provide the patient, often together with her partner, with appropriate psychological counseling. Behavioral modification is effective in treating many women with psychological sexual dysfunction. In one randomized trial, self-reported sexual satisfaction was increased in women treated with testosterone. However, dosing guidelines are not clear, and the therapy cannot be considered standard care based on current evidence.

APPROACH TO WOMEN'S HEALTH

KAREN FREUND

An approach to the care of women must go beyond an understanding of differences in the incidence of disease between men and women. Providers need to consider the impact of sex differences (those based on genetic and hormonal differences) and gender differences (those attributable to the roles men and women are ascribed in society). Therapeutic decisions should take into account both genetic and environmental differences in the presentation of disease and the effectiveness of therapeutic options, the patient's reproductive life stage, comorbidities, and social and cultural contexts of care. Empirical evidence about care for women has expanded since 1994, when the National Institutes of Health required the inclusion of women as research subjects. The increased number of women participating in clinical research, coupled with initiatives through the Office on Research and Women's Health, has led to a broad expansion of knowledge and a greater recognition of the need for gender-specific data when evaluating the impact of any therapeutic intervention.

LIFESPAN GROUPS

Many important women's health issues are linked to the social, psychological, and biologic context at certain ages and stages of life. When considering both preventive care and common causes of mortality and morbidity, these lifespan stages provide a context for organizing care (Table 245-1).

For the majority of women, young adulthood (15 to 44 years) is marked by social transitions in family structure, such as forming one's own family and parenting, and entering the work force. Mortality rates are low, and health visits can focus on behavioral decisions that will influence the risk for future disease, such as those pertaining to sexual behavior, smoking, alcohol and drug use, diet, and exercise. Major sources of morbidity include intentional and unintentional injury, including interpersonal violence (Chapter 249) and motor vehicle accidents. HIV is a leading cause of morbidity and mortality in this age group. Depression and anxiety are common in this and all life stages. Reproductive issues are considered in most therapeutic decisions.

The middle years (ages 45 to 65 years) continue to be influenced by behavioral decisions, especially diet, exercise, and alcohol and substance use. The social context includes role changes as children reach adulthood and caregiving responsibilities for children and possibly grandchildren, as well as aging parents. The menopausal transition may be accompanied by new symptomatic concerns. Common causes of morbidity, including diabetes and obesity, now reflect earlier behavioral decisions. Cancer is the leading cause of mortality.

Health issues in older women (65+ years) may occur in the context of loss of function and independence, and because women commonly survive their male partners, they are more likely at this stage of life to be single and possibly more isolated. Cardiovascular disease is the major cause of mortality, followed by cancer, cerebrovascular disease, chronic obstructive lung disease, and pneumonia. Loss of independence is related to cognitive decline, osteoarthritis, osteoporotic fractures, and incontinence.

HEALTH DISPARITIES AMONG WOMEN

It is critical to consider the racial and ethnic differences in outcomes for most common causes of mortality and morbidity when addressing the health status of women. American women with a minority racial or ethnic affiliation, including those of African descent (whether born in the United States or abroad), women from many Asian and Pacific Island nations, Native Americans, and women of Latino background, share poorer outcomes for a wide variety of conditions. This broad finding of poorer outcomes across many diverse ethnic and racial groups points away from specific genetic differences in these populations and toward social determinants of health. Minority racial and ethnic affiliation is correlated with lower educational attainment, lower income, residence in neighborhoods with higher crime and more environmental health hazards, and less access to comprehensive health insurance. Common recommendations for health promotion, including a diet low in fats and processed sugars and high in whole grains, fruits, and vegetables along with regular exercise, such as walking, may be difficult to follow in high-crime neighborhoods or in those without markets offering a variety of affordable, nutritious food options. Barriers to health care access and poor adherence to medical therapy are more common in low-income women. For instance, they may have difficulty scheduling appointments that do not interfere with their work schedules or unpaid time off from clerical or service jobs. The need to care for dependent children or elders may interfere with women's ability to address their own health care needs. Lack of health literacy and cultural barriers can create additional barriers (Chapter 5).

COMMON CAUSES OF MORTALITY IN WOMEN

Cardiovascular Disease

Cardiovascular disease (CVD; Chapter 51) is the overall leading cause of death in women. However because CVD-related death occurs most often in women older than 65 years, its impact is often underrecognized or underestimated. Racial ethnicity plays a large role in the risk for CVD; African American women have much higher rates of CVD and death from CVD than any other racial or ethnic group.

The incidence rate of CVD in women lags 10 years behind that of men from ages 40 through 70; that is, a 65-year-old woman has the same risk as a 55-year-old man. There is no abrupt increase in CVD risk at menopause in women, suggesting that menopause and changes in estrogen or progesterone status do not account for this sex difference. Furthermore, randomized clinical trials have confirmed that hormone therapy in women does not prevent CVD and is not indicated for CVD prevention.■ Re-analysis of the Women's Health Initiative confirmed the increased risk of CVD *with* hormone therapy, even when treatment is initiated within 10 years of menopause.■ Other risk factors for CVD in women are the same as those in men: elevated lipids, lack of physical activity, obesity, smoking, hypertension, and diabetes. Women with diabetes have the same risk of CVD as men of the same age with diabetes. Because smoking rates in current cohorts of young women are equal to or exceed those of men of the same age, it is becoming one of the more important behavioral risk factors of CVD in women. The incidence of many known risk factors, including obesity, hypertension, and hypercholesterolemia, is greater in African American women than in white women.

The presentation of coronary disease in women differs from that in men. Although chest pain is the most common presentation in women, atypical and noncardiac pain is a more common presentation in women than in men, and fewer women have typical chest tightness or pressure as their presenting complaint. For this and other reasons, women present for emergency care at a later time than men, which may limit some therapeutic options and increase the severity of disease complications, including congestive heart failure.

Guidelines for the management of lipid disorders in the prevention of CVD are the same for men and women (Chapter 213). The decision to begin pharmacotherapy is based on both the absolute low-density lipoprotein (LDL) level and risk factors for CVD events. Elevated high-density lipoprotein (HDL) levels confer protection and are therefore considered to reduce one's risk. This factor requires particular attention before beginning therapy in many women. Aggressive LDL management to levels below 100 mg/dL (some suggest <80 mg/dL) is recommended for women with diabetes or known vascular disease, including cerebrovascular disease.

Medical management is similar for men and women with acute coronary syndromes, including unstable angina and acute myocardial infarction (Chapter 72). The use of aspirin, β-blockers, angiotensin-converting enzyme (ACE) inhibitors, heparin, and thrombolytic therapy and recommendations for noninvasive testing are the same for women and men. Randomized controlled trial data show that low-risk women with unstable angina or non–ST segment elevation myocardial infarction do not benefit from early revascularization and that medical management is indicated.■

Type 2 Diabetes

The rates of type 2 diabetes (Chapter 237) continue to rise, with a greater risk in women who are overweight or obese and physically inactive. Rates are higher in many racial and ethnic groups than among white women, including African Americans, Asians, Native Americans, and Latinas. Although most guidelines do not currently recommend universal screening, given the high rates of undiagnosed diabetes, screening women for known risk factors (e.g., obesity, family history) seems prudent. For women who develop gestational diabetes (Chapter 247), the risk of developing type 2 diabetes later in life increases five-fold; therefore, screening with fasting glucose testing at least biennially is indicated.

TABLE 245-1 IMPORTANT HEALTH ISSUES FOR WOMEN THROUGH THE LIFESPAN

	Ages		
ISSUE	**15-44 YEARS**	**45-65 YEARS**	**65+ YEARS**
Behavioral issues	Risk behaviors Sexual behavior Smoking Alcohol and drug use Exercise Diet	Risk behaviors Smoking Alcohol and drug use Exercise Diet	Risk behaviors Smoking Exercise
Social roles	Entering work force Relationship transitions Parenting	Caregiving to several generations Transitions in family and work environments	Losses and social isolation
Reproductive issues	Reproductive health issues	Menopause transition	
Injury	Intentional and unintentional interpersonal violence Motor vehicle accidents		Falls
Common causes of mortality and morbidity	Depression Anxiety HIV/AIDS	Cancer Obesity Diabetes Depression Anxiety	Cardiovascular disease Cancer Cognitive decline Osteoporosis Osteoarthritis Incontinence Depression Anxiety

The incidence of diabetes is rising in women at younger ages, with significant perinatal implications. Ongoing discussion of fertility control and family planning is critical in diabetic women with childbearing potential. Tight glycemic control before conception and through the first trimester is critical to reduce the risk of birth anomalies, and it is important later in pregnancy to reduce the risk of adverse fetal events, including macrosomia (large for gestational age) and preterm birth (Chapter 247). Ideally, women planning a pregnancy should switch from oral agents to insulin, with home glucose monitoring for tight control (Table 245-2).

Cancer

Cancer is the leading cause of death in women 40 through 65 years, and it is the leading cause of years of life lost in women younger than 65. Breast cancer (Chapter 204) is the most common type of cancer and the second leading cause of cancer death in women, although most women who develop breast cancer do survive. Studies indicate that many women significantly overestimate their personal risk of the disease. The lack of understanding of the cause of most breast cancers and the limitations and uncertainties of the imaging modalities used as screening tests have limited efforts at breast cancer control. After decades of an increasing incidence of breast cancer in the United States, incidence rates have fallen in the past 3 to 5 years. The cause of this decline is not understood; reduced use of postmenopausal hormone therapy and recent declines in screening rates have both been implicated.

Lung cancer (Chapter 197) is the leading cause of cancer death in women, and rates continue to rise, commensurate with the number of women who took up smoking in the 1940s and 1950s and the lower rates of smoking cessation in women compared with men. Most lung cancers are smoking related, although women are more likely than men to have lung cancers that are not tobacco related. There is no effective screening modality for lung cancer.

Colorectal cancer (Chapter 199) has a similar incidence in both women and men. Testing for occult blood in the stool, sigmoidoscopy, and colonoscopy are effective at detecting precancerous lesions and thereby reducing rates of both new cancers and later-stage disease.

Ovarian cancer (Chapter 205) is relatively rare, with 21,500 cases in the United States annually, but mortality is high owing to its presentation at late stages in most cases. Lower abdominal or pelvic pain, urinary symptoms, and changes in bowel habits are nonspecific and common in many women, limiting the ability to detect this cancer at an early stage. There is no effective screening test for women at average risk. CA-125 has both low sensitivity and low specificity, with normal levels in early-stage disease and elevations with nonmalignant ovarian pathology. Recent studies suggest that serial CA-125 levels in postmenopausal women may have increased predictive value.

The greatest recent advance in cancer prevention is the development of vaccines against the most carcinogenic subtypes of human papillomavirus (HPV) associated with cervical cancer (Chapters 205 and 381) and anal cancer. The vaccine has the potential to reduce significant morbidity caused by the management of premalignant lesions, including the risk of cervical incompetence and preterm labor. New guidelines advocate delaying Pap test screening in women until age 21 years and increasing the screening interval to every 2 years in women aged 20 to 29 years and every 3 years in women 30 years and older if previous screening has demonstrated no high-risk subtypes of the HPV.

Osteoporosis

Hip fracture due to osteoporosis (Chapter 251) is one of the major causes of disability, loss of independence, and mortality in older women. Osteoporosis prevention through calcium and vitamin D intake and weight-bearing exercise begins at puberty and extends throughout adulthood. Women require a calcium intake of 1000 mg/day, increasing to 1300 mg in puberty and breast-feeding and 1200 mg after menopause, in order to maintain the structural strength of bone. Vitamin D is a necessary element for the absorption of calcium, and it is available through direct sun exposure or vitamin D supplementation of milk (not other dairy products) and some juices. Epidemiologic data suggest widespread vitamin D deficiency in women in the United States. This is attributed to low levels of dietary replacement, decreased sun exposure with the use of sunscreens, and lack of vitamin D production in the skin (even with sun exposure) in northern climates during the winter months. Screening for a single baseline serum 25-hydroxyvitamin D level can provide women with useful information about the adequacy of their diets, with levels above 30 ng/mL considered sufficient or ideal. Short-term, high-dose therapy consisting of 50,000 IU/week for 12 weeks is recommended in women with serum 25-hydroxyvitamin D levels less than 20 ng/mL, followed by daily replacement with 600 to 800 IU. Daily replacement of vitamin D of 600 IU is recommended for women, with 800 IU recommended after age 70.

Although no long-term outcome data exist on the benefits of dual-energy x-ray absorptiometry (DXA) screening (DEXA bone densitometry), many advocate a single screen within 2 years of menopause and a follow-up 2 to 5 years later to determine both absolute bone density and rate of loss. An algorithm to assess risk of bone fracture based on DXA and individual risk factors is available through the World Health Organization and can guide decision making on preventive therapy. Long-term estrogen therapy is not recommended for osteoporosis prevention. Initial enthusiasm for bisphosphonate therapy has been tempered by reports of rare but debilitating jaw osteonecrosis (Chapter 256). This complication has been seen in women with and without risk factors, such as dental disease. Raloxifene, a selective estrogen receptor modulator, has the benefits of preventing osteoporosis while reducing breast cancer risk without increasing the risk of CVD; it has been underutilized as a preventive agent.

COMMON CAUSES OF MORBIDITY IN WOMEN

Obesity

Obesity rates continue to rise, and the prevalence of obesity is higher in women than men, especially among minority and low-income women (Chapter 227). Dietary reduction in calories and increased caloric output with aerobic exercise are the short- and long-term strategies for care. Studies suggest that no single diet is superior to others, and many common diet strategies can reduce weight. Increasing activity during the course of one's daily routine is as effective as shorter intervals of more strenuous activity. The most effective programs include a combination of behavioral therapy, either individually or in groups, to address behavioral patterns in food intake, along with diet and exercise. Weight loss targets of 1 to 2 lb/week and a total loss of up to 5 to 10% of body weight are realistic goals. Even modest changes in weight and modest increases in physical activity reduce morbidity and mortality on a population basis.

Exercise and diet changes are difficult for many people to achieve, for a wide variety of reasons. The physical environment may not be conducive to

TABLE 245-2 PREFERRED MEDICATIONS FOR WOMEN OF REPRODUCTIVE POTENTIAL

COMMON CONDITIONS IN WOMEN OF REPRODUCTIVE POTENTIAL	ISSUES TO BE AWARE OF	PREFERRED MEDICATIONS OR GROUPS OF MEDICATIONS
Depression	Must consider effects of untreated depression on mother and infant Paroxetine may cause congenital heart defects	Avoid newer medications when older drugs with more information are available SSRIs are generally considered safe; fluoxetine is preferred, with most safety data
Anxiety	Commonly associated with depression in women	Benzodiazepines are not associated with cleft lip and have no known harmful effects; choose those with shorter half-life
GERD	No data on harmful effects of either H_2-blockers or PPIs Misoprostol is contraindicated; can cause miscarriage, fetal death, congenital anomalies	Calcium-containing antacids are first-line therapy H_2-blockers preferred over PPIs
Acne	Oral isotretinoin and topical tazarotene are contraindicated owing to congenital defects	Most other topical agents are considered classes B and C
Asthma	Extensive data on safety of common drug categories: benefit ratios far exceed risk in treating women	Cortisone inhalers Systemic prednisone for flares Short- and long-acting bronchodilators
Seizure disorders	Difficult to separate effects of medication from effects of seizure on fetal development All agents associated with some increased risk of fetal abnormality (4-8%, compared with 1-2% in general population)	Monotherapy at lowest doses recommended Avoid medication changes in first trimester Folate supplementation in preconception period
Hypertension (not preeclampsia)	ACE inhibitors and ARBs are contraindicated in pregnancy; possibly associated with cardiovascular and neurologic anomalies in first trimester; may cause abnormalities in renal hemodynamics in third trimester Most data suggest thiazide diuretics are safe if stable use before pregnancy	β-blockers, especially labetalol, and methyldopa are first-lines choices Calcium-channel blockers are also considered safe
Lipid disorders	Circulating lipid levels are elevated with pregnancy and breast-feeding.	No medications during pregnancy; ideally, stop statins before conception
Analgesics for fever and pain management	Controversy about whether NSAIDs slightly increase risk of miscarriage in first trimester	Acetaminophen preferred; aspirin also considered safe
Headache	Controversy about whether NSAIDs slightly increase risk of miscarriage in first trimester	Acetaminophen preferred; aspirin also considered safe
Diabetes	First-generation sulfonylureas contraindicated in pregnancy; may cause fetal hyperinsulinemia and birth defects	Conversion to insulin during planned preconception period Insulin, metformin, and glyburide preferred in women of childbearing potential
Autoimmune conditions	Must weigh benefits of immunosuppressive use against potential risks to both mother and infant Methotrexate is contraindicated in pregnancy, as it induces miscarriage No data on safety or risk of TNF and IL-1 inhibitors	Prednisone generally considered safe in pregnancy Azathioprine, sulfasalazine, cyclosporine, and hydroxychloroquine generally preferred if required
Tobacco control	Cigarette smoking has known harmful effects on fetus In one small randomized controlled trial, nicotine replacement was associated with reduced levels of nicotine and improved birth outcomes Bupropion is linked with reports of some fetal anomalies	Try nonpharmacologic approaches to cessation first Short course of nicotine replacement likely better for fetus than smoking
Polycystic ovarian disease	Metformin can restore ovulatory cycles; use with contraception	
Bacterial infections	Tetracyclines accumulate in fetal bone and teeth Sulfa drugs may increase risk of neural tube defects with use in first trimester and kernicterus with use in third trimester Trimethoprim interferes with folic acid metabolism Streptomycin and kanamycin associated with bilateral deafness	Penicillins, cephalosporins, erythromycin, azithromycin

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; GERD = gastroesophageal reflux disease; IL-1 = interleukin-1; NSAID = nonsteroidal anti-inflammatory drug; PPI = proton pump inhibitor; SSRI = selective serotonin re-uptake inhibitor; TNF = tumor necrosis factor.

physical activity owing to the sedentary nature of most workplaces, the lack of safe areas to exercise, and architectural design features, such as the lack of easy access to stairs instead of elevators. The use of prepared foods and the consumption of fast foods, high in fat and calories and low in nutritional content, increase the risk obesity.

There are currently no evidence-based interventions to support weight reduction in the setting of a brief office visit. Most guidelines focus on assessing body mass index (BMI) in all women and recommending weight reduction with diet restriction and exercise, including behavioral therapy to support these behavioral changes. For obese women with a BMI greater than 40, or those with a BMI greater than 35 and major comorbidities such as diabetes, sleep apnea, or osteoarthritis, bariatric surgery (Chapter 227) is indicated once other weight loss methods have failed. Bariatric surgery leads to short- and long-term benefits in multiple comorbidities and reduced mortality due to improvements in comorbidities. Critical to the success of this intervention is a team approach, with psychological assessment and diet and exercise programs beginning before and continuing after surgery.

Depression

Major depression and other related disorders, including dysthymia, predominate in women (Chapter 404). Multiple short screening tools have been developed to identify depression. Women with depression are highly likely to come to the attention of the health care system, for two reasons. First, chronic medical conditions are associated with higher rates of depression and are treated by both generalists and specialists. Depression is a significant comorbidity in many chronic medical conditions affecting both younger and older women. Screening for depression should be considered for women with chronic medical conditions, and management of depression is necessary to prevent adverse outcomes from these conditions. Second, somatic complaints are a common presentation of depressive disorders and are more

common in women than in men. All specialties are likely to see patients with unexplained symptoms, such as chest pain, headache, abdominal pain, and other complaints. It is critical to include depression as either a primary or a secondary diagnosis and to treat depression as part of the overall management plan.

Anxiety Disorders

Anxiety disorders also predominate in women. They commonly coexist with depressive disorders. Anxiety disorders, including post-traumatic stress disorder, may be a consequence of violence against women, which often remains unidentified (Chapter 249). Benzodiazepines have been demonstrated to be safe and effective in trials for short-term use. Selective serotonin re-uptake inhibitors (SSRIs) and behavioral therapies are effective for the long-term management of anxiety disorders.

Osteoarthritis

Osteoarthritis (Chapter 270) is one of the most common causes of morbidity and functional status limitation, especially as women age. Assessment of pain and functional status is at the core of management. Physical and occupational therapy to restore functional status is a critical component of care. Joint replacement (Chapter 285) should be considered and recommended when functional status interferes with activities of daily living and supportive care and other symptom management strategies are ineffective.

Smoking

Tobacco use, most commonly cigarette smoking, continues to be one of the major preventable causes of morbidity and mortality in women (Chapter 31). Although there has been much progress in smoking cessation efforts, lower-income women and younger women continue to start smoking and fail to quit smoking at high rates. In the 1990s more teenage girls than teenage boys started to smoke, and more than 25% of teenage girls became smokers owing to increased marketing to teens generally and to girls specifically. With community- and school-based efforts to promote tobacco control and the increased cost of cigarettes through taxes, smoking rates for girls and boys are now the same, with about 18% of teens smoking. Public health efforts and resources to promote smoking cessation are highly effective. Health care providers can achieve 1 to 2% smoking cessation rates by asking all patients about their smoking status and making a simple statement encouraging smokers to quit. Further gains in smoking cessation are possible with targeted counseling, which involves assessing the patient's stage of readiness to change and providing counseling relevant to that stage.

Nicotine replacement is equally effective in women and men. Smokers with a physiologic addiction to nicotine (those who smoke more than one pack daily or smoke within 20 minutes of awakening) benefit the most from nicotine replacement. Many women report weight gain as a major barrier to smoking cessation. Chapter 31 describes approaches to smoking cessation.

Incontinence

Urinary incontinence (Chapter 25) is a frequently overlooked cause of major functional status limitations in middle-aged and older women. As many as half of affected women underreport this problem to their physicians and alter their lifestyles to adapt to the problem, including reducing fluid intake, avoiding activities that exacerbate the problem, or restricting travel where access to facilities is uncertain. There are two broad categories of incontinence—stress incontinence and urge incontinence—although women commonly have aspects of both types. Stress incontinence is defined as leaking with increases in intra-abdominal pressure, such as occurs with sneezing or coughing as well as running or walking. The most common reasons are pelvic floor laxity, often from childbirth. Kegel exercises are frequently recommended but are of limited value. A number of surgical procedures are available to address this condition. Less invasive procedures may be tried first, include the fitting of a vaginal pessary or periurethral injections with biodegradable materials such as collagen or with nonbiodegradable materials. Urge incontinence, described as detrusor muscle instability, results in the urge to void with low volumes. Anticholinergic medications and bladder training are both effective. Urodynamic evaluation should be considered if the history does not clearly identify a cause.

HIV Disease

The risk factors for HIV disease in women are heterosexual contact in 80% of new cases and injection drug use in 20%. HIV continues to affect minority women disproportionately, with 61% of incident cases affecting African American women. Incidence rates remain lower in women than in men, with only 27% of incident cases affecting women; in large part, this is due to the fact that male-to-male sexual contact continues to account for 72% of new cases in men. However, the absolute number of new infections from heterosexual contact is twice as high in women as it is in men. Women with HIV/AIDS continue to have poorer survival than men, despite the availability of antiretroviral therapies. Some data suggest that women are less likely than men to adhere to an antiretroviral therapy regimen. The gender difference in therapy adherence was associated with caring for dependent children in one study, suggesting that women's caregiving roles may be a barrier to their own care. Cervical and anal dysplasia and cancer are more common among women with HIV than those without. Therefore, annual Pap tests are recommended for all women with HIV infection, even in the absence of positive HPV testing. There is insufficient evidence to support anal screening for dysplasia, but providers should be aware of the increased risk and perform an external examination for evidence of lesions.

REPRODUCTIVE HEALTH ISSUES

All providers caring for women with reproductive potential should consider the reproductive implications of preventive and therapeutic decisions. With half of all pregnancies in the United States unplanned, providers should routinely inquire about contraceptive practices and consider these in their care plans.

All primary care providers should be comfortable counseling patients about contraceptive choices and prescribing oral contraceptives. The absolute contraindications to oral contraceptives are a personal history of CVD, thromboembolic disease, or gynecologic or breast cancer. A family history of cancer is not considered a contraindication; in fact, data suggest that the use of oral contraceptives decreases the risk of both endometrial and ovarian cancer. Smoking while using oral contraceptives increases the risk of thromboembolic events in all women, but especially in those older than 30 years. Oral contraceptive use is considered safe in nonsmoking women until menopause. Although factor Leiden V has been associated with an increased risk of deep vein thrombosis in those taking oral contraceptives, the absolute risk to any woman is still very low; therefore, screening for this and other genetic thrombophilias is not indicated. Preexisting hypertension is a relative contraindication to oral contraceptive use. Some women develop elevated blood pressures on oral contraceptives; therefore, blood pressure should be monitored at 3 months after starting the drug and then annually.

Providers should consider the reproductive implications of all chronic medications in women of reproductive potential (Chapter 247). Given that the teratogenic effects of medications may occur during the first trimester and before an initial obstetric assessment, the principle when choosing chronic medications for women during their reproductive years is to select those with the greatest safety profile during the first trimester of pregnancy. Table 245-2 outlines common drug categories and recommendation for use in pregnancy.

Antidepressant medications deserve particular attention because of the conflicting data regarding their use in pregnancy. Some initial reports suggested that antidepressants, especially paroxetine, were associated with congenital defects; however, further study suggests that other medications are safe, with fluoxetine having the most data. For women who wish to take no medication during pregnancy, the recommendation is to gradually reduce the dosage over the course of several weeks and not to abruptly stop taking the medication. The risk of untreated depression during pregnancy and the risk of postpartum depression to the woman and her infant are substantial. Therefore, treatment goals should be to provide adequate dosing to prevent the worsening of depression during this period.

CONTRACEPTION

DANIEL R. MISHELL JR.

CONTRACEPTIVE USE AND EFFECTIVENESS

Contraceptive Use

Reversible contraception, the temporary prevention of fertility, includes all contraceptive methods except sterilization. Sterilization should be considered permanent despite the possibility of surgical reversal. There are advantages and disadvantages of each contraceptive method. During contraceptive counseling, these advantages and disadvantages should be thoroughly explained so that the individual will choose the most acceptable method and not discontinue use prematurely and have an unwanted pregnancy.

In the United States in 2006-2008 (the latest years for which data are available), there were about 61.8 million women in the reproductive age group (15 to 44 years), and 38 million (62%) were using a method of contraception. Of the remainder, about 2% were sterile (prior hysterectomy), 9% were pregnant or trying to conceive, and 19% were never sexually active or had no recent sexual activity. About 7.3% of women who were sexually active were not using a method of contraception, an increase from the 5.2% incidence of this group in 1995.

In the United States in 2006-2008, the most common methods of fertility prevention were oral contraceptives (OCs) and female sterilization, used by 17.3% and 16.7% of women aged 15 to 44 years, respectively. Next in frequency of use was the male condom (10.0%), followed by male sterilization (6.1%). The injectable progestin was used by 2.0%, but the intrauterine device (IUD), the most effective method of reversible contraception, was used by only 3.4%. Between 1982 and 2006-2008, there was a marked decrease in diaphragm use and an increase in condom use. Between 2002 and 2006-2008, diaphragm use virtually disappeared, IUD use tripled, and condom use stabilized. About 80% of reproductive-age women who have had intercourse have used OCs at some time.

Contraceptive Effectiveness

Despite an increased use of contraceptive methods by U.S. women since 1982, more than half the pregnancies that occur are unintended. Of the 6.4 million pregnancies that occurred in the United States in 2002 (the most recent data available), about half were unintended, and 42% of these pregnancies were terminated by elective abortion. Of the women with an unintended pregnancy, 50% stated they were using a method of contraception in the month they conceived.

Typical Use versus Perfect Use

The terms *method effectiveness* and *use effectiveness* (or *method failure* and *patient failure*) were previously used to describe the frequency of conceptions that occurred while the method was being used correctly or incorrectly. These terms have been replaced by the terms *typical use* and *perfect use*. Methods used at the time of coitus have higher failure rates than OCs, implants, injections, IUDs, and sterilization. Cumulative failure rates for use of long-acting methods are low. The cumulative pregnancy rate for 5 years' use of the levonorgestrel-releasing IUD is 0.5% and for 10 years' use of the copper T380 IUD is 1.7%. The cumulative failure rate of all types of tubal sterilization is 1.31% during the first 5 years after the procedure and 1.85% after 10 years, being highest for tubal fulguration and lowest for segmental resection. When women conceive while using these long-acting methods, the ectopic pregnancy rates are high: about 30% with tubal sterilization failure and 5% with copper IUD failure.

TYPES OF CONTRACEPTIVES

Spermicides and Barriers

All spermicidal agents contain a surfactant, usually nonoxynol 9, that immobilizes or kills sperm on contact. They also provide a mechanical barrier and need to be placed into the vagina before each coital act. There is no increased risk for birth defects in the offspring of women who conceive while using spermicides.

Diaphragm

A diaphragm must be carefully fitted by the health care provider. The largest size that does not cause discomfort or undue pressure on the vagina should be used. The diaphragm should not be left in place for more than 24 hours because it may cause ulceration of the vaginal epithelium. Diaphragm users have an increased risk for urinary tract infection.

Male Condom

Use of the latex male condom by individuals with multiple sex partners should be encouraged because it is the most effective way to prevent sexually transmitted infections (Chapter 293). The natural membrane condoms do not prevent sexually transmitted infections, but polyurethane condoms do.

Female Condom

The female condom consists of a soft, loose-fitting prelubricated sheath and two flexible polyurethane rings. The female condom can be inserted before beginning sexual activity and left in place for a longer time than the male condom after ejaculation occurs. Because the female condom covers the external genitalia, it may prevent transmission of genital herpes. Because polyurethane is stronger than the latex used in most male condoms, the female condom is less likely to rupture. Both polyurethane and latex prevent virus transmission and should reduce the risk for acquiring human immunodeficiency virus infection.

Oral Steroid Contraceptives

There are three major types of OC formulations: fixed-dose combination, combination phasic, and daily progestin. The combination formulations are the most widely used and most effective. They consist of tablets containing both an estrogen and a progestin, usually given continuously for 3 weeks. No steroids are given for the next 7 days (except for one formulation in which estrogen alone is given for an additional 5 days), after which time the active combination is given for an additional 3 weeks. Three formulations provide active tablets for 24 days with 4 days of inactive tablets. Other formulations provide active tablets for 84 days followed by 7 days without active tablets or a low dose of estrogen to allow withdrawal bleeding. The endometrium usually begins to slough 1 to 3 days after steroid ingestion is stopped, causing withdrawal bleeding, which usually lasts 3 to 4 days. The uterine blood loss with OC use averages about 25 mL per cycle, less than the 35 mL average for ovulatory cycles.

Constituents and Action

All formulations are made from synthetic steroids. There are two major types of synthetic progestins: derivatives of 19-nortestosterone (which are used in OCs) and derivatives of 17α-acetoxyprogesterone (pregnanes). Pregnanes are structurally related to progesterone and are used in injectable contraceptives but are not used in OCs.

The 19-nortestosterone progestins used in OCs are of two major types, estranes and gonanes, and both have androgenic activity. The estranes currently used in several OCs are norethindrone and its acetates, norethindrone

acetate and ethynodiol diacetate. Gonanes have greater progestational activity per unit weight than estranes, and thus a smaller amount of these progestins is used in OC formulations. One other progestin that is structurally related to spironolactone has been formulated in an OC. This progestin is called drospirenone and has antimineralocorticoid and antiandrogenic activity as well as progestational activity without androgenic activity.

With the exception of a daily progestin-only formulation, the progestins are combined with varying dosages of three estrogens, ethinyl estradiol and its 3-methyl ether, mestranol, as well as one agent with estradiol valerate. The estrogen-progestin combination is the most effective type of OC formulation because these preparations consistently inhibit the midcycle gonadotropin surge and thus prevent ovulation. The progestin-only formulation has a lower dose of progestin than the combined agents and does not consistently inhibit ovulation, even though it is ingested every day. Both types of formulations also act on the cervical mucus and tubal motility to interfere with sperm transport. Progestins also alter the endometrium so that if fertilization occurs, implantation may be prevented. For contraceptive effectiveness to be maintained with the combination formulations, it is important that the pill-free interval be limited to no more than 7 days. This is best accomplished by ingestion of either a placebo or an iron tablet daily during the steroid-free interval.

Metabolic Effects

The synthetic steroids in OC formulations have many metabolic effects in addition to their contraceptive actions. These effects can cause the more common, less serious side effects as well as the rare, serious complications. The magnitude of these effects is directly related to the dosage and potency of the steroids in the formulations.

Symptoms Due to Estrogen and Progestin

The most frequent symptoms produced by the estrogen component include nausea, breast tenderness, and fluid retention (bloating). The progestins can produce certain androgenic effects, such as weight gain, acne, and nervousness. Because estrogens decrease sebum production, women who have acne should be given a formulation with a low progestin-to-estrogen ratio. Unscheduled (breakthrough) bleeding is usually produced by insufficient estrogen, too much progestin, or a combination of both. This problem is more common with formulations containing 20 μg of estrogen than with those containing 30 to 35 μg and is increased in women who also smoke cigarettes. Shortening the pill-free interval to 3 or 4 days should prevent ovarian follicular development and may decrease the incidence of unscheduled bleeding with low-estrogen formulations.

The synthetic estrogens used in OCs cause an increase in the hepatic production of several proteins. The progestins do not affect protein synthesis except to reduce levels of sex hormone–binding globulin. Some of the proteins that are increased by ethinyl estradiol, such as factors V, VIII, and X and fibrinogen, have the potential to enhance thrombosis, whereas an increase in angiotensinogen levels may elevate blood pressure in some users. Blood pressure should be monitored in all users of OCs and the agent discontinued if there is a clinically significant increase. The incidence of both venous and arterial thrombosis in OC users is higher with 50-μg estrogen formulations than with those with 20 to 35 μg of estrogen.

Glucose and Lipid Metabolism

The effect of OCs on glucose metabolism is directly related to the dose, potency, and type of progestin. Although high-progestin formulations caused peripheral insulin resistance, the low-progestin formulations in current use do not significantly alter levels of glucose, insulin, or glucagon after a glucose load. High-progestin formulations have an adverse effect on the lipid profile; because of the direct beneficial effect of estrogen on the arterial wall and serum lipids, however, users of these agents do not have an increased risk for cardiovascular disease. The newer combination formulations with less androgenic progestins have a more favorable effect on the lipid profile.

Complications and Risk Factors

Thrombosis

The cause of the increased incidence of both venous and arterial cardiovascular disease in users of OCs is thrombosis, not atherosclerosis. The background rate of venous thrombosis and embolism in women of reproductive age is about 0.8 per 10,000 woman years. Among users of OCs with 30 or 35 μg of ethinyl estradiol, it is 3 per 10,000 woman years, about four times the background rate but half the rate of 6 per 10,000 woman years that occurs in association with pregnancy. The risk for venous thrombosis and embolism is higher among women ingesting OCs with 50 μg of ethinyl estradiol than those with 30 to 35 μg. In the presence of an inherited coagulopathy disorder (Chapter 179), the risk for venous thrombosis is increased several-fold. It is not recommended that screening for coagulation deficiencies be undertaken before women are started on OC use unless the individual has a personal or family history of thrombotic events. Women with known inherited or acquired thrombophilic conditions should not use estrogen-containing steroid contraceptives in pills, rings, or patches because each of these agents has thrombophilic effects. Some epidemiologic studies have found that the risk for venous thromboembolism is greater in individuals ingesting OCs with the newer less androgenic progestins than those containing levonorgestrel with the same amount of estrogen. However, other studies have reported that the risk is similar with formulations containing these two types of progestins. These studies are all observational and thus subject to bias.

Myocardial Infarction

The use of high-dose OCs by women who smoke cigarettes significantly increases the risk for myocardial infarction. Therefore, combination OCs should not be prescribed to women older than 35 years who smoke cigarettes or use alternate forms of nicotine. Epidemiologic studies indicate that use of low-dose OCs by nonsmoking women without hypertension is not associated with a significantly increased incidence of either myocardial infarction or hemorrhagic or thrombotic stroke.

Delayed Fertility

For about 2 years after the discontinuation of contraceptives, the rate of return of fertility is slightly lower for users of OCs than for users of barrier methods. OCs do not cause permanent infertility or adversely affect pregnancies that occur after their discontinuation. OCs are not teratogenic if they are accidentally ingested during pregnancy.

Breast Cancer

An analysis of worldwide epidemiologic data in 1988 showed that the risk for breast cancer diagnosis was increased by about 25% in young women who were currently using OCs, but this increased risk was no longer present 10 years or more after they stopped using OCs. Several studies have reported that use of OCs by women with a family history of breast cancer does not increase their risk of developing breast cancer (Chapter 204). A large study of women aged 35 to 64 years in the United States reported that there was no significantly increased risk for breast cancer among current and former OC users compared with women who had not used OCs. A very large cohort study in Great Britain of OC users and aged-matched nonusers was initiated in 1968. Data accumulated until 2004 showed a similar incidence of breast cancer in both groups.

Cervical Cancer

The epidemiologic data regarding the risk for invasive cervical cancer as well as cervical intraepithelial neoplasia and OC use are conflicting. Most well-controlled studies indicate that there is no change in risk for cervical intraepithelial neoplasia with OC use. However, it is likely that a causal relationship exists between OC use and a reported increased risk for cervical adenocarcinoma. OC users need annual cervical cytologic screening (Chapter 205).

Endometrial Cancer

Several studies have shown that the use of OCs has a protective effect against endometrial cancer. Moreover, the decrease in risk persists for many years after OCs are stopped. Women who use OCs for at least 1 year have a 50% reduced risk for endometrial cancer development between the ages of 40 and 65 years compared with nonusers. This protective effect is related to duration of use, increasing from a 20% reduction with 1 year of use to a 60% reduction with 4 years of use.

Epithelial Ovarian Cancer

In addition, OCs reduce the risk for development of epithelial ovarian cancer as well as cancers with low malignant potential. The magnitude of the decrease in risk is directly related to the duration of OC use, increasing from about a 40% reduction with 4 years of use to a 60% reduction with 12 years of use. The protective effect continues for at least 20 years after the use of OCs ends. As with endometrial cancer, the protective effect occurs only in women of low parity (fewer than four), who are at greatest risk for this type of cancer. Studies have reported that OCs significantly reduce the risk for development of colorectal cancer by about 20%.

Benign Hepatocellular Adenoma

The development of a benign hepatocellular adenoma was a rare occurrence in long-term users of high-dose OCs containing mestranol, but it is not increased by use of ethinyl estradiol OCs. There is no increased risk for liver cancer associated with OC use.

Contraindications

The OCs can be prescribed for most women of reproductive age. An absolute contraindication is a history of vascular disease, including systemic diseases that affect the vascular system, such as lupus erythematosus and diabetes with retinopathy or nephropathy. Cigarette smoking by a woman older than 35 years and uncontrolled hypertension are also contraindications, as are a personal history of cancer of the breast or endometrium and cholestatic jaundice of pregnancy. Pregnancy and any undiagnosed cause of uterine bleeding are also contraindications. Women with functional heart diseases should not use OCs because the fluid retention could result in congestive heart failure. There is no evidence, however, that individuals with asymptomatic mitral valve prolapse should not use OCs. Women with active liver disease should not take OCs. However, women who have recovered from liver disease, such as viral hepatitis, and whose liver function test results have returned to normal can safely take OCs. The presence of migraine headaches without aura is not a contraindication to OC use, but if auras are present, combination OCs should not be prescribed because of a possible increased risk for stroke. Relative contraindications to OC use include undiagnosed causes of amenorrhea and depression. OC use does not increase the risk for development of malignant melanoma or prolactin-secreting pituitary adenomas. In 2004, the World Health Organization established eligibility criteria for women with various medical problems for use of all types of contraception except female and male sterilization. Medical eligibility for each contraceptive was classified into four categories: (1) no restriction for use of the method, (2) advantages of use outweigh risks, (3) risks outweigh the benefits, (4) the method represents an unacceptable health risk. These criteria were updated in 2008 and are available on the Internet (see Suggested Readings). In 2010, the United States Centers for Disease Control and Prevention created the United States Medical Eligibility Criteria for Contraceptive Use, an adaptation of the WHO criteria. These criteria are also available on the Internet.

Initiation of Therapy and Surveillance

If a healthy woman has no contraindications to OC use, it is unnecessary to perform any laboratory tests, including cervical cytology, before use unless these are necessary for routine health maintenance. Routine use of laboratory tests is not indicated unless the woman has a family history of diabetes or arterial vascular disease at a young age, in which case a fasting glucose or lipid panel should be obtained. After the first three cycles of OC use, a nondirected history should be obtained and blood pressure measured. After this visit, the woman should be seen annually; at each visit, a nondirected history should again be taken, blood pressure and body weight measured, and a physical examination (including breast, abdominal, and pelvic examination with cervical cytology) performed. It is not necessary to measure lipids, other than the routine cholesterol screening every 5 years, in women with no cardiovascular risk factors, even if they are older than 35 years. There is no reason to discontinue OC use unless pregnancy is desired. Intermittent discontinuation is unnecessary and may result in an unwanted pregnancy.

Although synthetic sex steroids can retard the biotransformation of certain drugs (e.g., phenazone and meperidine) as a result of substrate competition, such interference is usually not important clinically. However, some drugs can interfere clinically with the action of OCs by inducing liver enzymes that convert the steroids to more polar and less biologically active metabolites. These drugs include barbiturates, sulfonamides, cyclophosphamide, griseofulvin, and rifampin. There is a high incidence of OC failure in women ingesting rifampin, and these two agents, as well as systemic griseofulvin, should not be given concurrently. Products containing St. John's wort reduce contraceptive effectiveness and cause breakthrough bleeding. Women taking certain medications for epilepsy should be treated with 50-μg estrogen formulations because many antiepileptic medications lower ethinyl estradiol levels and cause breakthrough bleeding, which may cause premature discontinuation of use. Because of their many health benefits, including reduction in risk for endometrial and ovarian cancer and induction of regular cyclic uterine bleeding, OC use can be continued until menopause in normotensive nonsmoking women without contraindications.

Transdermal and Intravaginal Steroid Contraceptives

Transdermal Patch

Two novel long-acting methods of delivering contraceptive steroids other than the oral route are marketed in the United States. One of these is a transdermal patch with an area of 20 cm^2, which delivers 150 μg of the progestin norelgestromin, the active metabolite of norgestimate, and 20 μg of ethinyl estradiol daily into the systemic circulation for 7 days. After this time span, the patch is removed and another is attached to a different area of the skin. The steroids are absorbed into the circulation at a constant rate, yielding fairly constant circulatory levels of each steroid while the patch is attached. This pharmacodynamic pattern differs from the peaks and valleys of steroid levels that occur after ingestion of an OC. After three patches are applied, no patch is used for the fourth week to allow withdrawal bleeding. Contraceptive efficacy, bleeding patterns, and side effects are similar to those associated with OCs, but in one comparative study, compliance was better with the patch than with the OC.

Intravaginal Ring

Another method of administering contraceptive steroids at a constant rate is by use of a flexible vaginal ring, which is 58 mm in outside diameter and 4 mm thick. The ring is composed of ethinyl vinyl acetate and contains the progestin etonogestrel and ethinyl estradiol. The rings are all the same size and do not have to be fitted. The ring is inserted and removed by the woman herself and is left in place for 3 weeks, after which time it is removed for 1 week to allow withdrawal bleeding. Each day, 120 μg of etonogestrel and 15 μg of ethinyl estradiol is released from the ring, and bleeding with the ring in place is uncommon. Contraceptive efficacy and side effects are similar to those of OCs.

Injectable Steroid Contraceptives

Constituents and Use

Several types of injectable steroid formulations are in use for contraception throughout the world. The one most widely used in the United States is depot medroxyprogesterone acetate (DMPA). The initial formulation of this contraceptive was administered as an intramuscular injection of 1 mL of an aqueous suspension containing 150 mg of crystalline medroxyprogesterone acetate once every 3 months. A recently developed formulation that is administered subcutaneously (DMPA-SC) contains 105 mg of DMPA in 0.15 mL of solution. This lower dose formulation has a lower peak medroxyprogesterone acetate concentration than DMPA and a long duration of action that suppresses ovulation for at least 13 weeks and is not affected by body mass. Other injectable contraceptives include norethindrone enanthate, given in a dose of 200 mg every 2 months, and several once-a-month injections of combinations of different progestins and estrogens. DMPA has a low failure rate, 0.1% at 1 year and 0.4% at 2 years. The major contraceptive action of both formulations is inhibition of ovulation, and they also impede sperm transport. With DMPA and DMPA-SC, serum medroxyprogesterone levels rapidly increase to contraceptively effective blood levels (>0.5 ng/mL) within 24 hours after the injection. With DMPA, medroxyprogesterone levels plateau for about 3 months, after which there is a gradual decline until levels become undetectable 7 to 9 months after the injection. With DMPA-SC, medroxyprogesterone levels steadily decline after the initial peak and reach 0.2 ng/mL 3 to 4 months after the injection.

Side Effects

With both formulations, mean endogenous estradiol levels remain above the postmenopausal range (40 to 60 pg/mL), and symptoms of estrogen deficiency do not occur. Although DMPA may decrease bone mineral density during use, it is unnecessary to measure bone mineral density or to administer bone antiresorptive agents in DMPA users because the bone loss is temporary and reversible after stopping DMPA.

Because of the lag time it takes to clear DMPA from the circulation, resumption of ovulation is delayed for a variable time after the last injection. It may take as long as 1 year for ovulatory cycles to return. After this initial delay, fecundity resumes at a rate similar to that found after discontinuation of a barrier contraceptive.

Disruption of the Menstrual Cycle

The major side effect of DMPA is complete disruption of the menstrual cycle. Because this formulation contains only a progestin, without an estrogen, endometrial integrity is not maintained, and usually light uterine bleeding occurs at irregular and unpredictable intervals. As duration of therapy increases, the incidence of frequent bleeding steadily declines and the

incidence of amenorrhea steadily increases, so that at the end of 2 years, about 70% of users are amenorrheic. Women who use this method of contraception should be counseled about this. Most DMPA users gain between 1.5 and 4 kg in their first year of use and continue to gain weight thereafter. If weight gain occurs, calorie intake should be decreased. Because there is no estrogen in DMPA, its use does not cause hypertension or thromboembolism.

In cycling women, the initial injection should be given no later than day 5 of the cycle to be certain to inhibit ovulation in the initial treatment cycle. The first injection should be given within 5 days after delivery in nonlactating women but not until after 6 weeks in lactating women. Because the major reason for discontinuance of all progestin-injectable contraceptives is menstrual irregularity, several combined progestin-estrogen injectables that are given once monthly and produce regular withdrawal bleeding have been developed.

Subdermal Implants

Constituents and Use

Several types of subdermal implants containing only progestins are effective long-acting methods of contraception. The initial formulation that was marketed consisted of six 3.4-cm polydimethylsiloxane (Silastic) capsules, each containing 36 mg of levonorgestrel, and was very effective.

A formulation containing levonorgestrel in two 4-cm Silastic rods has a pharmacologic pattern similar to that of the six capsules with similar effectiveness and side effects. The two rods are easier to insert and to remove than the six capsules and are effective for 5 years. A single 4-cm by 2-mm ethylene vinyl acetate rod containing 68 µg of etonogestrel, the active metabolite of desogestrel, provides effective contraception for 3 years. This rod is packaged in a disposable metal trocar inserter and does not require a skin incision for insertion, only for removal. Ovulation is inhibited by the circulating etonogestrel levels, and no pregnancies were reported in three large clinical trials. As with other progestin-only implants, irregular bleeding is the most common clinical complaint. This implant has recently become available in the United States and is the only implant currently marketed in the United States.

Emergency Contraception

For a woman not using contraception, if emergency contraception is given within 72 hours after a single coitus, about 75 to 85% of pregnancies will be prevented. If more than one episode of coitus has occurred, or if treatment was initiated later than 72 hours after coitus, the method is less effective. Previously, the most commonly used regimen was ingestion of four tablets of the OC containing 50 µg of ethinyl estradiol and 0.5 mg DL-norgestrel, in doses of two tablets 12 hours apart. The pregnancy rate with this regimen is 2%, about one fourth that of the 8% expected rate. Another formulation consisting of a 750-µg single tablet of levonorgestrel given once every 12 hours is more effective than the two tablets of the combination steroid formulation without the estrogenic side effects. This formulation prevents about 85% of the expected pregnancies, for a pregnancy rate of 1 to 3%. A single dose of 1500 µg of levonorgestrel is as effective as two doses of 750 µg and both formulations are now marketed. Another recently approved effective agent for emergency contraception is the selective progesterone receptor modulator ulipristal acetate given as a single 30-mg dose. This agent is as affective as levonorgestrel and is effective for 5 days after intercourse.

Intrauterine Devices

Constituents and Use

The main benefits of IUDs are a high level of effectiveness, a lack of systemic metabolic effects for copper IUDs, and the need for only a single act of motivation for long-term use. Despite these advantages, only about 3% of reproductive-age women use the IUD in the United States, compared with 15 to 30% in most European countries and Canada. The copper T380A IUD is approved for use in the United States for 10 years and maintains its high levels of effectiveness for at least 12 years. A levonorgestrel-releasing IUD is also marketed in the United States and elsewhere. A dose of 20 µg of levonorgestrel diffuses from the device into the endometrial cavity each day. Because of the progestational effect on the endometrium, the amount of uterine bleeding is markedly reduced with use of this device, and it is approved to treat menorrhagia. This device has a high level of effectiveness for 5 years, which is the approved duration of use.

The main mechanism of contraceptive action of copper-bearing IUDs is spermicidal. This effect is caused by a local sterile leukocytic response produced by the copper as well as the plastic IUD. The levonorgestrel-releasing IUD acts mainly by preventing transport of spermatozoa through the cervical mucus and thus preventing fertilization of the ovum. After removal of each type of IUD, the inflammatory reaction rapidly disappears and resumption of fertility is prompt.

Pregnancy Rate

In the first year of use, IUDs have less than a 1% pregnancy rate, a 10% expulsion rate, and a 15% rate of removal for medical reasons, mainly bleeding and pain. The incidence of each of these events, especially expulsion, diminishes steadily in subsequent years. Mefenamic acid ingested in a dosage of 500 mg three times a day during the days of menstruation has been shown to reduce significantly the amount of uterine bleeding in IUD users.

Side Effects

Development of acute salpingitis more than a month after insertion of the IUD is due to infection with a sexually transmitted pathogen and is unrelated to the presence of the device. All IUD-related upper genital tract infections occur only during the insertion process. If there is clinical suspicion that cervicitis is present, the endocervix should be cultured and the insertion delayed until the results reveal that no pathogenic organisms are present. It is not cost-effective to administer antibiotics routinely with IUD insertion.

The IUD is not associated with an increased incidence of either endometrial or cervical carcinoma. The IUD is a particularly useful method of contraception for women who have completed their families, and its effectiveness is similar to that of tubal sterilization. It was calculated that after 5 years of use, the IUD is the most cost-effective of all methods of contraception, including sterilization.

COMMON MEDICAL PROBLEMS IN PREGNANCY

KAREN ROSENE-MONTELLA

INTRODUCTION

There are 62 million women of childbearing age in the United States, 85% of whom will give birth by age 44 years. The majority of these women will not have obtained preventive health services in any given year, and more than half the pregnancies will be unplanned or unintended. At least 25% will enter pregnancy with a chronic medical illness, and more than half will be overweight or obese, making the role of the internist paramount in maternal health. In the most recent confidential inquiry into maternal mortality in the United Kingdom, more than half of all women who died from direct or indirect causes were overweight or obese, and more than 15% of all deaths were in morbidly obese women. Sixteen percent of pregnant women have depression in the perinatal period, and depression rates are even higher in those with chronic illnesses such as diabetes or asthma.

By the time pregnant patients are seen by their obstetricians, most major teratogenic abnormalities have already occurred (Fig. 247-1), and the window of opportunity to enter pregnancy in a quiescent disease state, on the safest possible medication profile, may have passed. For this reason, internists

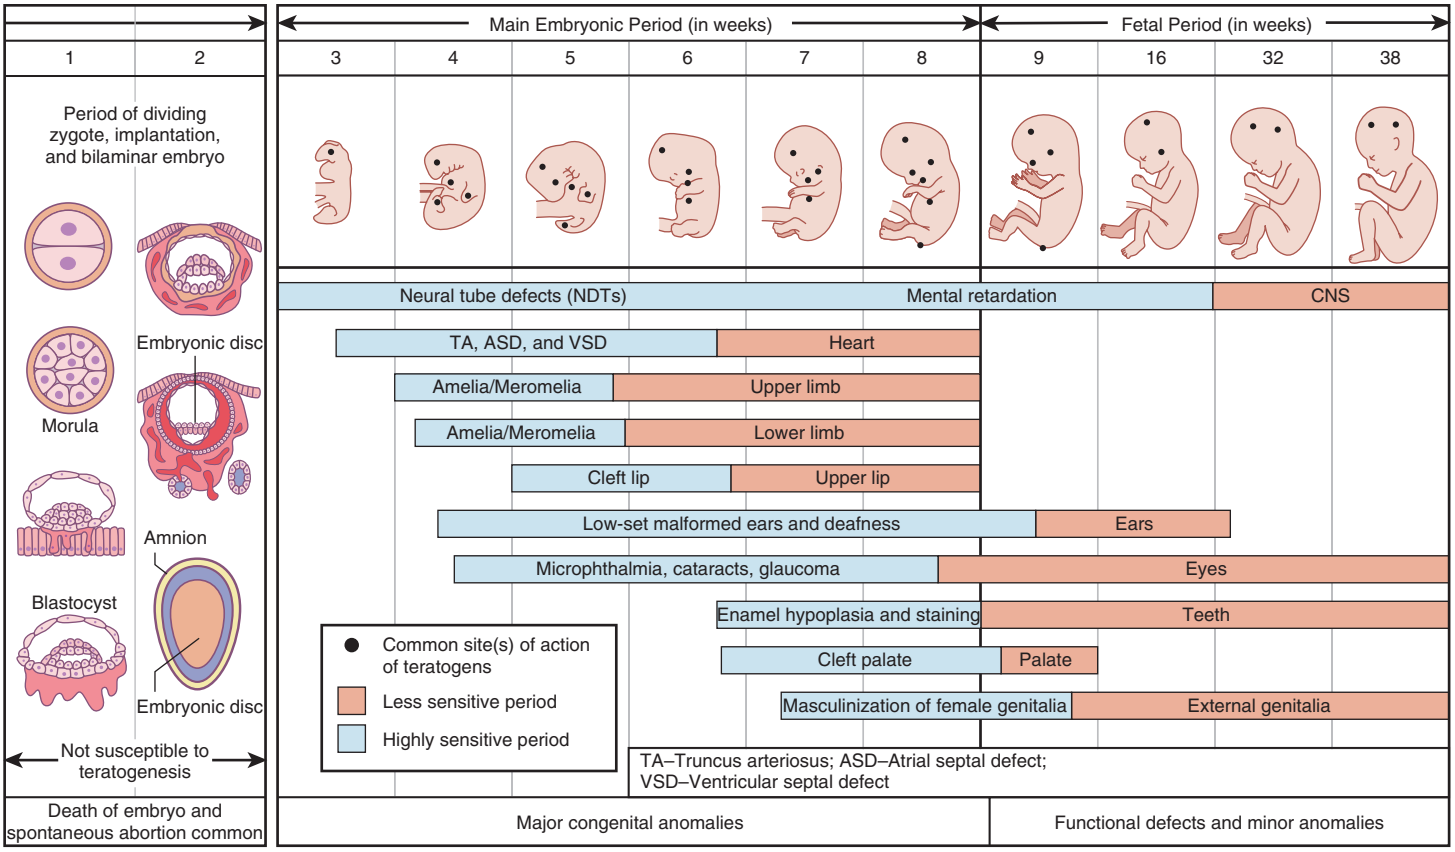

FIGURE 247-1. The developing fetus. CNS = central nervous system. (From Moore K. *The Developing Human: Clinically Oriented Embryology*. caring for women of childbearing age have a unique responsibility to provide preconception care at a time when interventions will be of maximum benefit to both the fetus and the mother. Table 247-1 describes preconception interventions for women with chronic medical illnesses.

The basic principles involved in the care of pregnant patients with medical disorders are reviewed here, followed by a more detailed discussion of certain medical conditions, selected because of their contribution to maternal mortality or because of the frequency with which they occur.

BASIC PRINCIPLES

Pregnancy is associated with significant but normal physiologic changes that impact the diagnosis and management of disease states and the pharmacokinetics of most drugs (Table 247-2). The physiologic changes required during pregnancy may stress the woman's ability to adapt, particularly in the presence of an underlying disease. The mother's response to pregnancy often unmasks diseases or predicts future risk, so pregnancy is an opportunity to identify women at risk for other non-pregnancy-related illnesses. For example, gestational diabetes is predictive of an increased risk for type 2 diabetes; preeclampsia is predictive of increased risk for ischemic heart disease and stroke; and thrombosis, late fetal loss, or preeclampsia may unmask an underlying thrombophilia.

Fetal well-being depends on maternal well-being. Although there is often thought to be a dichotomy between maternal and fetal needs, they are usually one and the same. The fetus is dependent on maternal perfusion, oxygenation, and nutrition. Thus, more harm may be done by withholding necessary treatments and investigations from pregnant women than by providing them. Uninvestigated symptoms lead to the progression of untreated disease, and untreated maternal disease compromises fetal safety, growth, and development. The major cause of asthma exacerbations and seizures during pregnancy is abrupt discontinuation of medications, exposing the fetus to hypoxemia and acidosis in an effort to save the fetus from drug exposure. In the U.K. Confidential Enquiry, in more than half the cases of maternal death from pulmonary embolism, failure to make the diagnosis was due to the unfounded fear that diagnostic testing would be harmful to the fetus. Most diagnostic imaging can be used safely in pregnancy. The effects of radiation in utero depend on both the gestational age at exposure and the level of exposure. Recommendations on fetal exposure from the National Commission on Radiation Protection (NCRP) are summarized in Table 247-3. Radiation exposure from specific diagnostic tests is provided in Table 247-4.

The effect of contrast agents is related to the bioavailability of iodine, and there is concern about the impact on the fetal thyroid. Iodine availability is extremely low, and single-dose exposures, even if they are high, are unlikely to be harmful. Therefore, contrast agents may be used when necessary. There are limited data on gadolinium, so the current recommendation is to avoid gadolinium exposure if possible.

The use of medications to treat pregnant women requires a rational risk-benefit analysis and a good understanding of the maternal indications. It is helpful to view treatment as justifiable or not justifiable, rather than as safe or not safe. It is important to consider (1) whether the condition is self-limited or harmless, (2) what the maternal and fetal consequences of discontinuing a medication will be, and (3) the safety data for the drug. U.S. Food and Drug Administration categories may be misleading and often do not include adequate data for a proper risk-benefit analysis. Resources such as the Teratology Information Service, TERIS, found at *http://departments.washington.edu/-terisweb/teris*, offer more complete information.

The list of known human teratogens is small and includes warfarin, cyclophosphamide, diethylstilbestrol, lithium, thalidomide, penicillamine, isotretinoin, methotrexate, acetazolamide, and the antiepileptic drugs phenytoin, carbamazepine, phenobarbital, and valproic acid. Of these, valproate has the most significant data, and it is the only antiepileptic drug for which discontinuation during pregnancy is recommended, if there is an effective alternative. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) should be added to this list, based on new data confirming that first trimester exposure is associated with fetal renal agenesis and renal failure. Tetracyclines should be avoided owing to later effects on fetal teeth and bone. Resources for prescribing drugs during pregnancy are listed in Suggested Readings.

TABLE 247-1 PRECONCEPTION INTERVENTIONS FOR WOMEN WITH MEDICAL ILLNESSES

TYPE 1 AND TYPE 2 DIABETES
Discuss importance of a normal hemoglobin A_{1C} before conception and importance of contraception until that is achieved
Evaluate for microvascular complications
Obtain remission for proliferative retinopathy
Emphasize need to discontinue ACE inhibitor after first missed period
Discontinue thiazolidinediones and statins
Consider change to insulin therapy for type 2 diabetic patients on oral agents unless using metformin for ovulation induction in PCOS
Discuss probable need to reduce insulin dose in first trimester
THYROID DISEASE
Screen for hypothyroidism in women at risk
Normalize TSH and free T_4 before pregnancy
Counsel women taking levothyroxine on probable need to increase dose soon after conception
Diagnose cause of hyperthyroidism and consider ablative therapy for women with Graves' disease requiring high doses of PTU
CHRONIC HYPERTENSION/RENAL DISEASE
Rule out secondary causes of hypertension if appropriate
Evaluate extent of end-organ disease
Quantify GFR and proteinuria
Discuss drugs of choice for hypertension and replace ACE inhibitor
Discuss risk of superimposed preeclampsia and use of low-dose aspirin for women at significant risk of preeclampsia
THROMBOEMBOLIC DISEASE
Consider evaluation for congenital or acquired thrombophilias in women with previous VTE, previous poor obstetric outcome, or family history
Discuss risks of warfarin in pregnancy, need to discontinue warfarin by 4-6 weeks' gestation, and conversion to unfractionated or low-molecular-weight heparin
Discuss options to combined oral contraceptives
EPILEPSY
Determine whether patient is a candidate for withdrawal of antiepileptic drugs
Consider monotherapy with most effective agent at lowest dose possible
Prescribe folate at 1 to 4 mg/day
Discuss possible ineffectiveness of low-dose contraceptives with phenobarbital, phenytoin, and carbamazepine
Consider discontinuing valproate
CARDIAC DISEASE
Obtain baseline echocardiography if congenital disease, stenotic lesion, or pulmonary hypertension suspected
Evaluate for coronary artery disease in women with multiple risk factors
ASTHMA
Verify patient's asthma action plan and peak flowmeter use
Discuss relative safety of all asthma medications except leukotriene modifiers
SYSTEMIC LUPUS ERYTHEMATOSUS AND AUTOIMMUNE DISEASE
Evaluate for renal and cardiopulmonary disease and antiphospholipid, anti-Ro, anti-La antibodies
Avoid pregnancy if disease is active
Discuss relative safety of most immunosuppressants

ACE = angiotensin-converting enzyme; GFR = glomerular filtration rate; PCOS = polycystic ovary syndrome; PTU = propylthiouracil; T_4 = thyroxine; TSH = thyroid-stimulating hormone; VTE = venous thromboembolism.

TABLE 247-2 NORMAL PHYSIOLOGIC CHANGES IN PREGNANCY

CARDIAC
Cardiac output increased 40%
Blood volume increased 30-50%
Heart rate increased 10-20 beats/min
Blood pressure decreased 10-15 mm Hg
ECG changes related to widened thorax, dextrorotation of heart, elevation of diaphragm
PULMONARY
Upper airway hyperemia and glandular hyperactivity leading to increased edema and friability
Nasal congestion, gestational rhinitis, snoring
Difficult airway management and failed intubation
Minute ventilation increased (owing to an increase in tidal volume, *not* respiratory rate, which remains unchanged), which leads to relative respiratory alkalosis (pH 7.4-7.45)
Normal Pa_{O_2} 100-105 mm Hg
Normal Pa_{CO_2} 28-32 mm Hg
RENAL
Increased GFR to 150-180 mL/min/1.73m^2
Normal serum creatinine <0.8 mg/dL
Increased renal excretion of bicarbonate, limiting buffering capacity in patients who become acidotic
Decreased oncotic pressure
ALTERED PHARMACOKINETICS
Increased renal and hepatic clearance of drugs
Altered absorption
Altered protein binding
Increased volume of distribution

ECG = electrocardiogram; GFR = glomerular filtration rate.

TABLE 247-3 NATIONAL COMMISSION ON RADIATION PROTECTION (NCRP) RECOMMENDED PREGNANCY EXPOSURES

TOTAL EXPOSURE DURING PREGNANCY (RADS)	NCRP RECOMMENDATIONS
≤5	Acceptable; low likelihood of problems
5-10	Low risk for problems
10-15 (at ≤8 wk gestation)	Higher risk; consideration of termination
>15	Termination of pregnancy recommended

HYPERTENSIVE DISORDERS OF PREGNANCY

DEFINITION

Hypertension in pregnancy is defined as a blood pressure (BP) of 140/90 mm Hg or higher. It is defined as chronic hypertension when it predates pregnancy, is diagnosed before 20 weeks' gestation, or persists post partum. Transient late or gestational hypertension occurs toward term and resolves post partum in the absence of any other signs or symptoms of preeclampsia.

EPIDEMIOLOGY

Chronic hypertension is the most common medical condition encountered in women of childbearing age. The incidence is increasing parallel to the

increase in obesity, insulin resistance, and pregnancies in women older than 30 years. Hypertension complicates 5 to 8% of pregnancies and is associated with a 20% risk for the development of preeclampsia.

PATHOBIOLOGY

Systemic arterial BP decreases by 10 to 15 mm Hg during normal pregnancy, with a greater fall in diastolic than systolic pressures, likely owing to the decreased sensitivity to angiotensin II that has been demonstrated in pregnant women. BP begins to fall in the first trimester, reaching a nadir toward the end of the second trimester and returning toward baseline at term. This decrease may be exaggerated in women with chronic hypertension, making the diagnosis of chronic hypertension very difficult during pregnancy and affecting both diagnostic and therapeutic considerations.

DIAGNOSIS

The diagnosis of hypertension relies simply on a BP measurement, in the sitting position at the level of the heart, of 140/90 or greater on two occasions 6 hours apart. Later in pregnancy, inferior vena cava compression by the gravid uterus may lower BP substantially in the supine position, so it is critical to measure maternal BP in the sitting position. The initial evaluation should also document target organ damage, such as left ventricular hypertrophy, renal disease (creatinine, urinalysis, and potassium), and retinopathy, so that a baseline is established. Consideration of secondary causes is necessary in this young population (Chapter 67), but the diagnosis of secondary causes of hypertension is complicated by normal pregnancy-related changes. The diagnosis of Cushing's syndrome is complicated by increased levels of cortisol and the placental production of adrenocorticotropic hormone and corticotropin-releasing hormone, so the best test is a 24-hour urine free cortisol using higher pregnancy-specific reference ranges. Primary hyperaldosteronism (Chapter 234) may also be difficult to diagnose in the face of normal pregnancy-related elevations in plasma renin activity and aldosterone, because progesterone ameliorates both the hypertensive and the kaliuretic effects of aldosterone. Primary hyperaldosteronism should be strongly considered in any patient with chronic hypertension in whom there is a marked increase in BP toward term or post partum. Pheochromocytoma (Chapter 235) is associated with a very high maternal and fetal mortality rate, in large part owing to a delay in diagnosis. Both magnetic resonance imaging and magnetic resonance angiography (which do not require gadolinium) can be used safely in pregnancy to evaluate the adrenal glands and renal arteries.

TREATMENT Rx

Patients previously on drug therapy can often discontinue antihypertensives and restart them when BP gradually rises to prepregnant values toward term. It is very difficult to determine whether rising BP represents a normal physiologic return to earlier pressure or the development of preeclampsia. Baseline preeclampsia laboratory tests (see later), very close follow-up, and comanagement with the patient's obstetrician are required. Patients with good BP control may prefer to continue safe medications or switch to another regimen. The drugs for which there is grade A evidence of efficacy and safety are methyldopa and labetalol (Table 67-5). Nifedipine, hydralazine and other β-blockers, especially those with intrinsic sympathomimetic activity, have also been studied and are acceptable second- and third-line agents.

Dosing should take into consideration the increase in renal and hepatic clearance and the increased volume of distribution, which may require narrowed dosing intervals during pregnancy. ACE inhibitors and ARBs should be discontinued at the diagnosis of pregnancy because of their teratogenicity and their association with fetal and neonatal renal agenesis and renal failure when used later in gestation.

The goal of antihypertensive therapy in pregnancy is not clear. Most consensus recommendations, which address fetal concerns and short-term maternal safety only, recommend keeping BP less than 160/100. Given the long-term data, most centers prefer to keep maternal BP, particularly in patients with diabetes or renal disease, below 140/90. Consensus recommendations agree that maintaining BP above 120/80 is necessary to preserve placental perfusion. There is no evidence that salt restriction or dietary changes improve BP control in pregnancy, and weight loss is not recommended. Likewise, there is no evidence that BP control decreases the risk of preeclampsia. It is important to obtain baseline preeclampsia laboratory tests (complete blood count, platelet count, creatinine, uric acid, aspartate transaminase, urinalysis) in all patients with hypertension, given the 20% risk of preeclampsia, and low-dose aspirin and calcium supplementation should be considered to prevent preeclampsia (see later). Fetal monitoring with serial ultrasound for growth and amniotic fluid volume, non-stress testing (fetal heart rate acceleration in response to movement) once or twice a week after 32 weeks, and consideration of Doppler flow velocimetry are recommended.

Most antihypertensives are safe for breast-feeding, which should be encouraged. Hydrochlorothiazides, α-methyldopa, nifedipine, acebutolol, and metoprolol are all approved by the American Academy of Pediatricians. There is no evidence that hydrochlorothiazides affect milk volume. There is evidence that propranolol and atenolol are concentrated in breast milk, so they should be avoided. Enalapril and captopril are the preferred ACE inhibitors in breast-feeding women, but it may be prudent to delay ACE inhibitors for the first few weeks of the baby's life and for mothers of premature babies, given the adverse pregnancy data.

PROGNOSIS

Hypertension may increase the risk of abruption, intrauterine growth restriction (IUGR), and low-birthweight babies. The major risk, however, is its contribution to the risk for preeclampsia and the associated increase in perinatal morbidity and mortality. Women who develop hypertension during pregnancy are at increased lifetime risk for the development of chronic hypertension, even if the BP normalizes post partum.

PREECLAMPSIA

DEFINITION

Preeclampsia is a multisystem disorder defined as BP 140/90 or greater, accompanied by proteinuria greater than 300 mg/24 hours after the 20th week of gestation in a previously normotensive patient. When it is diagnosed in a patient with preexisting chronic hypertension, it is referred to as chronic hypertension with superimposed preeclampsia.

A urine protein-creatinine ratio of at least 0.3 may become a criterion for proteinuria, but the American College of Obstetricians and Gynecologists has not yet added this to the definition. Edema and hyperreflexia are no longer considered diagnostic criteria, and the 30 mm Hg increase in systolic pressure and/or 15 mm Hg increase in diastolic pressure have been dropped from the criteria for hypertension. Severe preeclampsia is defined as the presence of one of the following symptoms or signs in the presence of preeclampsia: (1) systolic BP 160 mm Hg or greater, or diastolic BP 110 mm Hg or greater, on two occasions at least 6 hours apart; (2) proteinuria greater than 5 g in a 24-hour period; (3) pulmonary edema; (4) oliguria (<400 mL in 24 hours); (5) persistent headaches; (6) epigastric pain and/or impaired liver function; (7) thrombocytopenia; and (8) IUGR.

EPIDEMIOLOGY

Preeclampsia complicates 6 to 8% of pregnancies worldwide. Preeclampsia/eclampsia is a leading cause of maternal mortality in the developing world and continues to contribute to maternal mortality in the United States, despite the availability of antihypertensives and antiseizure medications. In the United States, preeclampsia is believed to be responsible for 15% of premature deliveries and 17.6% of maternal deaths. Worldwide, preeclampsia and eclampsia are estimated to be responsible for approximately 14% of maternal deaths per year (50,000 to 75,000).

Primigravida and multigravida women with new partners are at increased risk, suggesting a role for paternal antigens. Additional risk factors include prior history of preeclampsia, black race, diabetes or insulin resistance, systemic lupus erythematosus (SLE), renal disease, hypertension, thrombophilia, obesity, molar pregnancy, multiple gestation, and extremes of age (younger than 20 or older than 40).

PATHOBIOLOGY

Preeclampsia is a disorder of abnormal placentation that begins very early in gestation, well before its manifestations are clinically apparent. In normal pregnancy, uterine spiral arteries undergo remodeling when they are invaded by fetal cytotrophoblastic cells, resulting in an adhesion receptor switch from cells with characteristics of epithelial cells to cells with the phenotype of endothelial cells. This leads to the transformation of previously narrow, high-resistance maternal uterine blood vessels into dilated, high-capacitance blood vessels. The proximal portions of the spiral arteries are further dilated by the hormonal effects of estrogen and progesterone, resulting in an overall increase in uterine blood flow from 45 mL/minute during menstruation to 750 mL/minute at term. In preeclampsia, this cell switching does not occur, and the fetal cells' only superficial invasion into maternal vasculature results in limited

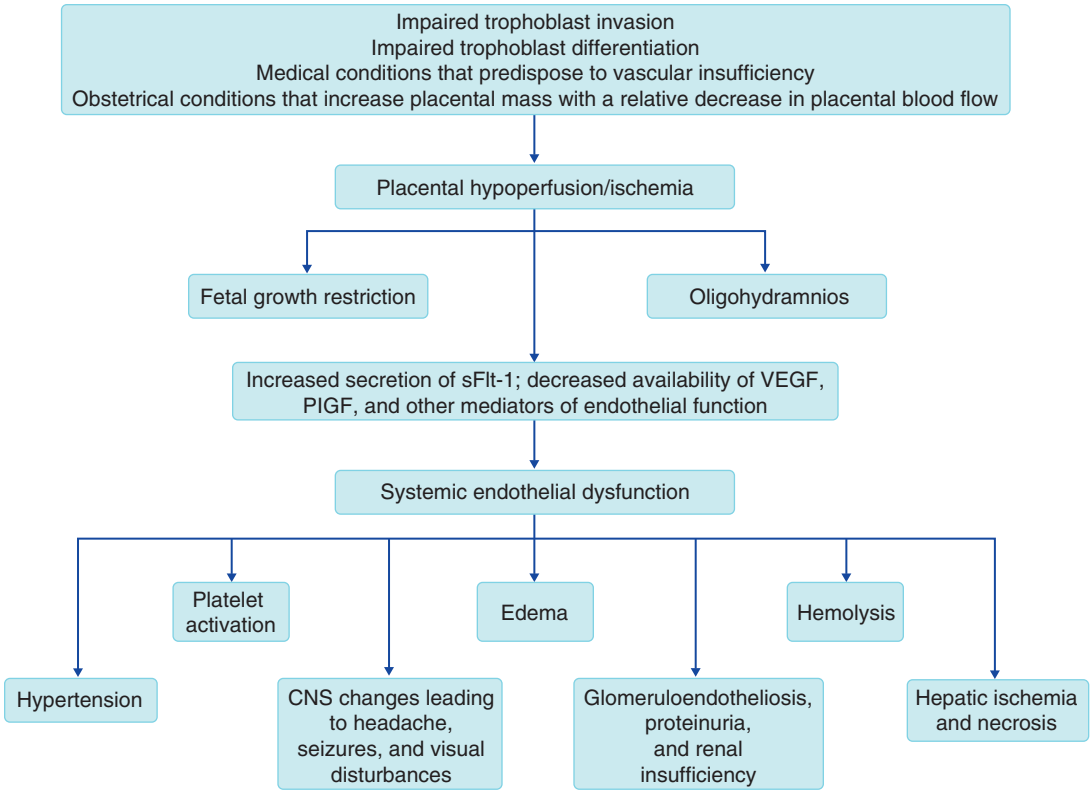

FIGURE 247-2. Model for the pathogenesis of preeclampsia. CNS = central nervous system; PlGF = placental growth factor; sFlt-1= soluble film-like tyrosine kinase; VEGF = vascular endothelial growth factor. (From Rosene-Montella K, et al. *Medical Care of the Pregnant Patient*, 2nd ed. Copyright 2008 by American College of Physicians, with permission.)

placental perfusion. As the pregnancy progresses, abnormal placentation produces relative hypoxia and ischemia as this compromised uterine blood flow cannot keep up with the growing demands of the fetus and the placenta. The result is diffuse endothelial dysfunction that manifests as the clinical syndrome of preeclampsia (Fig. 247-2).

Recent work on the potential mechanism of the endothelial dysfunction that underlies this disease state has focused on the imbalance between pro- and anti-angiogenic factors, arising from studies showing elevated concentrations of placental soluble film-like tyrosine kinase 1 in the plasma of women with preeclampsia. This protein prevents the interaction of placental growth factor and vascular endothelial growth factor with endothelial receptors, inducing endothelial dysfunction. A placenta-derived soluble transforming growth factor-β coreceptor, soluble endoglin, is elevated in the sera of patients with preeclampsia, inducing vascular permeability and hypertension; the degree of elevation correlates with disease severity, and levels fall after delivery. Current studies to address both the cause of and the mechanism linking preeclampsia and the risk of cardiovascular disease are ongoing and focus on endothelial dysfunction.

DIAGNOSIS

The diagnosis of preeclampsia depends on a BP of 140/90 or greater and proteinuria greater than 300 mg/24 hours after 20 weeks' gestation. Eclampsia is diagnosed when a patient with preeclampsia has a seizure. Additional abnormalities that contribute to the diagnosis include hyperuricemia, hemoconcentration, elevated creatinine or liver function tests, and thrombocytopenia. The HELLP syndrome (hemolysis, elevated liver function tests, and low platelets) is likely a more severe form of preeclampsia. The diagnosis of severe preeclampsia depends on the criteria previously listed.

Diagnostic evaluation should include a careful history, asking about headache, visual complaints, epigastric pain, weight gain, and edema and reviewing the presence of risk factors. The physical examination should include a careful neurologic examination, looking for funduscopic changes (retinal vasospasm, edema, or hemorrhage) or hyperreflexia, and any focal findings suggestive of mass effect, hepatic tenderness, and edema. Laboratory testing for preeclampsia includes a complete blood count, platelet count, urine protein-creatinine ratio or 24-hour urine protein, liver function tests, creatinine, and uric acid. Additional evaluation includes fetal testing and close maternal monitoring for life-threatening consequences such as severe hypertension, seizures, pulmonary edema, cerebral hemorrhage, hepatic infarction or rupture, disseminated intravascular coagulation, and renal failure.

Currently, diagnosis depends on development of the full clinical syndrome, but earlier diagnosis may be possible based on biomarkers. It is likely that a combined model that looks at soluble endoglin, soluble film-like tyrosine kinase 1, and placental growth factor concentrations will be a better prediction instrument before 20 weeks' gestation than any individual marker.

The differential diagnosis of each individual manifestation of preeclampsia is broad, so the diagnosis centers on the constellation of signs and symptoms that suggest preeclampsia. The clinical conditions that can mimic preeclampsia include SLE with nephritis, thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome. Differentiating preeclampsia from a flare of SLE with nephritis (Chapter 274) is very difficult because both can cause hypertension, proteinuria, thrombocytopenia, and rises in serum creatinine. The differential diagnostic features that favor SLE include falling serum complement levels, rising anti-DNA antibodies, and extrarenal manifestations of SLE such as rash and arthralgias. The proteinuria and hypertension in preeclampsia are more likely to be of sudden onset.

TREATMENT Rx

Once it occurs, the only known treatment of preeclampsia is delivery as soon as obstetrically feasible.[1] Nevertheless, it is important to note that preeclampsia can present post partum, and both preeclampsia and eclampsia have been reported up to 21 days after delivery. Management of preeclampsia includes treatment of hypertension, seizure prophylaxis, and limitation of fluids due to the risk of pulmonary edema. Treatment of severe hypertension in preeclampsia is reviewed in Table 247-5. Magnesium sulfate ($MgSo_4$) is recommended as first-line treatment for eclampsia as well as prophylaxis against eclampsia in women with severe and nonsevere preeclampsia.[2] Phenytoin and benzodiazapines should not be used for eclampsia prophylaxis or treatment, unless there is a contraindication to $MgSO_4$ or it is ineffective. There is evidence from two randomized controlled trials that magnesium is superior to phenytoin for the prevention of both primary seizures and recurrent seizures in eclampsia.

Treatment of acute seizures in eclampsia includes airway protection, fetal monitoring, magnesium, BP control, and benzodiazapines as needed to stop seizures acutely. Treatment of severe hypertension is as outlined in Table 247-5.

Severe maternal manifestations of preeclampsia that may warrant early delivery include seizure, renal failure, severe hypertension, severe thrombocytopenia or hemolysis, aspartate transaminase or alanine transaminase elevation greater than two to three times normal, pulmonary edema, retinal hemorrhage, or other symptoms suggestive of end-organ damage (headache,

visual disturbance, epigastric or right upper quadrant pain). Fetal indications for delivery may include significant IUGR, oligohydramnios, or nonreassuring fetal testing. Women with preeclampsia before 34 weeks' gestation should receive a corticosteroid that crosses the placenta, such as betamethasone or dexamethasone, to accelerate fetal lung maturation.

PREVENTION

Multiple trials of antihypertensives, antioxidant supplementation with vitamins C and E,[■] magnesium, protein or salt restriction, fish oil, and other dietary changes have failed to prevent preeclampsia. Low-dose aspirin in high-risk populations is the only intervention with data to support a positive effect. Initial trials showed limited effects, but a subsequent meta-analysis found that low-dose aspirin (<100 mg/day) decreases both the risk of preeclampsia and fetal and neonatal deaths.[■] We recommend aspirin 81 mg/day in all patients with risk factors for preeclampsia. Trials of calcium supplementation have shown conflicting results, but given the inverse relationship between dietary calcium intake and BP in the general population, calcium supplementation of at least 1 g/day is recommended for women with a low dietary intake of calcium (<600 mg/day). An alternative to supplementation may be to increase dietary calcium by eating three to four servings per day of dairy products (assuming 250 to 300 mg calcium per serving).

PROGNOSIS

Women who have had preeclampsia are at increased risk of heart disease, stroke, and cardiovascular death. Preeclampsia is also a marker for increased risk of end-stage renal disease. One year after delivery, preeclampsia patients had evidence of increased insulin resistance, BP, cholesterol, and triglycerides, which may be the first manifestations of the metabolic syndrome. It is unclear whether there is a shared pathogenesis, an unmasking of already established disease, or a contribution to the development of disease. It is possible that preexisting abnormal endothelial function predisposes to renal and vascular disease later in life and is, in fact, the same abnormality that disturbs implantation, resulting in preeclampsia and fetal loss. It is also possible that preeclampsia itself contributes to the later development of disease.

Continuing care beyond 6 weeks post partum is strongly recommended. Women with a history of severe preeclampsia should be screened for preexisting hypertension, underlying renal disease, thrombophilia, and possibly secondary causes of hypertension. They should also be informed of the risk for preeclampsia in subsequent pregnancies, particularly if the birth interval is less than 2 years or greater than 10 years. Women who are overweight should be advised to normalize their body mass index before another pregnancy and to reduce long-term risk. Both women with preexisting hypertension and those whose BP normalizes are likely to benefit from an overall assessment of cardiovascular risk that includes a lipid profile, smoking cessation, and early interventions to reduce risk.

TABLE 247-5 TREATMENT OF SEVERE HYPERTENSION IN PREECLAMPTIC PATIENTS

MEDICATION	ONSET AND DURATION OF ACTION	ACUTE DOSING FOR SEVERE HYPERTENSION	MAINTENANCE DOSE
Labetalol	Begins to work in 5-10 min Lasts 3-6 hr	Given as a series of boluses until BP reaches the desired level: 10 mg IV push; then in 10 min, 20 mg IV push; then in 10 min, 40 mg IV push; then in 10 min, 80 mg IV push; then in 10 min, 80 mg IV push, up to a total dose of no more than 300 mg Follow with PO labetalol or labetalol drip	100-200 mg PO bid-tid (100-600 mg bid–tid; maximum 2400 mg/day) IV infusion 0.5-2.0 mg/min (labetalol comes in vials of 100 mg/20 mL Put 5 vials (100 mL) labetalol into 150 mL IV fluid (D_5W, LR, or NS) to get a solution of 2 mg/mL Start at 15 mL/hr (0.5 mg/min) Titrate up to as high as 60 mL/hr (2 mg/min)
Nifedipine	Begins to work in <30 min Lasts 4-5 hr	10-20 mg PO q30min to a maximum of 50 mg	10-20 mg PO tid of short-acting nifedipine, or 30-120 mg once daily of long-acting formulation
Hydralazine	Begins to work in 10-20 min Lasts for 3-6 hr	2.5-10 mg IV q30min	Start at 10 mg PO qid; can be gradually increased to 50 mg PO qid

BP = blood pressure; D_5W= dextrose 5% in water (solution); LR = lactated Ringer's (solution); NS = normal saline.

DEEP VEIN THROMBOSIS, PULMONARY EMBOLISM, AND THROMBOPHILIA (CHAPTERS 81, 98, AND 179)

Pulmonary embolism (PE) is the leading medical cause of maternal mortality in the developed world. It was responsible for 30% of direct maternal deaths in the most recent U.K. Confidential Enquiry. Despite our best efforts, mortality rates from PE in pregnancy have not changed in more than 2 decades, and the incidence of PE in the United States is rising, likely owing to the increase in obesity and cesarean deliveries. Current strategies to reduce risk from PE must address the widespread use of appropriate prophylaxis, early detection of venous thromboembolism (VTE), and prompt, safe, and effective therapy.

EPIDEMIOLOGY

More than half the VTE events in women younger than 40 years occur in association with pregnancy. VTE is 10 times more common in pregnant versus nonpregnant women of comparable age. It occurs in 5 to 12 of 10,000 pregnancies ante partum and 3 to 7 of 10,000 post partum. The risk of VTE with pregnancy is increased by the presence of additional risk factors, including prolonged bedrest, cesarean section, preeclampsia, three or more children, smoking, obesity, previous superficial thrombophlebitis, previous VTE, thrombophilia, and family history of VTE.

PATHOBIOLOGY

Pregnancy is a hypercoagulable state (Chapter 179) characterized by venous stasis, increased clotting factors and decreased fibrinolysis, and endothelial disruption. Venous stasis occurs as a result of progesterone-induced venodilation early in pregnancy and is later increased by the compressive effects of the gravid uterus. Compression of the left iliac vein by the right iliac artery further increases venous stasis on the left, which may explain the finding that more than 90% of cases of deep vein thrombosis (DVT) in pregnancy occur in the left leg. Endothelial damage occurs with preeclampsia and with both vaginal and operative delivery, further contributing to VTE risk.

Genetic and Acquired Thrombophilias

A positive family history for VTE (possibly a marker for thrombophilia) or a known thrombophilia significantly increases the risk for VTE in pregnancy. The best-described genetic thrombophilias include deficiencies in protein C, protein S, and antithrombin III, all of which appear to have autosomal dominant inheritance with variable penetrance and the presence of the single gene mutations, factor V Leiden, or prothrombin G202010. Of these, antithrombin-deficient homozygotes and compound heterozygotes have the highest risk of VTE in pregnancy. The thrombophilias have also been associated with obstetric complications, including IUGR, abruption, both early and late pregnancy loss, and early, severe, or recurrent preeclampsia. The antiphospholipid antibody syndrome is the major acquired thrombophilia for which there are compelling pregnancy data supporting a link with both thrombosis risk and obstetric complications, as well as the use of thromboprophylaxis to prevent poor obstetric outcome. A large international, multicenter trial—the Thrombophilia in Pregnancy Prophylaxis Study (TIPPS)—is currently under way, randomizing patients with thrombophilias and adverse pregnancy outcomes to surveillance versus thromboprophylaxis.

DIAGNOSIS

The diagnosis of VTE during pregnancy is complicated by both normal pregnancy-related physiologic changes and the reluctance to use diagnostic

imaging in pregnancy. Clinical signs are unreliable, and leg swelling and complaints of dyspnea are common during pregnancy, making it very difficult to decide when to investigate for VTE. The finding that 90% of DVT occurs in the left leg led to the observation that the combination of symptoms in the left leg, calf circumference difference of 2 cm or greater, and first trimester presentation (when leg swelling is less likely) is highly predictive of DVT. Most DVTs occur ante partum, and events are evenly distributed throughout gestation. The majority of fatal PEs in most studies occurred in the postpartum period, so vigilance is required for a prolonged period following delivery. Diagnosis of DVT requires compression ultrasonography that includes the iliac veins and the inferior vena cava at the level of the liver. It also requires repeat compression ultrasonography if there is a negative scan but high pretest probability and continuing symptoms. In patients with suspected iliac or pelvic vein thrombosis and negative ultrasound studies, magnetic resonance imaging or magnetic resonance venography is recommended.

The diagnosis of PE is even more problematic, given the frequency of dyspnea, the likelihood of normal oxygenation in young patients with no underlying cardiopulmonary disease, and the more invasive nature of diagnostic testing. Arterial blood gases are not helpful; the A-a gradient was normal in 60% of pregnant patients with documented PE in a retrospective review done at two centers.

The radiation exposure from imaging required for the diagnosis of PE is well below that allowed by the NCRP (see Table 247-3), so testing should never be withheld out of concern for fetal exposure. Ventilation-perfusion (V/Q) scanning is still the diagnostic test of choice in most centers outside the United States. It is better validated in pregnancy, involves no contrast administration, and has good negative predictive value in normal scans and in low-probability scans when paired with leg studies. If V/Q is used, it must be understood that there is still a significant risk of PE in patients with "intermediate" and "indeterminate" scans, so additional testing is required in those cases. Computed tomography (CT) angiography has replaced V/Q scanning in most U.S. centers, based on its use in the nonpregnant population. The technique is dependent on cardiac output and plasma volume, both of which are increased during pregnancy. This may lead to poor opacification of the vessels, causing artifacts to be read as filling defects or the failure to visualize clots, so the technique must be adjusted for pregnancy. It is a sensitive, cost-effective test that offers an alternative diagnosis in 25 to 40% of cases, and it is preferred if there is an abnormal chest x-ray. It is well tolerated and has a shorter breath-holding time than V/Q scans, so it is also preferred in unstable patients, especially if an alternative diagnosis is suspected. It is important to note that CT angiography exposes the maternal breast to 2 to 3.5 rads, and exposure of the breast to 1 rad increases the lifetime risk of breast cancer by 13%. The use of breast shields decreases this exposure by about 50% without compromising the integrity of the test, so breast shields are strongly recommended.

The role of D-dimer testing in pregnancy has not yet been elucidated because D-dimer is elevated during normal pregnancy. It may have some use for its negative predictive value, but studies are inadequate to recommend its use at this time.

TREATMENT

Rx

The safety of unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) (Chapter 37) for the fetus is well established, so they are the drugs of choice for both the treatment and the prevention of VTE. Warfarin is a teratogen that crosses the placenta and has been associated with fetal bleeding and central nervous system abnormalities later in gestation, so it is not used for this indication in pregnancy. Initial treatment is either intravenous UFH followed by subcutaneous UFH or LMWH, or an initial adjusted dose of LMWH that is then continued; both are acceptable.

LMWH causes less thrombocytopenia and osteoporosis, so, given the prolonged exposure during pregnancy, it is the preferred agent. LMWH has increased bioavailability, but the ease of administration in pregnancy is mitigated by the need for twice daily dosing and frequent monitoring. Dosing requirements increase with increasing gestation, so it is necessary to follow anti-Xa levels. Because LMWH has limited reversibility with protamine, and because it has been associated with epidural hematomas in nonpregnant patients given spinal or epidural anesthesia, most centers recommend a switch to UFH by 34 to 36 weeks. This allows patients the option of epidural anesthesia for delivery, and in the event of an emergent delivery prior to holding anticoagulation, UFH can be reversed with protamine. Specific treatment recommendations are outlined in Table 247-6.

TABLE 247-6 TREATMENT OF VENOUS THROMBOEMBOLISM IN PREGNANCY: ANTEPARTUM ANTICOAGULATION

	Prophylaxis		*Aggressive Prophylaxis*		
DRUG	**FIRST 20 WEEKS**	**20-37 WEEKS**	**FIRST 20 WEEKS**	**20 WEEKS TO TERM**	**FULL TREATMENT**
Dalteparin	5000 U/day	5000 U q12h	100 U/kg/day	100 U/kg/day	100 U/kg q12h with anti-Xa monitoring
Enoxaparin	30 mg/day	30 mg q12h	1 mg/kg/day	1 mg/kg/day	1 mg/kg q12h with anti-Xa monitoring
Tinzaparin	4500 U/day	4500 U q12h	88 U/kg/day	88 U/kg/day	88 U/kg q12h with anti-Xa monitoring
Heparin	Alternative if LMWH unaffordable: 750 U bid first 20 wk; 10,000 U bid wk 20-37		Alternative if LMWH unaffordable: 10,000 U bid to achieve anti-Xa level of 0.1-0.3 U/mL		Adjusted to mid-interval anti-Xa of 0.35-0.67 with q12h SC injections

LMWH = low-molecular-weight heparin.

PREVENTION

The overall recurrence risk of VTE during pregnancy ranges from 5 to 20%, depending in part on the circumstances of the index clot. Patients with a previous idiopathic VTE (while not pregnant) or a secondary VTE that occurred during a previous pregnancy or while on oral contraceptives, and patients with a positive family history or identified thrombophilia, are at the highest risk. The thrombophilias with the highest recurrence risk are the antiphospholipid antibody syndrome and homozygosity or compound heterozygosity with more than one mutation and antithrombin deficiency. Thromboprophylaxis is required in all these groups, and its intensity is related to the severity of the risk (see Table 247-6). The lowest risk of recurrence, based on retrospective data, appears to be in patients without a family history or thrombophilia in whom the previous VTE occurred in association with a transient risk factor other than pregnancy or oral contraceptive use. The American College of Chest Physicians consensus guidelines allow surveillance in this group, but most U.S. centers would also offer antepartum thromboprophylaxis. Prophylaxis should be continued for at least 6 to 8 weeks post partum, when the hemostatic changes of pregnancy return to prepregnant values. Additional groups that should be considered for thromboprophylaxis are patients who have undergone cesarean section, particularly if they have an additional risk factor for VTE, and patients on prolonged bedrest. Patients on continued prophylactic or treatment doses post partum have the option of switching to warfarin, which is safe in breast-feeding women.

PROGNOSIS

VTE during pregnancy may be the first manifestation of a hypercoagulable state, as pregnancy acts as a stress test for thrombophilia. Fifty percent of initial episodes of VTE in women younger than 40 present in association with pregnancy. A thrombophilia evaluation is indicated in all patients who present with VTE during pregnancy to assess long-term maternal and family risk and to guide future secondary prophylaxis recommendations. Patients with an identified thrombophilia and an adverse pregnancy outcome are at risk for a similar outcome in a subsequent pregnancy and should be counseled about this risk and considered for thromboprophylaxis.

Patients who have had a DVT during pregnancy have a very high risk of postphlebitic syndrome and venous insufficiency. Two randomized controlled trials demonstrated a 50% risk reduction in symptoms of post-thrombotic syndrome when compression stockings were used within 1 month of diagnosis and continued for a minimum of 1 year after diagnosis.

ASTHMA (CHAPTER 87)

Maintaining adequate control of asthma during pregnancy is important for both maternal and fetal outcome. Asthma may be associated with increased perinatal mortality, preterm birth, IUGR, and preeclampsia. Well-controlled

asthma reduces the likelihood of these adverse outcomes back to baseline, so it is safer for both mother and fetus to treat maternal asthma than to allow exacerbations to occur.

EPIDEMIOLOGY

Asthma is the most common respiratory disease in pregnancy. It affects 3.7 to 8.4% of pregnancies in the United States and 12 to 13% of pregnancies in Australia and the United Kingdom.

Effect of Pregnancy on Asthma

The course of asthma in pregnancy is unpredictable, and most studies have found that a third of patients improve, a third worsen, and a third stay the same. The most likely predictor in any individual patient is her course during a previous pregnancy. In most studies, the majority of exacerbations occurred between 17 and 32 weeks, with some improvement reported by 36 weeks' gestation. Patients with mild asthma do well during labor and delivery, but almost 50% of patients with severe asthma worsen during labor and delivery. Risk factors for exacerbations include severe asthma; poor compliance with medications, especially inhaled corticosteroids; obesity; viral infections; rhinitis; and poor prenatal care. The highest morbidity and mortality are reported in African American patients.

Effect of Asthma on Pregnancy

Pregnancy and perinatal outcome are unchanged when asthma is well controlled. Poorly controlled asthma increases the risk of spontaneous abortion, low birthweight, IUGR, and cesarean section. Preterm delivery and preeclampsia have also been associated with poorly controlled asthma, but it is unclear how systemic steroids contribute to these complications. Systemic steroids have been associated with an increased risk of premature rupture of membranes, preeclampsia, prematurity and low birthweight, and gestational diabetes.

PATHOBIOLOGY

The normal physiologic changes of pregnancy may contribute to variations in asthma severity. Factors contributing to the worsening of asthma include gastroesophageal reflux disease (GERD) and rhinitis or sinusitis—triggers for asthma that are common during pregnancy. GERD may present initially during pregnancy or worsen in patients with preexisting reflux owing to both hormonal and mechanical effects. Progesterone acts as a smooth muscle dilator that reduces lower esophageal sphincter pressure and contributes to delayed gastric emptying. Later in gestation, uterine enlargement further contributes to gastric displacement and increased reflux. Rhinitis and sinusitis clearly contribute to asthma exacerbations in nonpregnant patients. Gestational rhinitis related to hormonal effects is present in most pregnant women, and its behavior seems to parallel that of asthma. Bacterial sinusitis is five to six times more common in pregnancy and should be treated aggressively.

Hormonal effects on the airway may also contribute to asthma status. There is a progressive increase in serum cortisol and estradiol, which impacts the quality of mucus production, and in progesterone, which decreases smooth muscle contractility and thereby causes airway dilation and improves minute ventilation. Immunologic factors during normal pregnancy may also contribute to the course of asthma. There is a suppression of cell-mediated immunity, with a predominant T_H2 environment and high interleukin-5 and tumor necrosis factor messenger RNA. In pregnant women with asthma (not receiving inhaled corticosteroid therapy), the T_H2/T_H1 ratio is even higher, possibly contributing to exacerbations.

The mechanism by which asthma exacerbations affect perinatal outcome is likely related to chronic maternal hypoxia, with consequent placental dysfunction and decreased uteroplacental flow, which contributes to decreased fetal growth. Poorly controlled asthma increases low birthweight 2.5-fold. Relative placental ischemia in asthma, particularly in disease that was poorly controlled before conception, is likely the link to an increased risk for preeclampsia. Placentas from women with asthma show a change in response to vasodilators and constrictors in vitro, similar to that seen in preeclampsia.

DIAGNOSIS

The diagnosis of asthma during pregnancy is the same as in the nonpregnant state: normal forced expiratory volume in 1 second (FEV_1)/forced vital capacity on baseline pulmonary function tests with an obstructive physiology during exacerbations that is reversible either spontaneously or with medications. Airway hyperresponsiveness, as demonstrated by a methacholine challenge causing a 20% drop in FEV_1 from baseline, is also useful for diagnosis in pregnancy. The classification of asthma severity in pregnancy is the same as in nonpregnant patients and uses the new classification of asthma severity that incorporates short-acting β-agonist use. The new classification includes both level of impairment (daytime and nighttime frequency, quality of life and interference with normal activities, lung function) and adds the risk of exacerbations based on frequency and severity of prior exacerbations.

Differential Diagnosis

Dyspnea of pregnancy is a benign condition that often occurs later in pregnancy and is characterized by an increased awareness of the work of breathing that is disturbing for many patients. It is not likely to be acute, occurs less with rest, and should not interfere with normal daily activities. Dyspnea of pregnancy should not be accompanied by an increase in respiratory rate, wheezing, or hypoxia. It is important to consider pulmonary edema in any pregnant patient complaining of shortness of breath. Pregnancy-related causes of pulmonary edema and acute respiratory distress syndrome include tocolytics (drugs that slow contractions), preeclampsia, gastric aspiration, amniotic fluid embolism, sepsis (related to pyelonephritis, chorioamnionitis, endometritis, septic abortion), abruption, and obstetric hemorrhage. Cardiac causes should be suspected when pulmonary edema presents at the peak of blood volume (28 to 32 weeks), when occult valvular disease is most likely to be unmasked. Additional cardiac considerations are peripartum cardiomyopathy, preeclampsia, and ischemic heart disease, which in pregnancy may also be caused by coronary dissection.

TREATMENT Rx

Management of asthma during pregnancy does not differ greatly from that of the nonpregnant patient. However, normal arterial carbon dioxide pressure ($PaCO_2$) in pregnancy is 28 to 32 mm Hg, so a tachypneic pregnant patient with a $PaCO_2$ above this range may be in impending respiratory failure. Minute ventilation in pregnancy increases via an increase in tidal volume, but respiratory rate is unchanged by pregnancy, so tachypnea is always an abnormal finding.

The goal of asthma therapy during pregnancy is to maintain adequate control to ensure maternal and fetal health. It is always safer for pregnant women with asthma to be treated with asthma medications than to experience symptoms and exacerbations. Careful monitoring during all prenatal visits, preferably with spirometry, and stepped-up therapy are required both for maternal asthma control and to ensure appropriate oxygenation of the fetus. Maternal arterial oxygen saturation should be maintained at 95% or greater, or the arterial oxygen pressure (PaO_2) should be maintained at 80 mm Hg or greater, to maintain fetal oxygenation. E-Figure 247-1 outlines the classification of asthma and care for pregnant patients with asthma. More detailed recommendations for the home management of exacerbations and for hospitalization and emergency care for pregnant patients can be found in the *National Asthma Education and Prevention Program Working Group Report for Managing Asthma during Pregnancy.*

Albuterol is the preferred short-acting β-agonist because it has an excellent safety profile and the most data related to safety during human pregnancy. Inhaled corticosteroids are the preferred medication for long-term control. Budesonide is the preferred inhaled corticosteroid solely because of the amount of reassuring data on its use in pregnant patients. There are, however, no adverse data on the other inhaled corticosteroids. Data on the effectiveness and safety of long-acting β-agonists during pregnancy are limited, although it is reasonable to assume that they have a similar safety profile to that of albuterol. Salmeterol is the preferred agent, based only on its longer availability and no reports of adverse outcomes in exposed pregnancies. Cromolyn has an excellent safety profile but has limited effectiveness compared with inhaled corticosteroids.

Minimal published reports are available on the use of leukotriene receptor antagonists during pregnancy; however, animal safety data are reassuring. Current guidelines do not recommend leukotriene receptor antagonists owing to the limited data, unless a patient's asthma was well controlled using this type of drug before pregnancy.

Intranasal corticosteroids are recommended for the treatment of allergic rhinitis, given the limited systemic effect. The current nonsedating antihistamines of choice are loratadine and cetirizine.

Patients at risk for fatal asthma are those with a large bronchodilator response, overreliance on short-acting bronchodilators, marked circadian variation in lung function, history of hospitalization or intubation, and frequent systemic steroid use. There are specific considerations in pregnant patients who require airway intubation, based on pregnancy physiology.

Pregnant patients have a low functional residual capacity and oxygen reserve, a more profound response to sedatives, airway edema, and larger airways. Intubation failure is much higher in pregnant women, so intubation should be performed by the most experienced professional available.

Breast-feeding should be encouraged in all patients with asthma, as there is some evidence that it decreases atopy in offspring. Data are conflicting regarding the development of asthma in offspring.

DIABETES (CHAPTERS 236 AND 237)

Diabetes affects 1.85 million women of reproductive age, and it is estimated that preconception management could reduce the risk for 113,000 births per year. All women of reproductive age with diabetes should be counseled about the relationship between glucose control and congenital anomalies. Hyperglycemia is a teratogen, and the incidence of congenital anomalies is directly related to the hemoglobin A_{1C} level at conception (Fig. 247-3). The anomaly rate was as high as 11% in women without preconception care, including cardiac anomalies, neural tube defects, and sacral agenesis. The single most important contribution an internist can make to the prevention of congenital anomalies is to address pregnancy risk with all women of childbearing age with diabetes. The responsibility to normalize hemoglobin A_{1C} before conception falls to the medical care provider; once pregnancy is diagnosed and the patient is seen by her obstetrician, the teratogenic effects of glucose have already occurred.

DEFINITION

Gestational diabetes mellitus (GDM) is defined as glucose intolerance that first occurs or is first identified during pregnancy. Either type 1 or type 2 diabetes in a pregnant patient is referred to as preexisting or pregestational diabetes.

EPIDEMIOLOGY

The frequency of GDM is rising in the United States; it now occurs in 4 to 14% of all pregnancies, depending on patient characteristics. The epidemic of type 2 diabetes has resulted in a higher prevalence at a younger age; in the United States, there has been a 70% increase in the prevalence of diabetes in the 30- to 39-year-old age group, versus 33% overall. The proportion of women with type 2 versus type 1 pregestational diabetes has also increased, from 26% in 1980 to 65% in 2000, and it is still increasing. The perinatal morbidity and mortality associated with type 2 diabetes is at least as great as that associated with type 1 during pregnancy.

PATHOBIOLOGY

Type 1 diabetes is caused by autoimmune destruction of pancreatic beta cells, resulting in an absolute insulin deficiency. Ninety percent of cases are diagnosed before age 25 years and are often associated with other autoimmune illnesses or a family history of autoimmune illness, including thyroid disorders, Addison's disease, and celiac disease. Type 2 diabetes is part of the metabolic syndrome, which includes insulin resistance, hyperinsulinemia, dyslipidemia, abdominal obesity, and hypertension with premature atherosclerosis and likely has a genetic component. GDM may also be a manifestation of the metabolic syndrome, unmasked by the insulin-resistant state of pregnancy. Patients with GDM have a 50% chance of developing type 2 diabetes in the ensuing 5 to 10 years and a long-term risk of approximately 70%.

Pregnancy is a state of accelerated starvation and marked insulin resistance. Lower fasting glucose levels are seen early in the first trimester, and nocturnal hypoglycemia is common. There is blunted hypoglycemic awareness owing to decreased epinephrine and norepinephrine release, with falls in blood sugar and increased ketogenesis, resulting in an increased risk for diabetic ketoacidosis. Insulin requirements may decrease 20% in weeks 7 to 12 but then gradually rise later in gestation, such that insulin doses need to be increased by 16 weeks' gestation. Marked insulin resistance is related to the presence of elevated levels of cortisol, prolactin, human placental lactogen, and human placental growth hormone. Insulin sensitivity is decreased by about 50% in the third trimester, resulting in increased serum insulin and postprandial glucose levels, explaining the timing of the onset of GDM.

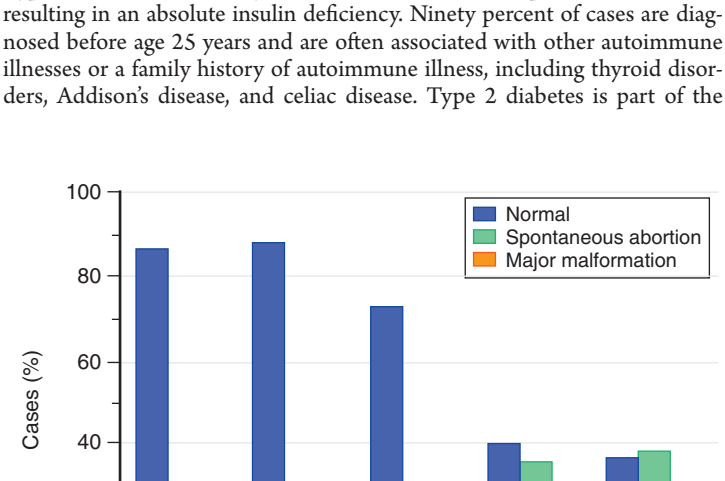

FIGURE 247-3. Relationship of hemoglobin A_{1c} ($HgbA_{1c}$), congenital anomalies, and spontaneous abortion.

DIAGNOSIS

The diagnosis of pregestational diabetes is based on the finding of a fasting blood sugar level greater than 125 mg/dL or a 2-hour or random blood sugar level 200 mg/dL or greater. The American Diabetes Association recently added a hemoglobin A_{1C} level of 6.5% or greater as an acceptable alternative diagnostic criterion. GDM is based on the results of a blood sugar screen after a 50-g glucose challenge test (≥140 mg/dL), followed by a 3-hour confirmatory 100-g oral glucose tolerance test. Positive results are any two of the following: fasting, 95 or greater, 1 hour, 180; 2 hours, 155; and 3 hours, 140 mg/dL. It may be difficult to distinguish between GDM and type 2 diabetes that was not diagnosed before pregnancy. Elevated fasting glucose levels before 24 weeks' gestation and elevated hemoglobin A_{1C} are both suggestive of type 2 diabetes. Any diabetes diagnosed during pregnancy is referred to as GDM; if it persists post partum, it is reclassified as type 2.

TREATMENT

Rx

Dietary recommendations are for 30 kcal/kg, with 40 to 50% carbohydrates, divided into three meals and three snacks. Aerobic exercise may decrease insulin resistance and reduce maternal glucose levels and may be an effective adjunct to diet in patients with GDM. Adjustment of medications should include the discontinuation of ACE inhibitors, ARBs, and statins and the institution of folate and prenatal vitamins. An assessment of baseline disease status in all patients with diabetes should include hemoglobin A_{1C}, ophthalmologic examination, electrocardiogram, assessment of urine protein excretion, serum creatinine, and thyroid-stimulating hormone. Baseline preeclampsia laboratory studies are also recommended.

The fetal assessment plan includes ultrasound to confirm dates and viability; this is done by the patient's obstetric care provider. There will also be a quad screen, looking for serum markers that suggest neural tube defects or Down syndrome, a level 2 ultrasound to assess for congenital anomalies, and a fetal echocardiogram.

Control of Blood Glucose

The goal of treatment for pregestational diabetes is the best hemoglobin A_{1C} level possible, without excessive hypoglycemia. This is achieved by frequent insulin adjustments and self-monitoring of blood glucose at least four times a day. The specific goals for both GDM and pregestational diabetes are fasting glucose of 65 to 95 mg/dL, 1-hour postprandial glucose less than 140, and 2-hour less than 120. This is best achieved by multiple doses of insulin, including basal, intermediate, or long-acting insulin, with preprandial bolus rapid-acting insulin to cover the anticipated carbohydrate load. This regimen requires self-monitoring of blood glucose six or seven times a day, so it may be difficult to comply with. Further, the risk of serious hypoglycemia may limit these glycemic targets, particularly in women with type 1 diabetes. Extreme vigilance is required to avoid serious hypoglycemia, particularly in weeks 7 to 12, when insulin requirements are the lowest during pregnancy. In patients with decreased glycemic awareness, the risk of nighttime hypoglycemia is significant, and patients' partners should be counseled about this risk.

Insulin analogues are being used with increasing frequency. Of the rapid-acting analogues, there are data that lispro does not cross the placenta; there are no data yet on aspart. Although long-acting glargine is being used in pregnancy, its placental transfer is unknown, and there are theoretical concerns about its binding to the insulin-like growth factor receptor and its mitogenic potential.

Of the oral agents for which there are data, glyburide is safe and efficacious in women with GDM. A recent trial comparing it with metformin concluded that the failure rate was twice as high in the metformin group. Oral agents are less useful with significant insulin resistance and type 2 diabetes, so insulin continues to be the "gold standard" in this group. Metformin does not appear to increase the risk of congenital anomalies or spontaneous abortion, but it does cross the placenta. It is important to recognize that women with polycystic ovary syndrome treated with metformin may regain their fertility and should be advised to use contraception. Recent trials support the safety of metformin in the second and third trimesters. In the United States, metformin is not yet recommended for the treatment of type 2 diabetes in pregnancy or for GDM. There are inadequate pregnancy data for the meglitinides and glitazones.

Maternal and Fetal Monitoring

During pregnancy, increased vigilance and continual assessment for the development of complications, including hypertension, preeclampsia, worsening nephropathy, and retinopathy, are required. The incidence of retinopathy in pregnant women with type 1 and type 2 diabetes is 34 to 50% and 3 to 5%, respectively. Nephropathy is found in 4% of diabetic pregnancies and is associated with increased maternal and perinatal morbidity. Most studies agree that pregnancy may accelerate the progression of nephropathy, but the reversibility of this complication is unclear. Most studies show a worsening of retinopathy in pregnant patients similar to that occurring over the same period in nonpregnant patients. The level of severity of retinopathy before pregnancy is most predictive of worsening during pregnancy, and treatment is recommended before conception.

Labor and Delivery

During labor and delivery, tight glucose control is necessary to avoid neonatal hypoglycemia due to hyperinsulinemia at birth. The goal is to maintain serum glucose levels of 72 to 144 mg/dL. The use of an insulin drip with dextrose infusion in active labor is recommended. Immediately after delivery, insulin requirements decrease to prepregnancy levels. Insulin needs should be one half to two thirds prepregnancy requirements, with a further decreased need found in breast-feeding patients.

Postpartum Considerations

Fifteen percent to 25% of type 1 diabetics develop postpartum thyroiditis, so all patients require postpartum measurements of thyroid-stimulating hormone and follow-up for 6 months. Other postpartum recommendations are to restart ACE inhibitors and to monitor closely for infection. It is important to discuss diabetes prevention in the offspring and to address contraception. It is most important to recommend an effective contraceptive method that is acceptable to the patient. Oral estrogens can increase triglycerides, and both oral and injectable progesterone-only contraceptives may increase insulin resistance. Low-dose combined oral contraceptives and the progesterone-releasing intrauterine device appear to have little effect on glucose.

Insulin is acceptable in breast-feeding women, and limited data suggest that glyburide and metformin are safe as well. One small study found that glyburide is not excreted in breast milk and that metformin is excreted in a small amount that is probably not clinically significant.

PROGNOSIS AND COMPLICATIONS

The maternal complications of diabetes may be impacted by pregnancy and may affect the course of the pregnancy. Patients with nephropathy experience an increase in proteinuria and a risk for progression of renal disease, especially if the serum creatinine is greater than 1.4 mg/dL. There is an increased risk for hypertension, which is seen in 30% during the first trimester and 75% of patients by the third trimester. Autonomic neuropathy may worsen, as manifested by increasing gastroparesis, orthostatic hypotension, and decreased hypoglycemic awareness. Patients with long-standing diabetes may need to be evaluated for ischemic heart disease, which may impair the heart's ability to meet the cardiovascular demands of pregnancy. Pregnant patients are also at risk for hyperlipidemia and for preeclampsia. Diabetes increases the risk for operative delivery and for infections, the most common of which are wound, urinary tract, and respiratory.

Diabetic ketoacidosis may be precipitated by steroid use for fetal lung maturity, hyperemesis, infection, and noncompliance with insulin regimens. Acidosis may occur more quickly and at lower glucose levels in pregnant than in nonpregnant patients. There is a very high fetal mortality associated with diabetic ketoacidosis (9 to 10%), and patients should be monitored in an intensive care setting.

Fetal and Neonatal Effects (Fig. 247-4)

There is an increased risk of spontaneous abortion, fetal loss, congenital anomalies, preeclampsia, and preterm delivery in patients with diabetes. Poor glycemic control during pregnancy, especially in type 2 diabetes and GDM, is also associated with macrosomia (baby weighing >4000 g) and fetal intraventricular septal hypertrophy. Poor control is also associated with the effects of maternal vascular and renal disease and ketoacidosis, which include fetal loss, preeclampsia, and low birthweight.

Neonatal complications include respiratory distress syndrome, hypoglycemia, hypocalcemia, cardiac hypertrophy, hyperbilirubinemia, and polycythemia. The risk of hypoglycemia may be ameliorated by careful control of maternal glucose during labor and delivery. Normalization of maternal glucose prevents hyperinsulinemia in the fetus and mitigates the risk of neonatal hypoglycemia.

Maternal Effects

GDM is a marker for type 2 diabetes: 50% of patients will develop type 2 diabetes within 7 to 10 years, and overall, 70% will develop the disease. Patients who have had GDM need directed testing at their 6-week postpartum visit, annual screening, and recommendations for lifestyle modification and cardiovascular risk reduction. Offspring of patients with GDM and type 2 diabetes are at increased risk for obesity and glucose intolerance.

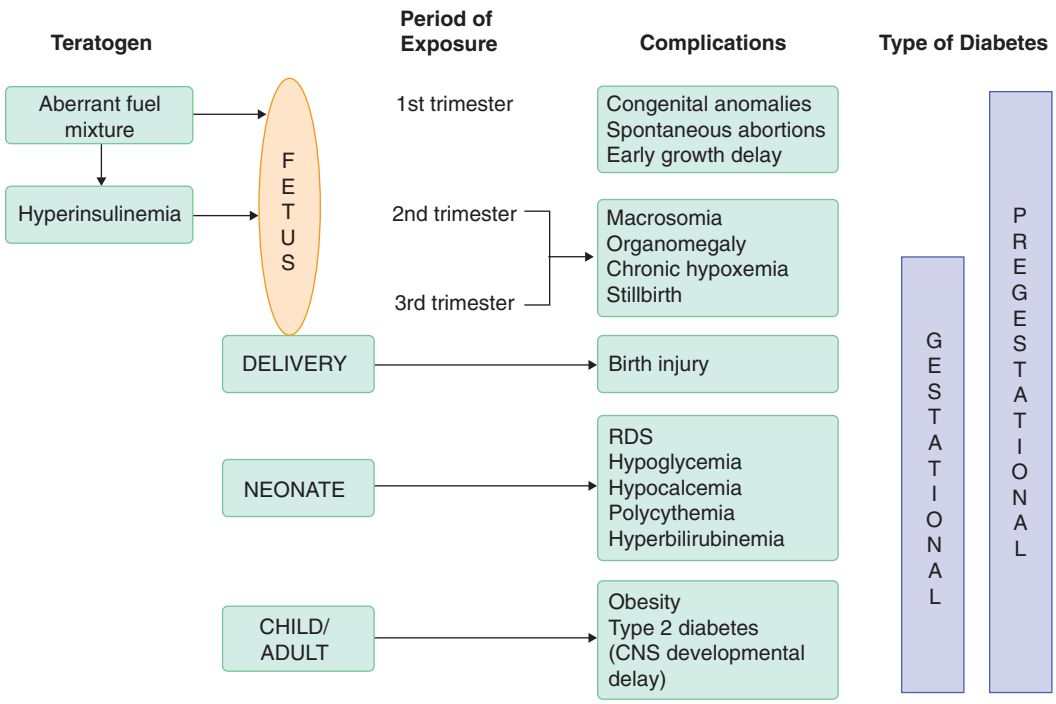

FIGURE 247-4. Fetal, neonatal, and childhood effects of exposure to hyperglycemia. CNS = central nervous system; RDS = respiratory distress syndrome.

SUMMARY

Women of childbearing age with chronic medical conditions benefit greatly from preconception counseling and interventions that address control of their disease and safety of their medications. Pregnant patients with acute or chronic medical illnesses require a multidisciplinary team that understands the maternal and fetal risks related to both the underlying illness and untreated disease. Pregnancy is a window of opportunity to address maternal health, and the maternal response to pregnancy may be predictive of future risk. The 6-week postpartum visit, rather than being the end of pregnancy care, should represent the beginning of a woman's long-term health care.

MENOPAUSE

DEBORAH GRADY AND ELIZABETH BARRETT-CONNOR

DEFINITION

All healthy women transition from a reproductive or premenopausal period marked by regular ovulation and cyclic menstrual bleeding to a postmenopausal period marked by infertility and amenorrhea (Fig. 248-1). The onset of the menopausal transition is generally marked by subtle changes in the length of the menstrual cycle and in the duration or amount of menstrual flow. As the menopausal transition progresses, menstrual cycles are missed until complete amenorrhea occurs, but the pattern of missed cycles is not predictable. Amenorrhea for a few months is not a good indicator of menopause because one half to three fourths of middle-aged women who are amenorrheic for 6 months resume cycles. Thus, menopause is typically defined retrospectively after 12 months of amenorrhea.

EPIDEMIOLOGY

The menopausal transition usually begins in the middle to late 40s and lasts approximately 4 years, with menopause occurring at a median age of 51 years and ranging in age from approximately 45 to 57 years. Age at menopause has not changed significantly over the past century. However, a century ago, most women in the United States did not live beyond menopause. A gradual increase in life expectancy to the low 80s now means that the average woman is postmenopausal for more than one third of her life. Age at menopause does not vary significantly by race or ethnicity, but on average, cigarette smokers experience menopause approximately 2 years earlier than nonsmokers.

BIOLOGY

During the early menopausal transition, estrogen levels are generally normal (50 to 200 pg/mL, depending on the stage of the menstrual cycle) or even slightly elevated, whereas the levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) begin to increase (see Fig. 248-1). As the menopause transition progresses, estrogen levels fall markedly, and FSH continues to increase. After menopause, women do not ovulate, and their ovaries do not produce estradiol or progesterone. However, a small amount of estrogen may be produced by metabolism of adrenal steroids to estradiol in peripheral fat tissue. In the early postmenopausal period, mean estradiol levels average approximately 40 pg/mL, and they fall to less than 15 pg/mL in the late postmenopausal period. Depending on the measurement method, approximately 15 to 30% of older postmenopausal women have unmeasurable estradiol levels. Testosterone levels after menopause are similar to premenopausal levels.

It is not clear what causes menopause, but two leading theories have been proposed. Age-related depletion of ovarian follicles may lead to decreased production of estrogen and inhibin and may thus cause altered hypothalamic-pituitary feedback that results in menopause. Alternatively, age-related changes in hypothalamic production of gonadotropin-releasing hormone and subsequent effects on FSH and LH may be responsible for the increased rate of loss of ovarian follicles, declining ovarian function, and menopause.

MENOPAUSAL SYMPTOMS

Menopause is a very positive occurrence in the life of many women. It marks the end of cyclic bleeding and the need for birth control. It occurs at an age when children generally have become independent adults, thereby reducing family and child care responsibilities. Conversely, menopause is a notable sign of aging in a culture that values youth. In addition, it often occurs with other stresses, such as caring for elderly or ill parents. Women in the menopausal transition commonly report a wide variety of symptoms, including hot flushes, night sweats, vaginal dryness, trouble sleeping, sexual dysfunction, depression, anxiety, labile mood, memory loss, fatigue, headache, joint pains, weight gain, and urinary incontinence.

Only vasomotor symptoms, vaginal dryness, and sleep disturbance are consistently associated with the menopausal transition. Other reported symptoms may result from aging or stress associated with menopause. Some symptoms, such as depression, anxiety, memory loss, and fatigue, may be the consequence of frequent hot flushes or poor sleep.

Vasomotor Symptoms

DEFINITION

Vasomotor symptoms include hot flushes, chills, and sweats. A *hot flush* is a sudden feeling of warmth, generally most intense over the face, neck, and chest. The duration is variable, but it averages approximately 4 minutes. It is often accompanied by sweating that can be profuse and followed by a chill.

EPIDEMIOLOGY

The prevalence of hot flushes is maximal in the late menopausal transition, occurring in approximately 50% of women (Fig. 248-2). However, prevalence varies markedly, depending on the definition of flushing (any flushing, daily flushing, troublesome flushing) and the population studied. Lower

Final menstrual period

	Reproductive			Menopause Transition		Postmenopause	
Reproductive stage	Early	Peak	Late	Early	Late	Early	Late
				Perimenopause			
Menstrual cycle	Variable or regular	Regular		Cycle length variable, 1 or 2 missed cycles per year	3 or more missed cycles	None	
Age (duration)	Puberty to mid-40s			Mid-40s to mid-50s (4 yr)		Mean of 51 years to death	
Steroid hormones	Estradiol 50 to 200 pg/mL			Same or slightly higher		40 pg/mL	0-15 pg/mL
	Testosterone 400 pg/mL			Same		same	same
Pituitary hormones	FSH 10 mIU/mL day 2-4			Same or higher		>100 mIU/mL	
	LH 10 mIU/mL day 2-4			Same or higher		>100 mIU/mL	

FIGURE 248-1. Stages of the menopause transition. FSH = follicle-stimulating hormone; LH = luteinizing hormone.

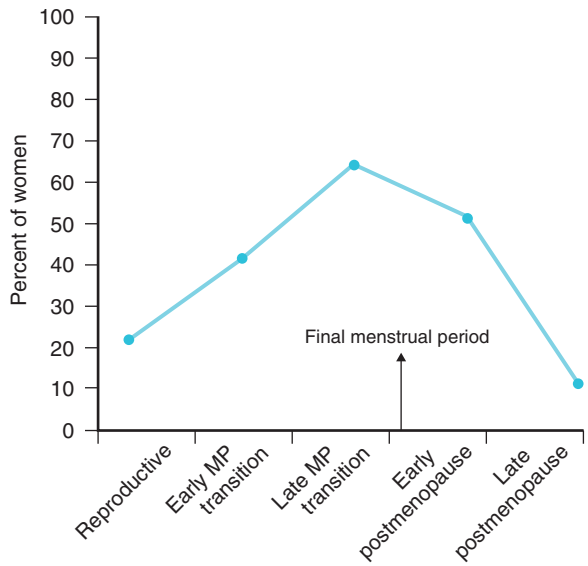

FIGURE 248-2. Prevalence of hot flushes during the menopause (MP) transition.

prevalence is reported among women in China, Japan, and other Asian countries. The reason for this variation is not clear, but investigators have suggested that it may result from differences in biology, cultural influences on experiencing or reporting flushes, or diet and lifestyle. In the United States, flushes are more common in African American and Latina women and less common in Chinese and Japanese women compared with white women. Approximately 15% of women with menopausal symptoms consult a physician.

Cigarette smoking increases the likelihood of flushing, but other potential risk factors, including surgical menopause, physical activity, body mass index, alcohol consumption, and socioeconomic status, have been inconsistently associated with hot flushes. Currently, there is no way to predict whether an individual woman will suffer from hot flushes.

NATURAL HISTORY

In most women, hot flushes are transient. Approximately 50% of women report resolution of symptoms within a few years, and symptoms resolve in about 90% within 8 years. However, some women continue to have frequent and severe flushes many years after menopause. Approximately 10% of women in their middle to late 60s report significant flushing. It is not clear why flushes persist for many years in some women and resolve in others.

PATHOBIOLOGY

In humans, body temperature is regulated by inducing vasodilation and sweating to release heat and vasoconstriction and shivering to conserve heat. Thermoregulation is complex and depends on central stimuli from the anterior hypothalamus and local changes in cutaneous vasoconstriction or dilation (Chapters 230 and 427). A hot flush is very similar to a heat dissipation response because both result in vasodilation, sweating, and reduction in core body temperature. The core body temperature at which postmenopausal women with hot flushes vasodilate and sweat is lower than in premenopausal women or in postmenopausal women without hot flushes. Variability in core body temperature does not appear to be greater in postmenopausal women with hot flushes than in premenopausal women or in postmenopausal women without hot flushes, but normal small fluctuations in core body temperature may exceed the lowered threshold for vasodilation and result in hot flushes.

The cause of altered thermoregulation in postmenopausal women with hot flushes is not clear. One theory suggests that changes in estrogen levels associated with menopause alter central nervous system adrenergic neurotransmission. This theory is supported by studies showing that metabolites of norepinephrine increase during spontaneous and experimentally induced hot flushes, and that systemic administration of yohimbine, an α_2-adrenergic antagonist that increases norepinephrine release, provokes hot flushes, whereas administration of clonidine, an α_2-adrenergic agonist that decreases norepinephrine release, reduces the frequency of hot flushes. Alternatively, some evidence indicates that declining estrogen levels during the menopause transition result in changes in serotonergic neurotransmission that could cause hot flushes. Lower estrogen levels are associated with lower levels of serotonin (5-hydroxytryptamine) in blood, resulting in increased sensitivity of 5-hydroxytryptamine-2A receptors in the hypothalamus. Stimulation of these receptors can alter the thermoregulatory set point in animals. Mild stressors, such as heat or anxiety, cause a brief release of 5-hydroxytryptamine that may stimulate central 5-hydroxytryptamine-2A receptors, lower the thermoregulatory set point, and cause flushing. This hypothesis is supported by the finding that drugs that increase central serotonin levels may be effective in the treatment of hot flushes.

Estrogen treatment effectively relieves hot flushes, but the exact role of estrogen in flushing is not clear. Fluctuations in estrogen levels in an individual woman do not correlate with the onset of flushes. Prepubertal girls with very low levels of endogenous estrogen, premenopausal women with marked fluctuations in estrogen during the menstrual cycle, and most postmenopausal women with low, constant levels of estradiol do not experience flushing. However, women with gonadal dysgenesis (Chapter 241) who are treated with estrogen for several months experience flushing when treatment is discontinued. Thus, withdrawal of estrogen, rather than the absolute estrogen level, appears to play a key role in the etiology of hot flushes.

In addition to changes in estradiol, menopause is associated with multiple other hormonal changes. In the Study of Women's Health Across the Nation (SWAN), a large cohort study in the United States, lower estradiol was

TABLE 248-1 DIFFERENTIAL DIAGNOSIS OF HOT FLUSHES

  - Gonadotropin-releasing hormone agonists or antagonists
  - Nicotinic acid
  - Nitrates
  - Selective estrogen receptor modulators (tamoxifen and raloxifene)

associated with flushing in middle-aged women in univariate models. However, higher FSH was the only measure independently associated with flushing after adjustment for other hormone levels. Hot flushes correlate with pulsatile increases in LH, but suppression of LH with gonadotropin-releasing hormone agonists does not eliminate flushing. Androgens may also play a role because men who are treated with androgen deprivation therapy for prostate cancer frequently report severe flushing.

DIAGNOSIS

Vasomotor symptoms are classic manifestations of the menopause transition, and the diagnosis is generally obvious from a woman's age and description of the symptoms. No abnormal physical findings are associated with hot flushes. Estradiol, FSH, and LH levels may be in the normal premenopausal range during the menopausal transition (see Fig. 248-1). A woman in her middle 40s to middle 50s who complains of classic hot flushes does not require any specific physical or laboratory evaluation unless there is good reason to suspect another cause of flushing (Table 248-1). However, an FSH determination may be helpful in assessing the risk for pregnancy. A woman in her middle 40s to middle 50s with an FSH level obtained on the third day after menses that is higher than 20 IU/L is not at risk of becoming pregnant.

TREATMENT

Rx

Because self-reported frequency and severity of hot flushes improve markedly with placebo, conclusive evidence of efficacy of treatments requires randomized, blinded trials. Clinical trials of treatments for hot flushes have typically been small and of short duration, limiting information about potential adverse effects.

General Measures

Behavioral and Alternative Therapies

Many women have mild flushes and obtain adequate relief with simple measures such as lowering ambient temperature and wearing lighter clothing. Moderate exercise does not improve flushing.

There is no convincing evidence that acupuncture, Chinese herbs, dong quai, evening primrose oil, ginseng, kava, or red clover extract improve hot flushes.[1,2] Evidence regarding black cohosh is mixed but primarily negative.[1,2] Multiple trials have been performed using different phytoestrogen preparations. Although some of these studies have reported benefit, the weight of evidence, especially from good-quality trials with blinded comparisons, suggests little benefit.[1,2] One trial of vitamin E supplementation found an improvement in flushes, but the decrease was only one hot flush per day. Many women prefer alternative medications because they believe that these treatments are harmless, but phytoestrogens and, possibly, black cohosh bind estrogen receptors and theoretically could cause adverse outcomes similar to those observed with estrogen. No studies of these preparations have been of adequate size or duration to document safety.

Medical Therapy

Estrogens

Multiple randomized trials have demonstrated that estrogen markedly improves the frequency and severity of hot flushes.[3] All types, preparations, and routes of administration of estrogen are effective. Estrogen reduces the frequency of hot flushes 60 to 95%, depending on the dose. Higher doses of estrogen may control symptoms more rapidly, but they are also associated with a higher rate of side effects, including uterine bleeding, breast tenderness, and headache.

At similar biologically active doses, oral and transdermal estrogens are approximately equally effective for treatment of vasomotor symptoms. Oral estrogens undergo "first-pass" metabolism in the liver that results in changes in hepatic proteins and enzymes. Hepatic effects are responsible for the beneficial effects of estrogen on lipoproteins (reduced low-density lipoprotein cholesterol and increased high-density lipoprotein cholesterol) but also for potentially adverse effects such as increases in clotting factors. The transdermal route may be safer because it minimizes these changes.

Many estrogen preparations are approved for treatment of vasomotor symptoms (Table 248-2). To individualize treatment, physicians should become familiar with several of these preparations.

Treatment with estrogen alone increases the risk for uterine hyperplasia and cancer. The risk for endometrial abnormalities appears not to be increased with the use of vaginal estrogens that deliver low systemic doses, especially if they are used only a few times per week, as is generally recommended (Table 248-3).

Adding a progestin to the estrogen regimen prevents the increased risk for uterine cancer. For this reason, a woman with a uterus who takes estrogen should also be given a progestin. There is no reason to add progestins to the hormone regimen in women who have had a hysterectomy. Several progestins are approved by the U.S. Food and Drug Administration (FDA) for this purpose and are available either to add to estrogen or in preparations combined with estrogen (see Table 248-2). Two general approaches are used to prescribing progestins to protect the endometrium. Sequential therapy (estrogen given daily with a progestin added on the last 10 to 14 days of a 28-day cycle) results in endometrial shedding and cyclic bleeding resembling a menstrual period in approximately 80% of women. Alternatively, the progestin can be added to the estrogen every day. This continuous regimen results in endometrial atrophy and unpredictable uterine spotting or bleeding that can be difficult for the woman to anticipate and manage. Bleeding occurs in approximately 80% of women in the first 6 months of continuous treatment. Amenorrhea becomes more common with prolonged use, but some women continue to bleed or spot for many years.

The most commonly used progestins in sequential regimens in women using standard doses of estrogens (0.625 mg oral conjugated estrogens, 1 mg oral estradiol, or 0.05 mg transdermal estradiol) are medroxyprogesterone acetate, 5 mg, and micronized progesterone, 200 mg, for 10 to 14 days per month. Continuous regimens generally include half these progestin doses given daily. In some situations, it may be slightly less costly to prescribe estrogen and progestins separately, but the convenience of taking a single pill and the assurance that the estrogen is adequately opposed by progestin make combination preparations preferred.

The use of "bioidentical hormones" is based on the concept that estrogens (estradiol, estrone, and estriol) and progestins (progesterone) made from plant products are identical to women's endogenous hormones and more natural, safe, and effective than FDA-approved hormone preparations. Bioidentical hormone therapy often uses doses and combinations of steroid hormones guided by patient symptoms or hormone levels, and prescriptions are generally filled by Internet-based compounding pharmacies. There is little scientific rationale for the mixtures and ratios of hormones employed, and there are no adequate clinical trial data to support the safety or efficacy of these regimens, some of which include very large doses of estradiol. Bioidentical hormones are not approved by the FDA for treatment of menopausal symptoms.

Side Effects and Risks of Postmenopausal Hormone Therapy

Estrogen is generally well tolerated, but it may cause headache (especially in women with a history of migraine) and breast tenderness. Added progestins tend to make these side effects more severe and also cause uterine bleeding.

The effects of hormone therapy on disease outcomes have been evaluated among postmenopausal women in the Women's Health Initiative (WHI) randomized trials[4,5] (Table 248-4). Both estrogen and estrogen in combination with progestin reduced the risk for hip fracture by 35 to 40%. Neither estrogen alone nor estrogen with a progestin reduced the risk for coronary events, and both increased the risk for stroke by approximately 40%.

Compared with estrogen alone, added progestin appears to increase the risk for coronary events, pulmonary embolism, breast cancer, and dementia (see Table 248-4). This finding suggests that adding a progestin should be avoided, but treatment with unopposed estrogen in women with a uterus markedly increases the risk for uterine hyperplasia and cancer as well as the rate of gynecologic procedures and hysterectomy.

The excess risk of any one of the adverse events listed in Table 248-4 in the WHI trials was about 2 per 1000 women treated for 1 year with estrogen in combination with progestin (4.3 per 1000 per year in women older than 65 years if dementia is included), and 0.6 strokes per 1000 women treated with unopposed estrogen. These risks are relatively small, but they cumulate such that treatment for 5 years is associated with an excess risk of one event per 100 women treated with estrogen in combination with progestin and three strokes per 1000 women treated with unopposed estrogen. Based on the findings of the WHI trials and the availability of other effective and safe drugs for prevention of osteoporotic fractures, postmenopausal hormone therapy currently has no role for prevention of disease. Some investigators have proposed that estrogen treatment, if started very soon after menopause, would reduce risk for coronary disease events. However, careful subgroup analyses of data from the WHI randomized trials do not support this hypothesis.[6]

The mean age of the women included in the WHI trials was 63 years, whereas the average age of women treated for menopausal vasomotor symptoms is approximately a decade younger. Because the risk for most diseases approximately doubles with each decade of age, the absolute risk for the outcomes listed in Table 248-4 is less for younger than for older women, and the absolute risk increase is proportionately smaller. However, hormone therapy is relatively contraindicated in women with a history of stroke, breast cancer, or venous thromboembolic events and should be avoided in women at high risk for these conditions.

Stopping Hormone Therapy

Given the possible adverse effects of hormone therapy, current guidelines recommend that women use the lowest effective dose for the shortest time necessary. Vasomotor symptoms improve or resolve spontaneously within a few years of onset in most women, a finding suggesting that most women should be able to discontinue hormone therapy within a few years of starting. Women using hormone therapy for treatment of symptoms should stop every 6 to 12 months to determine whether symptoms have improved to the point that treatment is no longer needed. A small percentage of women are unable to stop hormone therapy because vasomotor symptoms persist.

Women experiencing intolerable symptoms after stopping hormone treatment can be told to resume therapy and either to begin a slow taper or to wait 6 months before trying again to stop. Tapering can be accomplished by decreasing the dose of hormone therapy, but it may be easier to decrease slowly the number of days per week that hormone therapy is used. The *dose taper* involves progressively reducing the dose of hormone therapy, for example by reducing the dose of conjugated estrogens from 0.625 mg/day to 0.45 to 0.3 mg/day and then discontinuing therapy. If changing to a lower dose is associated with symptoms, the next reduction in dose should not occur until symptoms improve and are easily tolerable, which may require 3 to 6 months in some women. The *day taper* involves decreasing the number of days per week of hormone therapy use and effectively decreasing the weekly dose. For example, therapy with the same dose may be continued, but only Monday through Friday. If this reduced weekly dose is tolerated, therapy may be discontinued on Thursday, and so on. As with the dose taper, if symptoms develop, the weekly dose should be maintained until symptoms improve. Both these approaches to tapering can require many months or even years until therapy is discontinued. The day taper has the advantages of allowing smaller reductions in weekly dose, ensuring that the estrogen dose is appropriately opposed by a progestin in women using continuous therapy and does not require multiple new prescriptions for different doses of hormone therapy. For women who cannot tolerate even a slow taper, the value of symptom relief likely outweighs the risks of hormone therapy.

Other Prescription Drugs

A drug that appears to be as effective as estrogens for treatment of hot flushes is tibolone, a steroid hormone that is not marketed in the United States but is widely available elsewhere (Table 248-5). Tibolone preserves bone density, reduces the risks for fracture and breast cancer, but increases risk for uterine cancer and stroke.[10] The progestins megestrol and medroxyprogesterone acetate are effective for the treatment of hot flushes, but they have frequent side effects, and progestin use was associated with increased risk for adverse effects in the WHI trials. Several selective serotonin and serotonin-norepinephrine reuptake inhibitors and gabapentin have been studied.[11] Paroxetine and gabapentin appear to have modest efficacy in relieving hot flushes (see Table 248-5). Recently, the selective serotonin reuptake inhibitor escitalopram (10 to 20 mg per day) was shown to reduce the number and intensity of menopausal hot flashes.[12] However, clinical trials have not been adequately large or prolonged to detect uncommon adverse effects.

Summary of Approach to Treatment of Vasomotor Symptoms

Women with mild vasomotor symptoms may find adequate relief by wearing layered clothing and keeping the home and bedroom cool. Women with moderate symptoms may choose a low dose of estrogen or a nonestrogen therapy. Paroxetine is modestly effective and probably has the best side-effect profile of the nonhormonal drugs. For women with severe symptoms, hormone therapy is the most effective treatment.

Vaginal Dryness

EPIDEMIOLOGY

The prevalence of vaginal dryness, discomfort, itching, and dyspareunia increases as women transition through the menopause. Up to 30% of perimenopausal and early postmenopausal women and a higher proportion of older menopausal women express these complaints. Urologic symptoms, including urgency, frequency, dysuria, and incontinence, are not clearly correlated with the menopause transition.

TABLE 248-2 ESTROGEN AND PROGESTIN PREPARATIONS FOR TREATMENT OF MENOPAUSAL VASOMOTOR SYMPTOMS

HORMONES	GENERIC NAME	BRAND NAME	DOSE (mg/day)
ESTROGENS*			
Oral	Conjugated estrogens	Premarin	0.3, 0.45, **0.625**, 0.9, 1.25

*Results of the Women's Health Initiative estrogen plus progestin randomized trial: 16,608 postmenopausal women without hysterectomy randomized to 0.625 mg conjugated estrogen plus 2.5 mg medroxyprogesterone acetate per day or identical placebo and followed for 5.2 years.
†Results of the Women's Health Initiative estrogen-only randomized trial: 10,739 postmenopausal women with hysterectomy randomized to 0.625 mg conjugated estrogen per day or identical placebo and followed for 6.8 years.

PATHOBIOLOGY

Vaginal symptoms generally correlate with findings (often called vaginal atrophy) including pallor, dryness, friability, and decreased rugosity of the vaginal mucosa. Vaginal fluid in premenopausal women is acidic, ranging from a pH of approximately 4.5 to 5.5 with mild alkalinization to approximately 6.0 before ovulation. Acidity is produced by proton excretion from the vaginal epithelial cells and by metabolism of glycogen stored in vaginal epithelial cells by *Lactobacillus* species, the normal vaginal flora. The acid environment of the vagina inhibits growth of *Escherichia coli* and other enteric gram-negative bacteria that are a potential cause of urinary tract infections. Vaginal pH can easily be measured from lateral vaginal wall fluid.

In postmenopausal women, vaginal pH is generally neutral, and the predominant flora are often *E. coli* and other gram-negative bacteria. This appears to occur because estrogen deficiency associated with menopause causes vaginal epithelial cell dysfunction, including decreased storage of glycogen, less ability to acidify the vaginal fluid, and lowered production of vaginal lubrication. Vaginal epithelial cells, which are primarily superficial and intermediate cells in premenopausal women, shift to predominately immature parabasal cells in postmenopausal women. Treatment with estrogen improves

ANTIDEPRESSANTS				
Citalopram	No	No benefit of 30 mg citalopram compared with placebo	Suvanto-Luukkonen E, Koivunen R, Sundstrom H, et al. *Menopause.* 2005;12:18-26.	Selective serotonin reuptake inhibitors citalopram, escitalopram, fluoxetine, paroxetine, and sertraline: nausea, vomiting, diarrhea, insomnia or somnolence, anxiety, decreased libido, dry mouth, worsening depression, mania, suicidality, serotonin syndrome, withdrawal syndrome, and possible decreased tamoxifen effectiveness.
Escitalopram	Yes	Among generally healthy women, frequency of hot flushes reduced 47% with escitalopram 10 to 20 mg/day compared with 33% with placebo.	Freeman EW, Guthrie KA, Caan B, et al. *JAMA.* 2011;305:267-274.	
Fluoxetine	Mixed	Among breast cancer survivors, frequency of hot flushes reduced 50% with fluoxetine 20 mg/day compared to 36% with placebo. No benefit among women with breast cancer treated with 30 mg fluoxetine compared with placebo	Loprinzi CL, Sloan JA, Perez EA, et al. *J Clin Oncol.* 2002:20:1578-1583. Suvanto-Luukkonen E, Koivunen R, Sundstrom H, et al. *Menopause.* 2005;12:18-26.	
Paroxetine	Yes	Among generally healthy women, frequency of hot flushes reduced 62% with 12.5 mg and 65% with 25 mg paroxetine CR compared with 38% in placebo. In a crossover trial in which 81% of participants had a history of breast cancer, paroxetine 10 mg reduced hot flush frequency by 41% compared with 14% with placebo, and paroxetine 20 mg reduced hot flush frequency by 52% compared with 27% placebo.	Steans V, Beebe KL, Lyengar M, et al. *JAMA.* 2003;289:2827-2834. Stearns V, Slack R, Greep N, et al. *J Clin Oncol.* 2005;23:6919-6930.	
Sertraline	No	Among women with a history of breast cancer, no benefit of treatment with 50 mg of sertraline compared with placebo. Among generally healthy women, no benefit of 100 mg of sertraline compared with placebo.	Kimmick GG, Lovato J, McQuellon R, et al. *Breast J.* 2006;12:114-122. Grady D, Cohen B, Tice J, et al. *Obstet Gynecol.* 2007;109:823-830.	
Venlafaxine	Mixed	Among breast cancer survivors, frequency of hot flushes reduced 61% with 75 or 150 mg venlafaxine compared with 27% placebo. Among women without breast cancer, no effect on frequency of flushes with 75 mg venlafaxine, but women treated with venlafaxine were more likely to report that flushes improved compared with placebo.	Loprinzi CL, Kugler JW, Sloan JA, et al. *Lancet.* 2003:356:2059-2063. Evans ML, Pritts E, Vittinghoff E, et al. *Obstet Gynecol.* 2005;105:161-166.	In addition to the side effects noted above, the selective serotonin-norepinephrine reuptake inhibitors venlafaxine and desvenlafaxine can also cause hypertension.

TABLE 248-5 EVIDENCE FROM RANDOMIZED, CONTROLLED CLINICAL TRIALS OF THE EFFICACY OF NONESTROGEN DRUGS FOR TREATMENT OF MENOPAUSAL HOT FLUSHES—cont'd

TREATMENT	EVIDENCE OF BENEFIT	COMMENTS	REFERENCES	SIDE EFFECTS*
Desvenlafaxine	Yes	Frequency of hot flushes reduced by 60% with 100 mg per day and 66% with 150 mg per day compared with 47% in placebo.	Archer DF, Seidman L, Constatine GD, et al. *Am J Obstet Gynecol.* 2009;200:238.	
ANTIHYPERTENSIVES				
Clonidine	Mixed	Small trials suggest little or no benefit.	Nelson HD, Haney E, Humphrey L, et al. AHRQ Publication No. 05-E016-2. Rockville, MD: Agency for Healthcare Research and Quality; 2005. Goldberg RM, Loprinzi CL, O'Fallon JR, et al. *J Clin Oncol.* 1994;12:155-158. Pandya KJ, Raubertas RF, Flynn PJ, et al. *Ann Intern Med.* 2000;132:78-93.	α-Adrenergic antagonists clonidine and methyldopa: dry mouth, drowsiness, dizziness, hypotension, rebound hypertension
Methyldopa	No		Nelson HD, Haney E, Humphrey L, et al. AHRQ Publication No. 05-E016-2. Rockville, MD: Agency for Healthcare Research and Quality; 2005.	
HORMONES				
Medroxyprogesterone acetate	Yes	Frequency of hot flushes was reduced 74% with 20 mg medroxyprogesterone acetate compared with 26% with placebo.	Schiff I, Tulchinsky D, Cramer D, et al. *JAMA.* 1980;244:1443-1445.	Progestins medroxyprogesterone and megestrol: nausea, vomiting, constipation, somnolence, depression, breast tenderness, uterine bleeding; possible increased risk for venous thromboembolism, cardiovascular events, and breast cancer
Megestrol	Yes	Among breast cancer survivors, frequency of hot flushes reduced 74% with 20 mg megestrol twice a day compared with 27% with placebo	Loprinzi CL, Michalak JC, Quella SK, et al. *N Engl J Med.* 1994;331:347-352.	
Tibolone†	Yes	Several trials reported improved hot flushes compared with placebo and efficacy equivalent to standard doses of estrogens with 1.25-5.0 mg tibolone	Modelska K, Cummings S. *J Clin Endocrinol Metab.* 2002;87:16-23. Nelson HD, Haney E, Humphrey L, et al. AHRQ Publication No. 05-E016-2. Rockville, MD: Agency for Healthcare Research and Quality; 2005.	Steroid hormone: headache, weight gain, uterine bleeding; effects on venous thromboembolism, cardiovascular disease, and breast and uterine cancer
OTHER DRUGS				
Gabapentin	Yes	Among healthy women, frequency of hot flushes was reduced 45% with gabapentin 300 mg three times/day compared with 29% with placebo. Frequency of hot flushes was reduced 31% more than placebo among breast cancer survivors	Guttuso TJ, Kurlan R, McDermott MP, et al. *Obstet Gynecol.* 2003;101:337-345. Pandya JK, Morrow GR, Rosco JA, et al. *Lancet.* 2005;366:818-824.	Nausea, vomiting, somnolence, dizziness, rash, ataxia, fatigue, leukopenia

*Side effects were reported in clinical trials of the therapy or from Epocrates RX drug reference (available at *http://www.epocrates.com*).
†This drug had not been approved by the U.S. Food and Drug Administration at the time of publication.

or relieves vaginal dryness, lowers vaginal pH, and increases the proportion of superficial cells in the vaginal epithelium.

DIAGNOSIS

Diagnosis is primarily based on typical complaints of vaginal dryness, discomfort, itching, or dyspareunia in women undergoing the menopause transition or older postmenopausal women. Pelvic examination should exclude other causes of discomfort, including infections, lesions, and trauma. Physical findings of vaginal dryness, pallor, friability, and vaginal pH greater than 5.5 support the diagnosis. Cytologic examination of the proportion of superficial, intermediate, and parabasal cells from a scraping of the lateral vaginal wall (vaginal maturation index) showing primarily parabasal cells also supports the diagnosis. In clinical practice, measurement of pH and vaginal maturation index are not necessary to make the diagnosis.

TREATMENT

Many women with vaginal symptoms obtain adequate relief with use of over-the-counter vaginal moisturizers, such as Replens. Estrogen therapy is highly effective. Topical therapy is efficacious and is preferred because it generally results in smaller increases in systemic estrogen levels than oral or transdermal therapy. Estrogen vaginal creams, tablets, and rings approved for treatment of vaginal dryness are listed in Table 248-3.

Most clinicians do not add a progestin to protect the uterus in women treated with vaginal estrogen, but evidence to support the uterine safety of vaginal estrogen is limited to short-term studies. Low-dose, intermittent treatment (e.g., 1 to 2 g conjugated estrogen cream or 0.025 mg estradiol tablet twice a week) results in very small increases in systemic estrogen levels that appear not to cause endometrial stimulation. However, full-dose daily treatment has been shown to increase estradiol levels to 50 pg/mL or higher in approximately half of treated women and has been associated with uterine bleeding and hyperplasia.

Sleep Disturbance

The prevalence of self-reported sleep disturbance increases from about 40% of premenopausal women to approximately 60% of postmenopausal women. Sleep disturbances, including trouble falling asleep and early awakening, are reported by menopausal women, but awakening during the night appears to be most bothersome.

The etiology of sleep disturbance associated with menopause is unclear. Postmenopausal women with hot flushes are more likely to report sleep disturbance than are those without flushes, and women commonly report that they are awakened by hot flushes. However, studies using polysomnography find that nocturnal hot flushes do not consistently occur at the same time as sleep disturbance. Thus, disturbed sleep appears to be part of a menopausal syndrome, but it may not be caused by flushing.

Menopause-related sleep disturbance can be treated using standard approaches to sleep hygiene and prescription medications. Both oral and transdermal estrogen preparations improve sleep in perimenopausal and postmenopausal women with hot flushes.

249 INTIMATE PARTNER VIOLENCE

GENE FEDER AND HARRIET MACMILLAN

DEFINITION

Intimate partner violence (IPV) is defined as any behavior within an intimate relationship or ex-relationship that causes physical, psychological, or sexual harm. This includes physical aggression, such as hitting, kicking, and beating; psychological violence, such as intimidation, constant humiliation; various controlling behaviors, such as isolation from family and friends, monitoring movements, financial control, and restricting access to services; and sexual violence, including forced intercourse and other sexual coercion. Lifetime prevalence of isolated violent acts within relationships is comparable for men and women, but repeated coercive, sexual, or severe physical violence is perpetrated largely against women by men. Although IPV also occurs in same-sex relationships, research evidence on the health consequences of IPV and the care of survivors is largely confined to women in heterosexual relationships.

Historically, there has been the stereotype of a male batterer as one who uses severe, repeated, and unilateral violence against a nonviolent female victim. It is now recognized that *bilateral violence* is a common form of IPV, even though the overwhelming burden of morbidity and mortality related to IPV is experienced by women. Bilateral violence, sometimes referred to as *common couple violence*, is considered less severe that the pattern of abuse known as *battering* or *intimate terrorism*—a severe and escalating form of IPV characterized by threats, terrorization, multiple forms of abuse, and controlling behavior on the part of the abuser. Current research suggests that women rarely subject men to battering.

IPV is a risk factor for a wide range of medical and psychiatric conditions and therefore can be understood as an epidemiologic exposure. Yet violence perpetrated by an intimate partner or ex-partner is essentially a violation of human rights and a preventable psychosocial issue that needs to be addressed through social and educational policies.

EPIDEMIOLOGY

The prevalence of IPV against women varies internationally but is universally high, comparable to chronic conditions like diabetes and asthma. The most robust comparative study (24,097 women from 15 sites in 10 countries), conducted by the World Health Organization (WHO) found a lifetime prevalence of physical or sexual violence, or both, ranging from 15 to 71%. Prevalence of physical or sexual violence during the past year ranged from 15 to 54%. In all sites but one, women were more at risk for violence from a partner or ex-partner than from violence by other people.

A Canadian survey highlights a comparable prevalence of physical violence against men by their female partners (6% 5-year prevalence), which is replicated in most community surveys, but with substantially less serious violence (beaten, choked, or threatened with or had a weapon used against them), sexual violence, or fear of their partner.

Causation

Several theories about the causes of IPV have been proposed over the years. Social learning theory suggests that IPV is a learned behavior. The fact that male perpetrators and female victims are more likely to report histories of exposure to violence in childhood supports this theory. However, most individuals exposed to violence in childhood do not go on to commit violence as adults, and not all abusers have violent upbringings. Furthermore, the link between poor parenting generally, including neglect, and subsequent IPV in adulthood suggests that the effect is not simply one of modeling abusive behavior. Exposure to rejecting or neglectful parenting is associated with adverse effects on intrapersonal (e.g., poor self-worth) and interpersonal development, which are associated with IPV.

A feminist perspective views IPV against women as a form of social control that results from society's patriarchal structure leading to inequality in power relationships between men and women. Lending support to this perspective is the finding that IPV appears to be less common in more democratic and less economically polarized societies. Although IPV occurs more often in contexts in which there is support for male authority in the family and women have less access to economic security, it is not clear why some individuals are more likely to be violent under such conditions than others.

With regard to psychological theory, there are conflicting views about the association between IPV and psychopathology. Some researchers argue that abusive males have deficits in one or more coping mechanisms, anger control, and communication skills, whereas others suggest that IPV results from dysfunctional interactional patterns between partners. Because types of IPV are not the same for all couples, there are likely multiple causes for its occurrence. Most of the research has focused on factors associated with increased risk of men abusing women (Table 249-1); however, whether these factors are "causal" is unknown.

TABLE 249-1 FACTORS ASSOCIATED WITH A MAN'S RISK FOR ABUSING HIS PARTNER

INDIVIDUAL	RELATIONSHIP	COMMUNITY	SOCIETAL
Young age	Poor family functioning	Weak community sanctions against intimate partner violence	Traditional gender norms
Heavy drinking	Marital instability	Poverty	Social norms supportive of violence
Depression	Marital conflict	Economic inequality	
Personality disorders	Male dominance	Low social capital	
Low academic achievement	Economic stress		
Low income			
Exposure to violence in childhood

CLINICAL MANIFESTATIONS

The information in this section pertains to female patients because most of the research examining clinical manifestations associated with IPV exposure has focused on women. However, recent studies of male victims suggest that they also experience increased risk for poor health as well as chronic physical and emotional health problems and injuries.

Patients seldom present with a chief complaint of IPV. Injuries are the most obvious manifestation; a clinician should have increased suspicion for IPV if there are multiple injuries, the presenting history of injuries is not consistent with the physical examination, and there is a delay in seeking medical care for injuries. Patients exposed to physical violence may present with injuries that vary from minor abrasions to life-threatening trauma. Although there can be overlap between injuries resulting from IPV and injuries from other causes, the former typically involve trauma to the head, face, and neck, whereas the latter are more typically injuries of the extremities. Multiple facial injuries are suggestive of IPV rather than from other causes, and those that are more specific for IPV include zygomatic complex fractures, orbital blowout fractures, and perforated tympanic membrane. Although facial injuries are the most common injuries associated with IPV, they have low specificity. Musculoskeletal injuries are considered the second most common type of injuries, including sprains, fractures, and dislocations. Blunt-force trauma to the forearms should raise suspicion of IPV because these can occur when trying to block being struck.

Victims of IPV often experience multiple mechanisms of injury; being struck by a hand is the most common, followed by use of a household object. Injuries from weapons such as knives and guns are far less common (<1%) but are associated with higher risk for mortality. Strangulation also occurs frequently, but less is known about the types of clinical manifestations that result from this form of IPV. Other injuries that raise suspicion of IPV include fractures of the spine or trunk, bites, hair pulling, and open wounds. Those exposed to sexual abuse may show signs of trauma to the genital area, but sexual assault is associated with signs of injury in less than one third of cases.

Most victims of IPV presenting to health care settings do not have signs of obvious trauma, but rather a constellation of overlapping physical and mental health problems. A patient presenting with vague signs and symptoms or chronic somatic complaints, including pain, suggests the possibility of IPV. Other behaviors that suggest IPV include delay in seeking medical care or multiple cancellations of medical appointments.

There are no systematic reviews of studies on the overall physical health consequences of IPV, but a recent overview of studies reported increased rates of chronic physical conditions, particularly gynecologic, gastrointestinal, and nervous system disorders, as well as increased cardiovascular risk, although most of the studies were small and poorly adjusted for other risk factors. The overview also found that women with a history of abuse, particularly physical and sexual violence, were more likely to experience chronic pain and nonspecific symptoms, although an association between abuse and number of physical symptoms is also found in women who experience emotional abuse without any physical abuse. The WHO study reported significant associations between women's lifetime experiences of partner violence and self-reported poor health and specific health problems in the previous 4 weeks, such as difficulty walking, difficulty with daily activities, pain, memory loss, dizziness, and vaginal discharge. Other physical conditions that should raise suspicion of IPV include chronic gynecologic or gastrointestinal symptoms, such as irritable bowel syndrome or chronic pelvic pain. It should not be assumed, however, that there is a specific association between functional disorders such as irritable bowel syndrome or fibromyalgia over and above the greater reporting of physical syndromes in general. IPV exposure is associated with an increased risk for sexually transmitted infections, including human papillomavirus.

Exposure to any type of IPV can be associated with a wide range of emotional and behavioral symptoms; depression and post-traumatic stress disorder (PTSD) are the two most commonly associated emotional conditions, but other anxiety disorders and substance abuse are also associated with IPV exposure. In the WHO study, women who reported IPV at least once in their life reported three to four times more emotional distress, suicidal thoughts, and suicide attempts than nonabused women. There is strong evidence of increased risk for depression, anxiety, substance abuse, and PTSD, with longitudinal studies reporting increased morbidity following violence. The cross-sectional design of most studies examining associated impairment precludes conclusions about the causal role of IPV in these conditions, but the few published longitudinal studies show the onset or worsening of depression, PTSD, and substance abuse *after* exposure to IPV.

Pregnant women deserve special mention because IPV can threaten the health of both mother and fetus. Injury patterns during pregnancy are more likely to be central, including blunt trauma to the head, torso, abdomen, breasts, and genitalia. Abuse directed to the abdomen may lead to poor pregnancy outcomes and perinatal death. Although the evidence regarding a direct association between IPV in pregnancy and low birthweight has been conflicting, the increased risk for preterm birth as well as other factors such as psychosocial stress may play a role in adverse outcomes for infants, but more investigation is required.

Although beyond the scope of this chapter, there is increasing recognition that children's exposure to IPV shows a significant association with children's internalizing and externalizing problems, including trauma symptoms, developmental delay, educational problems, and long-term mental health conditions.

Identification

Screening for IPV can be performed by interview or with computer assistance,■ but there is insufficient evidence for a policy of universal IPV screening of women presenting to health care settings. For example, a multisite randomized trial that evaluated the effectiveness of screening and communication of a positive result to clinicians in health care settings compared with no screening concluded that the benefits were too small to justify screening.■ However, it is important to be alert to the signs and symptoms associated with IPV, including those associated with the broad range of physical and mental health conditions referred to previously. Risk indicators that point to a higher likelihood of IPV include symptoms of depression, somatization and PTSD in the female patient, and a history of alcohol or drug abuse and unemployment in the male partner (or ex-partner). It is important when asking about exposure to IPV, to do so privately, with no one else present, including a child (beyond infancy) or partner; if the inquiry or response is overheard, it could put the patient at risk for further IPV. A recent meta-analysis of qualitative studies of women's expectations and experiences reported that when the topic of IPV is raised, patients want questioning that is nonjudgmental, compassionate, and caring. Women want to be asked about IPV with confidentiality assured, but do not want to be pressured to disclose. In some jurisdictions, however, disclosure of IPV when a patient has children in the home can lead to mandatory reporting to child protection services. It is important that patients be advised about the limits of confidentiality before being asked about IPV exposure.

Possible questions to ask if IPV is suspected include the following: (1) Sometimes partner or ex-partners use physical force. Has this ever happened to you? (2) Have you felt humiliated or emotionally harmed by your partner or ex-partner? (3) Are you now or have you ever been afraid of your partner or ex-partner? (4) Have you ever been physically threatened or hurt by your partner or ex-partner? (5) Have you been forced to have any kind of sexual activity by your partner or ex-partner? (6) Has your partner or ex-partner ever tried to control your behavior; for example, control where you go or whom you see?

The initial clinical response when IPV is identified should include validation of the experience (e.g., everyone deserves to feel safe at home); affirmation that violence is unacceptable; and expression of support. The clinician needs to acknowledge the complexity of IPV and respect the patient's individual concerns and decisions. The assessment should include an evaluation of safety; the patient should be asked if it is safe for her (or him or any children) to return home. The following are examples of safety considerations: (1) Has the frequency or severity of the violence increased? (2) Is the partner

or ex-partner obsessed with the patient? (3) How safe does she (he) feel? (4) Does the partner or ex-partner have a weapon or access to one? (5) Has she (he) been threatened with a weapon? Although a general discussion of gun violence is beyond the scope of this section, having firearms in the home is associated with an increased risk for homicide associated with IPV. Another predictor of domestic homicide is threats of deadly violence.

TREATMENT

Rx

The initial response of clinicians to the disclosure of IPV by female patients, whether the disclosure is spontaneous or the result of clinical inquiry, routine inquiry, or screening, is crucial in gaining trust and is the basis of further management. IPV is a highly stigmatized condition, akin to sexually transmitted infection or substance abuse, with the added dimension of risk for further harm from breach of confidentiality. A meta-analysis of 25 qualitative studies of women's expectations and experiences (847 informants) reported consistent messages about how clinicians can respond appropriately to disclosure. *Before disclosure or questioning*, they should understand the problem, including knowing about the available community services and appropriate referral systems; ensure that the clinical environment is supportive, welcoming, and nonthreatening; place brochures and posters in the clinical setting; try to ensure continuity of care; assure abused women about matters of privacy, safety, and confidentiality; be alert to the signs of abuse and raise the matter when indicated; use verbal and nonverbal communication skills to develop trust; and be compassionate, supportive, and respectful toward abused women. *When the topic of IPV is raised*, they should be nonjudgmental, compassionate, and caring when questioning about abuse; be confident and comfortable asking about domestic violence; not pressure women to disclose abuse because simply raising the topic may be helpful to women; ask about abuse over the course of several interviews because a woman may disclose abuse at a later date; ensure that the environment is private and confidential; and provide time. *Immediate response to disclosure* should be nonjudgmental, with compassion, support, belief of experiences; acknowledge the complexity of the problem and respect the woman's unique concerns and decisions; put the needs identified by the woman first and help to ensure that social and psychological needs are met; take time to listen, provide information, and offer referrals to specialist help; validate her experiences, challenge assumptions, and provide encouragement; and respond to any concerns about safety. *Response in later interactions* should be patient and supportive, allowing her to progress at her own therapeutic pace; understand the chronicity of the problem and provide follow-up and continued support; respect the woman's wishes and not pressure her into making any decisions; be nonjudgmental if a woman does not follow up with referrals immediately; give abused women an opportunity to disclose abuse at a later date.

Beyond their initial response and managing the medical sequelae of abuse, most generalists have neither the expertise nor the capacity to meet the specific needs of women experiencing IPV, which include legal, financial, housing, and safety needs. A key step, particularly in the context of current or recent violence, is an offer of referral to some sort of specialist support. Two main types of services have been evaluated: advocacy programs and psychological interventions (individual or group based). Generally, advocates engage with individual clients who are being abused, aiming to empower them and linking them to community services. Core activities of advocacy include provision of legal, housing, and financial advice, facilitating access to and use of community resources, such as refuges (shelters, safe houses), emergency housing, and provision of safety planning advice. Advocates can also provide ongoing support and informal counseling. A Cochrane review of 10 randomized controlled trials (1527 participants) of domestic violence advocacy concluded that there was equivocal evidence that advocacy for women recruited in domestic violence shelters (refuges) had a beneficial effect on their physical and psychosocial well-being and were unable to draw any conclusions for women receiving advocacy in or referred from health care settings.[3] A broader systematic review that included all controlled studies of domestic violence advocacy concluded that most showed a reduction in abuse, increased social support, and improved quality of life as well as increased use of safety behaviors and accessing of community resources. Only two of the studies had participants referred from health care settings. Clinicians should be able to refer patients to specialist IPV advocacy and are more likely to ask about abuse if they have the support of these services. If such services are not immediately available, shelters and refuges often provide these kinds of services for women both in residences and on an outreach basis.

A systematic review of controlled studies of psychological interventions for survivors of IPV identified 17 studies, 7 of individual and 10 of group interventions. There was a wide range of individual psychological interventions that demonstrated improvements in psychological outcomes, including depression, PTSD, and self-esteem. Two well-executed trials[4,5] of individual cognitive therapy–based interventions for women with PTSD who were no longer experiencing violence provided reasonable evidence for this intervention, but this cannot be extrapolated to women still in an abusive relationship. All the studies of group psychological interventions showed improvement in one or more psychological or mental health outcomes, but with the exception of one study, they were poorly executed. Consequently, the effectiveness of this type of intervention remains uncertain, particularly for women who are still experiencing IPV.

Although the assessment and treatment of the abuser should be carried out by mental health professionals with expertise in this area, it can be helpful for general clinicians to have some awareness of the effects of treatment. The evidence for batterer treatment is mixed, with the better-designed studies generally indicating little or no benefit[6] or potential harm (i.e., increased recidivism). The evidence for couple therapy is mixed, with trial-level evidence indicating no benefit in a military sample. Most authors caution that these couple therapy programs are not safe for many abused women, particularly those experiencing "intimate terrorism." Furthermore, when abusers are enrolled in treatment programs, it is important that women are provided with concurrent advocacy and support. There is some evidence to suggest that permanent, but not temporary, civil protection orders may be effective in reducing future violence.

PREVENTION

From a public health perspective, primary prevention of IPV is desirable, although most of the available research focuses on the health care response to the survivors of IPV, both while a woman is still exposed to abuse (secondary prevention) and when she is experiencing the long-term health problems associated with IPV (tertiary prevention).

Efforts aimed at primary prevention of IPV through educational programs have focused on changes in attitude and knowledge rather than actual reduction in IPV. In one study of adolescent dating violence, considered a precursor to IPV in adulthood, an interactive curriculum for grade 9 students that included information about dating violence and healthy relationships was associated with a statistically significant reduction in self-reported physical dating violence, but the differences were small (9.8% in control versus 7.4% in experimental group).[7]

There is no clinical trial evidence for the effectiveness of interventions provided in general medical settings with the aim of secondary prevention. However, an advocacy and empowerment program in antenatal clinics reduced psychological and minor physical violence,[8] and a program for pregnant African American women based on individual counseling sessions reduced violence and improved pregnancy outcomes.[9] Outside of health care settings, intensive advocacy (12 hours or more duration) may reduce physical abuse among women leaving shelters or refuges after 12 to 24 months of follow-up, but not for shorter or longer follow-up.[3]

PROGNOSIS

The prognosis of IPV with and without intervention is uncertain. Trials of interventions have small samples and short follow-up, and most have substantial attrition of participants. As far as the "natural history" of the condition is concerned, cohort studies are rare, and cross-sectional studies are potentially misleading. In a 3-year follow-up of participants who received an advocacy intervention after leaving a shelter, 36% had been assaulted by their original partner or a new partner in the 6 months before the interview. The difference in re-victimization at 2 years between intervention and control arms did not persist, but there was still a significant difference in quality of life and social support among women receiving advocacy. In a U.S. cohort study, 44% of participants were still being abused after 3½ years.

MINERAL AND BONE HOMEOSTASIS

MURRAY J. FAVUS

HOMEOSTATIC SYSTEMS FOR CALCIUM, MAGNESIUM, AND PHOSPHATE

Metabolic bone diseases and mineral disorders may arise from excesses or deficiencies of the calciotropic hormones, vitamin D and its metabolites, and parathyroid hormone (PTH), or of the steroid or peptide hormones that have direct actions on bone (estrogens, androgens, glucocorticoids, thyroid hormone, insulin-like growth factor-I [IGF-I]), and excessive or deficient intake of the key minerals that form the bone mineral phase (calcium, magnesium, and phosphorus). Genetic or acquired defects in osteoblast or osteoclast function, bone matrix synthesis, mineralization, bone turnover, or repair may also cause metabolic bone diseases. Maintenance of Ca, Mg, and P (biologic forms of P are mostly in the form of inorganic phosphate, and P is expressed as PO_4) homeostasis is achieved through a coordinated trafficking of the ions across intestine and kidney to ensure delivery of sufficient amounts to support mineralization of the bone matrix. Disorders that impair intestine, kidney, parathyroid, or bone may disturb homeostasis and may cause bone loss and fractures. Measurements of blood levels of PTH, the vitamin D metabolites 25-hydroxyvitamin D [25(OH)-D], and 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$], other key steroid and peptide hormones, biomarkers of bone turnover, and the blood and urine levels of Ca, Mg, and PO_4 are critical for accurate diagnosis. Mineral levels in blood and urine permit inferences about mineral balance, intestinal absorption, renal handling, and bone mineralization and resorption. This chapter reviews the homeostatic systems for Ca, Mg, and PO_4. Bone cellular functions and turnover and matrix composition are discussed in Chapter 251. Details of parathyroid gland function and regulation of PTH secretion are discussed in Chapter 253.

Total Body Divalent Elements

Calcium

In a healthy 70-kg man, the total body Ca content is 25 mmol (mg/40 = mmol), of which 99% exists in the mineral phase of bone as the hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] crystal. The molar ratio of Ca to P in $Ca_{10}(PO_4)_6(OH)_2$ is approximately 2:1, so as bone is resorbed, Ca and P ions are released into the extracellular fluid (ECF) at a ratio of 2:1. The serum total Ca concentration is 10^{-3} mol/L. Ca is present in the freely ionized state (48%) or protein bound (46%) largely to albumin. Clinical laboratories measure total serum Ca. The blood ionized Ca fraction is the most informative measurement because the ionized Ca fraction is readily exchangeable with pools of Ca in bone, blood, and intracellular sites. Errors in drawing and processing blood samples may compromise the accuracy of ionized Ca; therefore, automated measurements of total Ca are more reliable if the albumin level is not reduced and blood pH is normal.

Magnesium

The average adult body contains 1.0 mol of Mg, of which 54% is located within the skeleton and 45% is intracellular in soft tissues. Mg is not consistently incorporated into the $Ca_{10}(PO_4)_6(OH)_2$ crystal structure of bone. Mg is the most abundant intracellular divalent cation (cytosolic concentration 5×10^{-4} M). Blood ionic Mg is the fraction that most closely correlates with Mg-dependent biologic actions. Serum total and ionic Mg levels are not accurate estimates of Mg concentrations in the intracellular, soft tissue, or total body spaces.

Phosphate

P exists in tissues and blood primarily as PO_4. In bone, PO_4 is a major constituent of the $Ca_{10}(PO_4)_6(OH)_2$ crystal structure and accounts for 85% of total body PO_4. The soft tissue contains 15% of total body PO_4. Serum PO_4 levels fluctuate depending on age, sex, dietary intake, and growth rate. Serum levels of PTH, $1,25(OH)_2D_3$, growth hormone, IGF-I, and phosphotonins, which include fibroblast growth factor-23 (FGF-23), control serum PO_4 levels primarily by regulating the efficiency of renal proximal tubule reabsorption of filtered PO_4, $1,25(OH)_2D_3$ increases serum PO_4 through stimulation of intestinal PO_4 absorption, and PTH and $1,25(OH)_2D_3$ release bone PO_4 through stimulation of bone resorption.

Normal serum PO_4 contributes to the maintenance of the $Ca \times PO_4$ ion product, which, through physicochemical forces, drives bone mineralization. Low serum PO_4 lowers the $Ca \times PO_4$ ion product and may thus impair mineralization. A high serum and ECF $Ca \times PO_4$ product may result in extraskeletal soft tissue calcification.

Maintenance of Blood Levels

Calcium

Ca homeostasis has two goals: (1) sufficient delivery of Ca to support skeletal mineralization; and (2) maintenance of blood ionized Ca (Ca^{2+}) within a narrow normal range. A decline in blood Ca^{2+} is defended against by the actions of PTH (Chapter 253). $1,25(OH)_2D_3$ increases serum PO_4 levels by stimulating both intestinal PO_4 absorption and bone resorption with mineral dissolution that releases bone Ca and PO_4. A large PO_4 load could increase blood PO_4 and lower Ca^{2+}, but PTH decreases renal proximal tubule PO_4 reabsorption and dissipates the PO_4 load by increased urinary excretion.

Magnesium

Mg blood levels are influenced by the influx and efflux of Mg across intestine, bone, and kidney with the major influence being the regulation of renal proximal tubular Mg reabsorption. Like Ca^{2+}, Mg may downregulate PTH secretion but is less potent than Ca^{2+}. Serum Mg levels are regulated by renal proximal tubular reabsorption.

Phosphate

Serum PO_4 levels decline rapidly during periods of low dietary PO_4 intake, but proximal tubular reabsorption becomes more efficient and thereby lowers urine PO_4 losses to 1 to 2% of the filtered load within 2 to 4 days of ingesting a diet low in PO_4.

Mineral Intake and Intestinal Absorption

Calcium

Dietary Ca is incompletely absorbed with an efficiency of absorption between 25 and 60%. The range reflects the influence of age, habitual Ca intake, skeletal requirements, vitamin D status, the state of the homeostatic system, and the bioavailability of Ca contained in foods. Fractional Ca absorption is positively correlated with circulating $1,25(OH)_2D_3$ levels. Conditions of increased Ca requirements, such as during growth, pregnancy, and lactation, or when dietary Ca intake is low, stimulate its intestinal adaptive increase though increased renal $1,25(OH)_2D_3$ production. The intestinal adaptation is lost with aging, and the practice of increasing dietary Ca or using Ca supplements in postmenopausal women and in older men is an attempt to compensate for this age-related decline. Negative Ca balance (urine Ca + fecal Ca > net intestinal Ca absorption) occurs as Ca net absorption falls to less than 5.0 mmol/day. Fecal Ca is the sum of unabsorbed dietary Ca, Ca in secreted pancreatic and biliary juices, and mucosal secretions. Fecal Ca losses are between 2.5 and 5.0 mmol/day and are not regulated by Ca^{2+}, PTH, or $1,25(OH)_2D_3$.

Sites and Mechanisms of Absorption

The large surface areas of duodenum and jejunum are responsible for 90% of Ca absorbed. The physiologic adaptation to low Ca intake increases fractional Ca absorption from 25 to 45% to 55 to 70%. The increases are largely in the duodenum and ileum.

There are two absorptive mechanisms: (1) cell-mediated, active transport that dominates absorption at low luminal Ca concentrations; and (2) a passive, diffusional absorption driven by transepithelial electrochemical gradients that dominates at normal and high luminal Ca concentrations (>1.0 mmol/L) when serum $1,25(OH)_2D_3$ levels are low. Intestinal epithelial transcellular Ca transport is stimulated by high ambient $1,25(OH)_2D_3$ levels and by upregulation of the vitamin D receptor, which in turn mediates expression of vitamin D–dependent genes encoded for proteins that are required for Ca active transport (e.g., the brush border Ca transport protein TRPV6). Once within the cell, Ca is bound to the high-affinity Ca-binding protein, calbindin.

Phosphate

PO_4 absorption increases linearly with dietary PO_4 intake. At normal to high intake, absorption occurs by passive diffusion and is driven by the luminal

PO_4 concentration. During low PO_4 intake, PO_4 absorption largely occurs through an active, cell-mediated transport process that is stimulated by $1,25(OH)_2D_3$. During adequate intake (25 to 60 mmol/day), PO_4 absorption is highly efficient, with 60 to 80% of dietary PO_4 absorbed. Transcellular PO_4 transport begins with influx across the brush border by overcoming the electrochemical gradients through either an energy-dependent transport process or a secondary active transport process coupled to the influx of a cation such as Na. $1,25(OH)_2D_3$ stimulates net PO_4 absorption by increasing saturable brush border PO_4 uptake. The saturable active transport mechanism is present primarily in the proximal duodenum and jejunum.

Magnesium

Mg is abundant in highly cellular foods. During usual Mg intake of 7 to 30 mmol (mg/24 = mmol)/day, fractional Mg absorption averages 35 to 40%, and net intestinal Mg absorption increases in direct relation to dietary Mg. $1,25(OH)_2D_3$ does not stimulate Mg absorption, and serum $1,25(OH)_2D_3$ and net Mg absorption do not co-vary. Dietary PO_4 and other dietary anionic constituents may form nonabsorbable complexes with luminal Mg and reduce Mg absorption.

Renal Handling and Urinary Excretion

The fine tuning adjustments of Ca, Mg, and PO_4 balances occur at the level of the kidney, where filtered loads and tubular reabsorptions are highly regulated under changing body mineral requirements and wide variations in intakes and net absorptions.

Calcium

Approximately 98% of Ca in the glomerular ultrafiltrate undergoes tubular reabsorption that permits precise regulation of serum Ca^{2+}. Ultrafilterable Ca contains serum complexed and ionized Ca fractions and undergoes complete filtration when Ca concentration is 1.5 mmol/L. The amount of Ca filtered each day, more than 270 mmol, is far in excess of the Ca content contained in the ECF and exceeds net intestinal Ca absorption. Therefore, 98% of the filtered Ca must be reabsorbed to maintain neutral Ca balance. Seventy percent of filtered Ca is reabsorbed in the proximal tubule. Another 20% is reabsorbed in the thick ascending limb of the loop of Henle (TALH). The collecting duct is the final site of Ca reabsorption (5%). The urine contains only 2% of the filtered Ca load.

Volume expansion increases and volume contraction decreases urine Ca and Na excretion, respectively. Hypercalcemia decreases glomerular filtration rate (GFR) and proximal tubule, TALH, and distal convoluted tubule Ca reabsorption, resulting in a greater urinary excretion of Ca than Na. In the TALH, Ca sensing receptor (CaR) activation by hypercalcemia decreases Ca reabsorption; Ca may also alter paracellin-1-regulated Ca and Mg permeability with decreased reabsorption of both ions. PTH is also the principal regulator of Ca reabsorption by reducing GFR and stimulating tubule reabsorption. Acute and chronic metabolic acidosis increases and alkalosis decreases urine Ca excretion.

Thiazide diuretics (hydrochlorothiazide, chlorthalidone), indapamide, and amiloride increase urine Na excretion and decrease urine Ca through an increase in distal tubule Ca reabsorption. Loop diuretics increase urine Ca and Na excretion by inhibiting the Na-K-2Cl transporter in the TALH. Hypercalciuria continues as long as urinary Na losses are replaced.

Magnesium

Urine Mg averages 24 mmol/day, indicating that approximately 95% of Mg filtered in the glomerulus is reabsorbed. The proximal tubule reabsorbs only 15% of the Mg ultrafiltrate. Seventy percent of Mg is reabsorbed in the cortical TALH, and 10% of filtered Mg is reabsorbed in the distal convoluted tubule. High serum Mg may decrease Mg reabsorption.

Urine Mg reabsorption is highly regulated by ECF volume expansion and high serum Mg, which increase urine Mg excretion. Hypomagnesemia increases TALH Mg reabsorption. Hypercalcemia decreases Mg reabsorption in the proximal tubule and TALH. Loop diuretics markedly increase urine Mg excretion.

Phosphate

Ultrafilterable PO_4 represents 85% of total serum PO_4, and 12.5% of the filtrate appears in the final urine. Eighty-five percent of PO_4 reabsorption occurs in the proximal tubule through an Na-PO_4 cotransporter, which reabsorbs PO_4 against the brush border electrochemical PO_4 gradients. Three genes encode for related Na gradient-dependent PO_4 transporters *(Npt1-Npt3)*, with the apical brush border membrane Npt2 accounting for 85% of proximal tubule PO_4 reabsorption. The *Npt2* gene is regulated by FGF-23.

Mineral Balance and Adaptation to Changing Requirements

Mineral balance (retention or loss) is maintained by the calciotropic hormones PTH and $1,25(OH)_2D_3$. Insufficient dietary mineral supply stimulates an adaptation of the homeostatic systems through hormonal changes to maintain external balance (balance = net absorption − [fecal excretion + urine excretion]). Mineral balance becomes positive (intake and retention exceed urinary and intestinal losses) during rapid skeletal growth in childhood and adolescence and during pregnancy and lactation. Negative balance (gastrointestinal or urinary losses, or both, exceed intake and retention) may occur during high rates of bone remodeling, as seen during estrogen deficiency, aging, and accompanying diseases such as hyperthyroidism and primary hyperparathyroidism. PTH and 1,25(OH) increase intestinal Ca and PO_4 absorption and regulate renal tubule Ca, PO_4, and Mg reabsorption. The Ca homeostatic system maintains blood ionized Ca within the normal range despite wide variations in dietary Ca intake and changing rates of bone mineralization.

OSTEOPOROSIS

CLIFFORD ROSEN

DEFINITION

Osteoporosis is a disorder characterized by enhanced skeletal fragility as a result of reduced bone quantity and quality. The clinical symptoms of this disease may include back pain, height loss, and a history of fractures. Bone mineral density (BMD), which can be determined by several techniques, is often markedly reduced in osteoporotic patients with fractures. The World Health Organization (WHO) defines osteoporosis as a condition in which a BMD is less than −2.5 standard deviations (SD) below peak bone mass (i.e., a T-score measured as the units of SD below the normative mean of a 35-year-old woman). However, several large observational studies have shown that osteoporotic fractures can occur across a wide spectrum of BMDs. These events are likely related to altered bone quality, as a result of microarchitectural changes in the trabecular and cortical skeleton. Qualitative determinants of osteoporotic fractures include trabecular perforations, microcracks, mineralization defects, changes in bone size, and rapid bone turnover (Fig. 251-1). Unfortunately, most of these qualitative changes in the skeleton cannot be captured by clinical measurements, even though they strongly influence overall fracture risk. Recently, introduction of extreme high-resolution computed tomography (CT) and more refined quantitative CT measurements have allowed investigators to measure trabecular size, number, and shape accurately, although to date fracture prediction is not markedly enhanced with these new tools. Hence, although low BMD defines osteoporosis, this diagnosis should not be excluded in susceptible individuals, particularly those with a history of a low-impact fracture. Finally, although the WHO defined *osteopenia* as a condition with a T-score between −1.0 and −2.5, and therefore places a given individual at a greater risk for fracture, the clinical significance of this term remains nebulous. Introduction of the FRAX

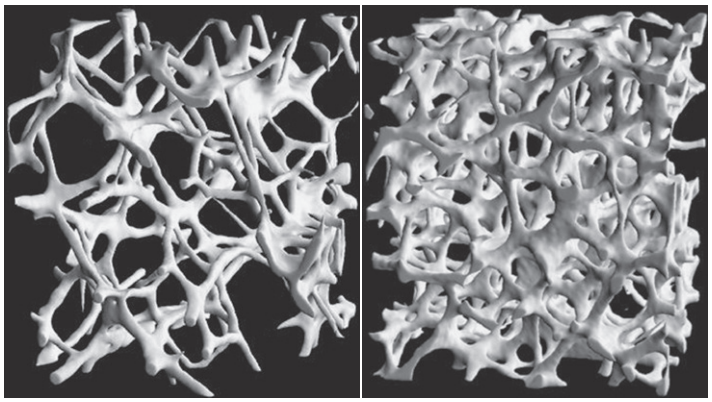

FIGURE 251-1. Microcomputed tomography images of trabecular bone from the vertebrae of an osteoporotic individual (*left*) and a healthy age-matched normal woman (*right*).

Internet tool, which weighs clinical risk factors with BMD of the hip, may provide greater insight into the long-term fracture risk in individuals with low bone mass. In sum, low BMD is a strong risk factor for subsequent fractures, but there is no threshold BMD above or below which fractures occur. Other risk factors, such as a previous fracture history, age greater than 65 years, a strong family history, and recent significant weight loss must be considered.

EPIDEMIOLOGY

By the age of 50 years, the lifetime risk of developing a fracture resulting from osteoporosis in a white woman is nearly 40%, similar to that for coronary heart disease; in men, the corresponding figure is 13%. In the United States, approximately 350,000 hip fractures, close to 1 million vertebral fractures, and 200,000 wrist fractures occur every year. In addition, other fragility-related fractures, particularly those of the pelvis and humerus, are significant causes of morbidity in elderly persons. The incidence of osteoporotic fractures increases markedly with age. In women, this increase is seen after the age of 45 years and is mainly the result of forearm fractures. After the age of 65 years, the incidence of hip fractures rises exponentially. In men, the incidence of fragility-related fractures increases after the age of 75 years, and in both sexes the hip is the most common fracture site after the age of 85 years. The incidence of vertebral fractures in both men and women is less well documented because many such patients are asymptomatic. Clinical vertebral fractures increase dramatically with age in men, whereas a more linear age-related increase is noted in women. This age-related increase in fracture prevalence is independent of the change in BMD and almost certainly relates to qualitative changes in trabecular and cortical bone. Hence, age alone is an independent risk factor for fracture.

Marked geographic variations in the incidence of osteoporotic fractures are reported. This characteristic may partly be explained by racial differences in skeletal size; osteoporosis is most common in Asian and white populations and is less frequent in African and American blacks. In many parts of the world, evidence indicates that osteoporotic fractures have increased considerably, even allowing for aging of the population. However, a recent report in Canadian individuals demonstrated that in the past 10 years, there has been a decline in hip fractures. Notwithstanding, greater life expectancy alone is expected to increase the number of hip fractures over the next 50 years.

Ethnic and gender differences play a major role in the epidemiology of fractures. Men have higher bone density than women, and African Americans have significantly greater BMD during their adult life than whites, both in the cortical and trabecular compartments. These differences are related in part to the effects of body composition, including muscle strength, body fat distribution, and bone size. Hence, significantly fewer fractures occur in African Americans than in Asians or whites, particularly whites of European descent. However, the role of fat mass relative to BMD has recently undergone reexamination. Clearly, low body mass index (<20) is associated with low BMD and a greater risk for fracture. This in part is due to lower peripheral conversion of testosterone to estrogen and less insulation during impact. On the other hand, the relationship of bone mass to increased fat mass (BMI > 30) is less clear-cut. Increased subcutaneous fat positively affects cortical bone area, but several recent reports suggest that visceral fat may have a negative impact on bone mass and may be associated with a higher fracture risk.

TABLE 251-1 FACTORS THAT MAY AFFECT PEAK BONE MASS

Gender
Race
Genetic factors
Gonadal steroids
Growth hormone
Timing of puberty
Calcium intake
Exercise

Although often considered protective, it is now established that obesity does not prevent fractures and in some circumstances may increase risk.

BIOLOGY

Bone Remodeling

Even though trauma is the principal cause of fracture, factors that alter the quality or quantity of bone predispose an individual to osteoporotic fractures. Thus, an understanding of bone remodeling is essential for determining how bone mass can be altered by heritable and environmental influences. Briefly, skeletal remodeling preserves serum calcium and bone strength in adults through *remodeling* or *basic multicellular units*. Bone remodeling begins with bone dissolution or resorption and ends with new bone formation, leaving no net change in bone mass. In adulthood, each remodeling unit is balanced—resorption equals formation—and lasts between 90 and 130 days. Remodeling preserves bone mass, ensures a ready source of calcium for bodily function, and maintains bone strength through changes in architecture. However, remodeling units can become imbalanced, and over several cycles, this scenario can result in significant bone loss. These imbalances are a result of greater bone resorption relative to bone formation and can be traced to changes in systemic hormones, environmental factors, and mechanical loading.

Peak Bone Mass

Acquisition of peak bone mass occurs between 12 and 15 years of age but is highly dependent on gender (i.e., girls reach peak earlier than boys) and type of bone (i.e., trabecular versus cortical). During this time, there is a rapid increase in bone mass as a result of growth and modeling of the skeleton, which favors formation over resorption. Pubertal surges of gonadal steroids and growth hormone are critical to propel this increase in bone mass with adolescence. Longitudinal studies suggest that several factors regulate peak bone density, including dietary intake of specific nutrients, physical activity, and most importantly, genetic determinants (Table 251-1). The latter view was established in several ways in both humans and animal models. Daughters of mothers with severe osteoporosis have low BMD. Monozygotic twins have much greater concordance in bone mass than dizygotic pairs, and inbred strains of mice differ significantly in peak BMD. However, despite intense efforts over the past decade to identify the heritable determinants of bone mass, minimal progress has been made. Polymorphic differences in the most promising candidate genes, including the vitamin D and estrogen receptors, insulin-like growth factor-I (IGF-I), parathyroid hormone (PTH), collagen A1a, Lrp5, and others are associated with bone mass. But these genetic determinants individually contribute only 1 to 3% to the variance in BMD. It is likely, although not yet proved, that nucleotide polymorphisms in multiple genes contribute more to bone mass than changes in single genes.

Bone Formation

Investigators have uncovered two new pathways in the osteoblast that are genetically regulated and affect the rate of bone formation: (1) the Wnt/Lrp5/β-catenin signaling system, and (2) the lipoxygenase pathways. In the former, activating mutations of the low-density lipoprotein receptor–related protein 5 (LRP5) leads to high bone mass, whereas inactivating mutations lead to the osteoporosis pseudoganglioma syndrome, a condition related to low bone mass in children. The canonical LRP5 signaling pathway is stimulated by Wnt ligands and leads directly to greater osteoblast proliferation and differentiation. In the latter system, two critical enzymes determine when and how stromal cells enter into either the fat or bone lineage: *12,15-lipoxygenase* (*12 LO* or *Alox 12,15*) produces prostaglandins and other endogenous

ligands that bind to the nuclear receptor peroxisome proliferator activator receptor-γ (PPARG) and stimulate adipocyte differentiation; *5′LO*, or *Alox 5*, generates leukotrienes that can also activate PPARG through generation of prostaglandin J2. Polymorphisms in these two genes in mice and humans have been associated with differences in peak bone mass. Twin studies have shown that the genetic regulation of peak bone mass can be modified by both hormonal and environmental factors. In particular, adequate and timely secretion of sex steroids, balanced nutrient intake, and physical activity can optimize peak BMD even in people with a genetic predisposition to low bone mass. It is likely that disturbances in peak bone acquisition contribute to osteoporosis later in life. For example, men with constitutionally delayed puberty have lower BMD in their 30s and 40s than do men who went through puberty at the appropriate age. Women with anorexia nervosa during their teen years have significantly lower BMD at the time of menopause than do healthy adolescents who do not develop amenorrhea. Women with delayed menarche also have lower BMD in adulthood than do women with a normal timing of menses onset. One area of controversy relates to whether childhood fractures are a sign of subsequent osteoporosis. At least two studies have shown that adolescent radial fractures are associated with lower area bone density and reduced cortical bone size compared with findings in children who do not have fractures. These determinants could predispose children to fractures with relatively low impact and may provide some indication of future risk, although more studies are needed. Interestingly, obesity in children is a risk factor for future radial fractures.

PATHOBIOLOGY

Adult BMD is determined both by the acquisition of peak bone mass during adolescence and by the degree of subsequent bone loss over a lifetime (Fig. 251-2). These two processes are regulated at the level of the bone remodeling unit, which is composed of bone-forming osteoblasts, bone-resorbing osteoclasts, and deeply imbedded cortical osteocytes capable of sensing gravitational forces. The remodeling sequence is tightly orchestrated at several levels by the interaction of genetic, environmental, and hormonal factors (Chapter 250). Even small changes in bone formation or bone resorption can result in bone loss or impairment in the capacity to acquire peak bone mass during adolescence. Although an osteoporotic fracture inevitably occurs as a result of trauma—major or minor—to a bone with reduced bone quantity or quality, a strong inverse relationship exists between BMD and fractures. Hence, changes in remodeling that lead to lower bone mass are major factors in determining the overall risk for osteoporosis.

Bone loss occurs when the bone remodeling unit is uncoupled such that bone resorption exceeds formation. The timing of bone loss is a critical determinant of future fracture risk. For example, rapid bone loss in elderly persons is rarely recouped and leaves these individuals at very high risk for fracture independent of BMD. Conversely, accelerated bone turnover over a short period (such as that related to transient glucocorticoid excess in childhood or adolescence) may be reversible. Once the inciting event (i.e., pituitary tumor) has been removed or the treatments have stopped, fracture risk returns to baseline, and BMD can be restored. However, bone loss can also be incessant, particularly in postmenopausal women, in whom estrogen deprivation results in markedly increased osteoclastic activity and high-turnover remodeling. Although the basic multicellular unit is tightly coupled, rapid bone resorption over a prolonged period results in an imbalance because formation cannot be maintained at the same accelerated rate as resorption. During the first few years of menopause (and possibly during the latter phases of premenopause), as estrogen levels decline, trabecular bone loss occurs first. This is followed by cortical thinning. Both conditions are a result of a mismatch between resorption and formation. Surprisingly, during adult bone loss, periosteal expansion occurs in an attempt to preserve bone strength.

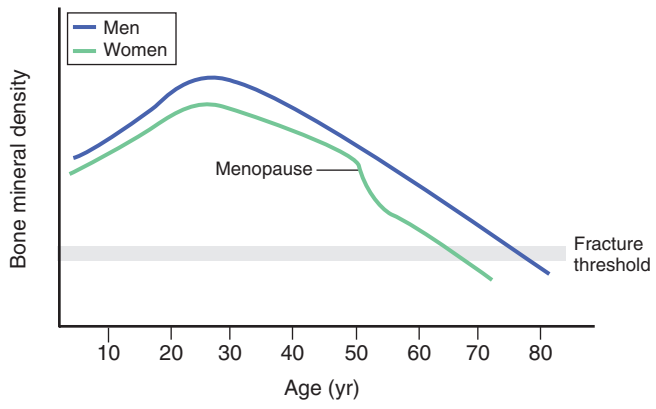

FIGURE 251-2. Cortical bone mineral density versus age in men and women. Women have lower peak cortical bone density than men and experience a period of rapid bone loss at menopause, thus reaching the fracture threshold (the level of bone density at which the risk of developing osteoporotic fractures begins to increase) earlier than men.

In menopause, bone loss averages about 1% per year, but in a few women, loss of spine BMD can be as great as 5% per year. At present, it is impossible to identify those women prospectively. Moreover, premature menopause, chemotherapeutically induced ovarian dysfunction, and amenorrhea related to heavy exercise result in even higher rates of bone resorption that cannot be matched by any increase in bone formation. However, tremendous heterogeneity exists in the response to estrogen deprivation among postmenopausal women. A few women during their first few years of menopause may lose bone at a rate of 2 to 4% per year. Even among "fast losers," this decline slows over time. Estrogen replacement prevents postmenopausal bone loss even among fast losers, although the popularity of this type of prevention has waned in the years following publication of the Women's Health Initiative (WHI).

Bone Loss in Elderly Persons

Later in life, particularly in the eighth and ninth decades, bone loss can accelerate dramatically. Several potential mechanisms are responsible for this change. First and foremost, elderly individuals generally have reduced vitamin D and calcium intake, as well as less sun exposure. This, combined with a reduced capacity to generate pre-vitamin D in the skin, results in secondary hyperparathyroidism and enhanced bone resorption. Remarkably, more than 50% of women who are older than 70 years and who live in northern latitudes have insufficient or deficient levels of vitamin D (i.e., serum 25-hydroxyvitamin D < 20 ng/mL). Other factors also play a role in the accelerated bone turnover of senescence. Increasing levels of homocysteine may enhance bone resorption or may alter the nature of reactive oxygen species within the skeletal milieu. Inflammatory cytokines such as interleukin-6 (IL-6) and tumor necrosis factor (TNF) also increase with age and can stimulate bone turnover.

The uncoupling of the bone remodeling unit in an older person may be associated with a defect in bone formation because both osteoblast number and function decline with age. These changes may be related to low levels of circulating or skeletal IGF-I or to other trophic factors that either enhance osteoblast survival or stimulate stromal cell recruitment. Alterations in lineage allocation among stromal cells can lead to increased marrow adipogenesis at the expense of osteoblast differentiation. The process of fatty infiltration of the bone marrow, particularly in the vertebrae of older individuals, is due in part to an age-related increase in activation of PPARG, a nuclear receptor and transcription factor essential for adipocyte differentiation. Drugs may also enhance PPARG activation, and these include the thiazolidinediones (e.g., rosiglitazone and pioglitazone) and glucocorticoids. Interestingly, PPARG activation may also stimulate new osteoclast development resulting in a marked uncoupling between resorption and formation. Thus, as a result of impaired osteoblast function, the remodeling deficit becomes more pronounced, particularly in the setting of greater bone resorption. Irrespective of the cause of bone loss with aging, estrogen and other antiresorptive therapies are effective in inhibiting bone resorption and in resetting the bone remodeling units, so the two processes are now coupled.

Classification of Osteoporosis

Earlier work proposed two types of osteoporosis, based on age of onset: type I, or postmenopausal, osteoporosis, caused by estrogen deprivation around the time of menopause; and type II osteoporosis, related to high turnover from calcium and vitamin D insufficiency. However, it is clear that this type of classification is outdated and has little clinical purpose. Many younger postmenopausal women can have vitamin D deficiency, and elderly individuals may suffer just as much from bone loss as a result of progressive estrogen insufficiency as younger women. Similarly, even though wrist fractures are more common, as are vertebral fractures, in younger, healthy postmenopausal women, these fractures are very characteristic of any type of osteoporosis, and they represent skeletal failure related to impaired bone quantity or quality, or both, irrespective of age.

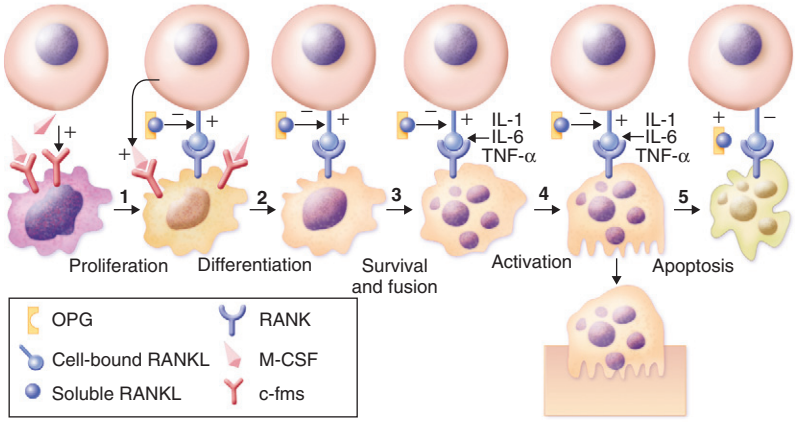

FIGURE 251-3. Regulation of osteoclast development by receptor activator of nuclear factor-κB ligand (RANKL), receptor activator of nuclear factor-κB (RANK), and osteoprotegerin (OPG). c-fms = receptor for M-CSF; IL = interleukin; M-CSF = macrophage colony-stimulating factor; TNF-α = tumor necrosis factor-α. (From Hofbaurer LC, Heufelder AE. The role of receptor activator of nuclear factor-κ ligand and osteoprotegerin in the pathogenesis and treatment of metabolic bone diseases. *J Clin Endocrinol Metab*. 2000;85:2355-2363.)

Molecular and Cellular Mechanisms of Normal Remodeling

To understand the pathophysiologic mechanisms of bone loss more fully, it is necessary to define the key molecular and cellular events that occur during normal adult remodeling. Mesenchymal stromal cells (MSCs), or osteoblast precursor cells, undergo a series of differentiation stages that culminate in a mature osteoblast capable of laying down matrix and secreting growth factors. These cells, as noted previously, are multipotent, and under the influence of various factors, they may become adipocytes, muscle cells, chondrocytes, or osteoblasts. The ultimate fate of the stromal cells is a critical determinant of normal remodeling. During MSC differentiation, stromal cells release a series of cytokines that target osteoclast progenitors, resulting in the differentiation of multinucleated cells from the macrophage lineage. Once these cells become osteoclasts, they have the capacity to cause bone resorption by secreting hydrogen ions and enzymes that dissolve the bone matrix. Within the matrix are several key trophic factors, activated by bone dissolution; as these enter the skeletal milieu, cells of the osteoblast lineage are pushed into differentiation. In this manner, bone resorption is coupled to bone formation.

Several cytokines, including IL-1, IL-6, TNF, receptor activator of nuclear factor-κB ligand (RANKL), and osteoprotegerin (OPG), a soluble decoy receptor for RANKL, are secreted by preosteoblasts during their differentiation. RANKL is expressed on the surface of the osteoblast precursors, and its receptor RANK is the receptor for RANKL on the surface of the osteoclast, a convenient match that actually permits cell-cell interaction (Fig. 251-3). Binding of RANKL to RANK in the presence of permissive levels of another cytokine, macrophage colony-stimulating factor, stimulates the differentiation of osteoclasts into mature bone resorbing cells. In contrast, OPG, a circulating protein also produced by stromal cells, can bind to RANKL and can prevent its occupation of RANK, thereby reducing osteoclastogenesis.

PATHOGENESIS

Cellular and Molecular Mechanisms of Bone Loss

Osteoporosis results from an imbalance in bone remodeling. Changes in bone turnover can be due to a number of factors that target both osteoblasts and osteoclasts and result in greater resorption than formation. For example, declining estrogen levels during menopause or after oophorectomy result in an upregulation of all the stromal cytokines, particularly RANKL. Conversely, OPG secretion is suppressed. This scenario results in greater osteoclastogenesis and accelerated bone resorption. Because bone formation is coupled to resorption, the entire remodeling unit is activated. Bone resorption is a rapid process, taking about 2 weeks for the osteoclasts to attach and resorb matrix. Formation is much more deliberate, meaning that with the release of soluble cytokines, an imbalance in remodeling immediately occurs, and this favors bone resorption. Eventually, this imbalance leads to increased breakdown of collagen and matrix and an inability to match this loss with increased formation. Estrogen administration can prevent bone loss by enhancing OPG production as well as by suppressing RANKL expression. Other systemic and local factors can cause imbalanced remodeling. High levels of PTH for long periods can stimulate RANKL expression and cause bone loss. Glucocorticoid excess from exogenous steroids or Cushing's disease also stimulates RANKL production, but in addition shifts stromal cell differentiation away from the osteoblast lineage and toward adipogenesis. Immobilization suppresses bone formation and enhances bone resorption. Aging in general leads to a reduction in several osteoblastic trophic factors such as IGF-I, as well as increased PPARG activation, and these changes can impair the rate of new bone formation.

Secondary Causes of Bone Loss in the Adult

Although most cases of osteoporosis can be labeled idiopathic and result from the cellular and molecular processes that are related to estrogen deprivation and aging, it is important to exclude secondary causes, primarily because these disorders are sometimes reversible with resolution of the underlying disease (Table 251-2). Hypogonadism of any cause, in either men or women, is probably the most frequent secondary cause of osteoporosis, particularly in younger patients. Anorexia nervosa, hypothalamic amenorrhea, hyperprolactinemia, and exercise-induced amenorrhea lead to early and rapid bone loss that can result in subsequent osteoporotic fractures if these conditions are sustained over a prolonged period. In male patients, primary or secondary hypogonadism results in low peak bone mass and can cause significant bone loss during middle life. Hormonal disorders that interfere with the normal hypothalamic gonadal axis, such as hypercortisolemia, also lead to reduced bone mass. Glucocorticoid excess dampens gonadotropin-releasing hormone signaling, thereby lowering estrogen or androgen levels and enhancing bone resorption; these changes are accompanied by alterations in osteoblast recruitment and function, increased marrow adiposity, reduced IGF-I signaling, and impaired calcium absorption. As the remodeling unit is uncoupled, bone loss occurs rapidly, and fractures are a frequent component of this syndrome. Other endocrine disorders are associated with low bone mass or high bone turnover (see Table 251-2). These include severe hyperthyroidism, primary hyperparathyroidism, and growth hormone deficiency. In primary hyperparathyroidism, bone loss is principally confined to cortical bone sites and is reversible with surgical removal of the tumor.

Other systemic diseases can cause osteoporosis (see Table 251-2). Patients with hepatobiliary disorders often have osteoporosis or osteomalacia, or both, resulting from impaired absorption of vitamin D and secondary hyperparathyroidism. Gluten enteropathy is one of the most common heritable diseases, and patients frequently present in adult life with low bone mass (Chapter 252). These patients often have low 25-hydroxyvitamin D levels and markedly increased PTH concentrations with modest elevations in total alkaline phosphatase. The definitive diagnosis is made by small bowel biopsy, although tissue transglutaminase levels can be very helpful when screening individuals with low bone mass. Patients with systemic disorders such as lupus erythematosus (Chapter 274), scleroderma (Chapter 275), rheumatoid arthritis (Chapter 272), and mixed connective tissue disease may also present with low bone mass independent of whether they have been treated with glucocorticoids. This form of secondary osteoporosis most likely results from a combination of immobility, malabsorption, and the release of inflammatory cytokines both locally and systemically as well as the use of other medications that may be detrimental to the skeleton, such as heparin, ethanol, cyclosporine, tacrolimus, and anticonvulsant agents. Chronic alcohol ingestion (Chapter 32) may be particularly detrimental to the skeleton because it can suppress osteoblast function, increase stromal cell differentiation into adipocytes, and enhance bone resorption. Many patients who suffer from chronic alcoholism are hypogonadal (either primary or secondary) and frequently have low vitamin D levels. Male patients with hypercalciuria or

kidney stones are also at risk for low bone mass and osteoporotic fractures. The pathogenesis of this relationship is not entirely clear, but secondary hyperparathyroidism in patients with hypercalciuria leads to enhanced bone resorption and gradual bone loss. Finally, drug-induced bone loss is a major cause of secondary osteoporosis. Besides glucocorticoids, chronic heparin therapy, some anticonvulsants, the thiazolidinediones, and some second-generation antipsychotics can cause osteoporosis. Recently, use of second-generation selective serotonin reuptake inhibitors (SSRIs) and proton pump inhibitors has been linked to both bone loss and osteoporotic fractures in older women and men. If confirmed in prospective trials, these agents may become the most common cause of secondary osteoporosis.

Malignancy

Metastatic neoplasms to the skeleton can sometimes manifest as an osteoporotic fracture or as a lytic lesion of uncertain significance. Usually, these lesions are atypical in location (e.g., midshaft of long bones, or pelvis), and the underlying disease frequently is obvious. Less commonly confused with osteoporosis are osteoblastic lesions of vertebrae or long bones. However, primary hematopoietic and lymphoproliferative disorders are often insidious and can be associated with low bone mass and fractures. Multiple myeloma (Chapter 193) is the most common hematologic malignancy related to osteoporosis because patients with this disease often have diffuse osteopenia, occasionally with classic osteoporotic fractures of the spine or long bones. Unlike other metastatic processes to bone, multiple myeloma is associated with very high rates of bone resorption but no change or suppression in bone formation. This situation can lead to rapid bone loss. Plasma cells release cytokines, particularly TNF-α, IL-1, and IL-6, that stimulate osteoclastogenesis. Simultaneously, these cells produce Dickopf I and III, soluble factors that block the Wnt/LRP5/β-catenin canonical network. Hence patients have dramatic uncoupling of bone remodeling, rapid bone loss, and fractures. Debate is ongoing about the relationship of osteoporosis to monoclonal gammopathies of uncertain significance (MGUS), although osteopenia is often reported in these patients. Other secondary causes of osteoporosis are noted in Table 251-2.

CLINICAL MANIFESTATIONS

Although osteoporosis is often considered a silent disease, its presentation has changed dramatically in the past two decades. Previously, fractures of the vertebrae, with or without height loss, were the most frequent presenting complaints. Until recently, hip fractures in elderly patients, which can be a late manifestation of osteoporosis, were frequently considered traumatic but not metabolic. Similarly, wrist fractures in early postmenopausal women are a sentinel indication of underlying osteoporosis. They were treated in the past by orthopedic surgeons without regard for any underlying skeletal pathologic processes. However, these patterns began to change in the early 21st century, particularly with the availability of dual-energy x-ray absorptiometry (DXA), the method of choice for measuring BMD. Now, the most frequent presenting complaint to a provider regarding osteoporosis is a low BMD measurement, done either routinely or for screening purposes. Because bone mass is only one of several risk factors for osteoporosis, other clinical manifestations of this disease must be considered. Loss of more than 2 inches in height is a reasonable surrogate of previous vertebral fractures. A clinical history of wrist or ankle fractures is another indication of underlying osteoporosis and may be the first manifestation of the disease in younger postmenopausal women. Compression fracture of the spine with minimal stress is another presenting complaint of osteoporosis. Such fractures cause significant midlumbar and lower thoracic back pain that may radiate to the flanks or anteriorly. Sharp, knifelike back pain after an acute injury is disabling, frequently requires narcotics, and often subsides over a period of weeks to months unless a new fracture intervenes. Patients have an approximately 20% likelihood of a new vertebral fracture in the first year after a spinal fracture. In addition, some patients have chronic back pain as a result of one or more vertebral fractures. Low bone mass in and of itself does not result in back pain, and other diagnoses should be considered in that situation. Cervical lordosis and dorsal kyphosis are the classic manifestations of "dowager's hump" but are less frequently seen in young women. Hip fractures resulting in femoral neck, trochanteric, or cervical injuries generally occur following a fall. The direction and height of the fall are critical elements in determining the type of hip fracture, the ensuing surgery, and disability. Hip fractures can be extremely catabolic, both because of the trauma and because of the resultant major surgery. These factors, combined with underlying illnesses, enhance the mortality of hip fractures in older individuals to approximately 20% in the first year alone.

Osteoporosis can also be diagnosed by a radiologist or a primary care provider from plain radiographs, as shown in Figure 251-4. Most often, patients have an obvious loss of bone mass, resulting in the radiographic term *osteopenia,* although at that stage BMD by DXA is usually well below −2.5 SD. Radiographs of the spine can demonstrate kyphosis, osteopenia, and compression fractures in the thoracic or lumbar vertebrae. For the upper lumbar or lower thoracic areas that are the most vulnerable to injury, compression fractures can frequently be visualized. Collapse of either the anterior or posterior elements is often visible on lateral radiographs of the spine; anterior wedging or the so-called codfish deformity results from weakening of the subchondral plates and expansion of the intervertebral discs (see Fig. 251-4). CT scanning of the spine for other reasons will sometimes be able to detect fractures and can be used clinically to measure density. Magnetic resonance imaging (MRI) is now more frequently used as a diagnostic tool; it may demonstrate a compression fracture with or without marrow edema resulting in a bright signal on T1-weighted images. Technetium-99m bone scans are

FIGURE 251-4. Radiograph showing radiolucency, compression fractures, and kyphosis in the spine of a patient with osteoporosis.

very sensitive to fracture and can be used to detect stress fractures in the pelvis, femur, or tibia. However, because of its high sensitivity, this test is not a useful tool for diagnosis of osteoporosis. In fact, it is rare for the bone scan to be the initial clue to osteoporosis, and in the setting of a positive bone scan, alternative diagnoses, including malignant disease, should be considered.

DIAGNOSIS

A recent fragility-related fracture of the spine, hip, wrist, ankle, shoulder, or other appendicular sites in postmenopausal women or men should lead to a diagnosis of osteoporosis. However, secondary causes of this condition (as discussed earlier and listed in Table 251-2) should be excluded before therapy is initiated. Similarly, because the WHO has established that a BMD at any site lower than −2.5 SD from the young normal value meets the definition of osteoporosis, a diagnosis can be made from a densitometry report or measurement. However, this finding must be interpreted in relation to the patient's age, ethnicity, fracture history, family background, previous medications, timing of menopause, and other concomitant disorders. Based on the WHO criteria, most providers make the diagnosis of osteoporosis by measuring bone density with or without biochemical markers of bone turnover. Recently the introduction of the FRAX Internet tool by WHO has made long-term fracture risk prediction an important and easy tool for the patient and the provider.

Bone Densitometry

Several techniques are available for measuring areal BMD (i.e., two-dimensional measurements expressed as g/cm^2) in the axial and appendicular skeleton. Multiple prospective studies have convincingly shown that a low BMD at virtually any site (i.e., hip, spine, radius, total body, calcaneus) predicts subsequent osteoporotic fractures whether these are in the same area or elsewhere. In general, regardless of the technology, for every 1 SD below a young (i.e., 35-year-old) normal value (i.e., T-score), the risk for future osteoporotic fractures increases by nearly 50%. However, site-specific measurements, for example, spine BMD, usually predict spine fractures better than a hip BMD. Because of the inverse relationship between fracture risk and BMD, a very strong rationale exists for measuring bone mass at least once during the lifetime of every postmenopausal woman.

Dual-Energy X-Ray Absorptiometry Measurements of Bone Mineral Density

Techniques for measuring bone mass include the following: DXA of the spine, hip, radius, or total body; CT of the spine; ultrasound scanning of the calcaneus or wrist; finger DXA; and peripheral quantitative CT of the wrist or tibia. Other experimental techniques that are being tested for evaluating trabecular bone and bone quality include MRI of the calcaneus and radius, virtual MRI using computerized reconstructions of trabecular bone, and "extreme CT" with high-resolution imaging of the radius. The most popular, least expensive, and most precise tool is DXA. Results from DXA measurements are traditionally expressed as either the T-score or the Z-score. The T-score is the number of SDs below or above which the patient's BMD differs from peak bone density of an individual of the same gender and ethnicity. The Z-score is the number of SDs by which the patient's bone density differs from that of an individual matched for age, gender, and ethnicity. Not surprisingly, there can be disparity in absolute BMD by skeletal site within the same individual. This disparity can be attributed to the relative proportion of trabecular and cortical bone at a particular site. For example, the vertebra is 85% trabecular bone, whereas the femoral shaft or neck is principally cortical bone. Several studies have shown that nearly one in three subjects has disparate hip and spine T-scores. This finding can be attributed to the differences in skeletal composition; in other words, cortical or outer shell bone is thicker and remodels less frequently, whereas trabecular bone, which is the inner spongiform bone bathed by marrow elements, is metabolically very active. DXA integrates both skeletal compartments as an areal measurement. However, because skeletal sites often differ in composition and function, this disparity is frequently noted. Furthermore, age-related changes in the two skeletal compartments differ, and their genetic determinants may be completely distinct. In general, it is recommended that the lowest BMD measurement at any site be used for fracture risk assessment.

The two most common skeletal sites recommended for measuring BMD by DXA are spine and hip. For the spine, both anteroposterior and lateral spine DXAs can be obtained, although most providers use the anteroposterior spine, which is both a sensitive indicator of early bone loss and a precise measure. However, anteroposterior spine DXA can often show high bone mass resulting from increases in degenerative arthritis, disc collapse, vertebral fracture, or calcification of the aorta. Hence, in patients who are more than 65 years old, femoral neck and total hip BMD measurements are preferable. Both have good precision, are accurate, and are not complicated by those processes. Either site has strong predictive value for subsequent fractures.

Other Tools for Measuring Bone Mass

Other means of measuring BMD are available, and each provides T-score equivalents, although these cannot easily be translated across technologies. Quantitative CT scanning of the vertebrae provides a true volumetric measure of bone mass (mg/cm^3), can detect early bone loss, is accurate, and is available at many centers. However, its reproducibility is not as good as that of DXA, and T-scores can be quite disparate from DXA measurements. Moreover, significantly greater radiation exposure occurs with CT than DXA, and CT requires more time. Ultrasound scanning of peripheral sites has the advantages of portability and ease of operation, and the technique enables the clinician to predict fractures; however, the parameters used to measure sound transmission do not change much with age, or with treatment, thereby making this tool difficult to use for follow-up examination. Peripheral quantitative CT is expensive but accurate; it has greater radiation exposure but provides information about both cortical and trabecular elements. Fewer data on fracture risk are available with this technique, which is primarily a research tool.

In summary, DXA provides the most accurate and precise tool to assess fracture risk. The DXA measurement, combined with age, history of previous fracture, and family history, gives the clinician the most accurate assessment of osteoporotic risk. For follow-up, BMD measurements by DXA are preferable to other technologies because of the low precision error and greater reproducibility.

Risk Assessment Using FRAX

Since the introduction of widespread bone density measurements, it has become clear that BMD alone is not sufficient to define overall fracture risk and that consideration of clinical risk factors is essential. Often this is done at the point-of-care using age (>65 years), previous fracture, and family history. However, this combination does provide an estimate of 10-year risk, which clinicians often use to assess other diseases such as myocardial infarction. Hence, the WHO in collaboration with international osteoporosis foundations developed a virtual tool, FRAX, that can be used alongside the patient to determine his or her 10-year fracture risk. On any computer, BMD by DXA of the hip is entered into a box along with age, height, gender, country, and responses to queries about family history, use of glucocorticoids or alcohol, previous fracture, and weight loss. A 10-year fracture risk in percent is then calculated for a major osteoporotic fracture (i.e., spine, hip, wrist, and humerus) as well as hip fracture alone. Current guidance suggests that

high-risk individuals are those with a 10-year risk of more than 3% for hip fracture and 20% for major osteoporotic fracture.

The FRAX tool has been widely praised, and its use has increased significantly since its introduction in 2007. Its strengths lie in the point-of-care nature of performing risk assessment, the country-specific assessment (e.g., United States vs. England vs. France), the recent revisions that incorporate new data sets providing more up-to-date fracture incidences for the United States, and ease of use. Concerns persist about several limitations, including that only hip BMD can be entered for fracture risk; FRAX should not be used in patients already receiving treatment; and in some populations, risk is overestimated, particularly in the younger postmenopausal female. Notwithstanding, fracture risk evaluation provides a reliable estimate for both the patient and provider and is preferred over a single BMD measurement to establish risk.

Biomarkers: Biochemical Markers of Bone Turnover

Newer methods of measuring bone breakdown and synthesis products have been developed since the mid-1980s. Previously, urinary calcium and hydroxyproline were the two urinary markers used to assess bone resorption; both were nonspecific, and their precision was poor. Subsequently, serum and urine biochemical markers have been perfected and tested in large clinical trials and are now available for clinical use. Markers of bone resorption mediated by osteoclasts include urinary pyridinoline and deoxypyridinoline as well as urine cross-links of the C- and N-terminal peptides of type I collagen. The latter can be measured either in urine or in serum. Markers of osteoblast-mediated bone formation include bone-specific alkaline phosphatase, osteocalcin, type I procollagen amino-terminal propeptide, and type I procollagen carboxy-terminal propeptide. Increases in markers of formation or resorption, or both, imply accelerated remodeling. For example, immediately after estrogen production ceases, markers of bone formation and bone resorption increase significantly. Similarly, later in life, and during states of secondary hyperparathyroidism, these markers can be extremely elevated. In addition, antiresorptive drugs such as estrogen or the bisphosphonates significantly lower urinary and circulating concentrations of these markers. Both longitudinal and cross-sectional studies have demonstrated that high turnover markers predict fracture in elderly women. These markers are independent of BMD and imply that accelerated bone turnover itself is a risk for fracture. Such indices of bone turnover provide a current estimate of the state of the skeleton, whereas bone density measurements are stoichiometric and reflect all the events leading up to the measurement.

In addition its potential for defining risk for fracture, several groups have shown that suppression in turnover markers with bisphosphonates or estrogens can predict fracture risk reduction in older postmenopausal women. Notwithstanding, the use of markers in clinical practice has been disappointing for several reasons. First, the variability in individual measurements, particularly for urine studies, is quite high. Therefore, even a single measurement has significant measurement error; follow-up to assess change from baseline is often even more confusing because of the variability issue. Second, most women have turnover marker values within the normal range, making interpretation difficult. Third, the number of older women with high bone turnover has probably been overestimated, particularly in the early postmenopausal period. These issues have limited enthusiasm for a single blood or urine test to help determine risk and assist in management once therapy has commenced. Occasionally, these tests can be helpful: in the young woman who undergoes premature menopause resulting from chemotherapy, for example, knowledge not just of the BMD but also of the rate of bone turnover could help in managing her condition with either aggressive antiresorptive therapy or a more measured approach using calcium and vitamin D. It is not recommended that these markers be used routinely to assess compliance with antiresorptive therapies.

Diagnostic Evaluation

The diagnosis of osteoporosis is usually made by bone mass measurements and a history of previous osteoporotic fractures. Secondary causes of osteoporosis must be excluded, and follow-up is required to ensure that the disease is not rapidly progressive. Routine profiles for renal and thyroid function are indicated. A serum 25-hydroxyvitamin D measurement in an older individual, particularly in northern latitudes, is recommended because deficiencies can be corrected with vitamin D supplementation. At present, DXA, combined with fracture risk assessment such as performed in the FRAX model, represents the best tool for assessing overall fracture risk and determining the course of therapy. Biochemical markers may be helpful in some cases.

TREATMENT Rx

Treatment Plan

A comprehensive management plan for osteoporosis includes diagnosing those at highest risk, excluding secondary causes of low BMD, and selecting appropriate treatment. Decision making should also take into account several caveats. First, osteoporosis therapy can reduce fracture risk by as much as 50%, but some women will continue to have fractures despite treatment. Identifying those women at greatest risk for progressive disease is mandatory. Second, lifestyle and pharmacologic interventions are lifetime commitments such that cost, compliance, and safety must be factored into therapeutic decisions. Studies suggest that even with weekly or monthly bisphosphonate therapy, more than 40% of individuals treated will not continue therapy beyond 1 year. Third, it is not uncommon for women with T-scores higher than −2.5 to have fractures. In fact, in the National Osteoporosis Risk Assessment cohort of more than 140,000 postmenopausal women in the United States, almost one third of the women who had fractures also had BMD scores in the "osteopenic" range. Thus, treatment decisions should not be based solely on BMD.

Therapy for postmenopausal osteoporosis is framed in terms of *primary prevention* when it is prescribed for those at risk who do not have low bone mass (T-score < −2.5) or fractures or in terms of *treatment* for those with established disease, including previous osteoporotic fractures or markedly reduced BMD, or both. Thus, selection of an appropriate treatment regimen depends on whether the therapy is designed principally to prevent bone loss or to reduce the likelihood of a new spine or nonvertebral fracture in high-risk individuals.

General Measures

Diet

Calcium

Calcium supplementation should be an adjunct to drug treatments for women with established osteoporosis and must be part of any prevention strategy to ameliorate bone loss independent of other treatment choices. Increased calcium intake reduces the secondary hyperparathyroidism often seen with advancing age and can enhance mineralization of newly formed bone. Evidence that calcium and vitamin D together or individually reduce fracture risk in the osteoporotic individual remains somewhat controversial. However, a recent meta-analysis of calcium and vitamin D intervention trials demonstrated a consistent albeit small increase in BMD and a reduction in nonvertebral fractures when at least 1200 mg of calcium is combined with more than 400 units of vitamin D. Calcium supplementation alone has not been shown to reduce the incidence of nonvertebral fractures in high-risk women. A very large calcium intervention trial from WHI did not demonstrate hip fracture reduction with 1000 mg of daily calcium supplements and 400 IU of vitamin D for all postmenopausal women. However, for those older than 60 years, the risk reduction was statistically significant.■ Interestingly, calcium supplementation in this cohort was associated with a 17% greater risk for kidney stones. This may have been due to the finding that baseline calcium intake in these women averaged 1100 mg per day. New Institute of Medicine (IOM) guidelines recommend 1200 mg per day of calcium in women over age 70 and 800 IU of vitamin D per day in that same age group. Certainly, with intakes greater than 2000 mg per day, the risk for nephrocalcinosis increases.

Vitamin D

Vitamin D is essential for skeletal maintenance and for enhancement of calcium absorption. Insufficiency of this vitamin is a growing problem; as many as two thirds of all patients who have hip fractures are classified as vitamin D deficient (Chapter 252). However, the results from randomized trials are conflicted. Elderly people in chronic care living situations are particularly vulnerable to vitamin D deficiency and may benefit from supplementation. One large randomized placebo-controlled trial (RPCT) demonstrated a 33% reduction in hip fractures for nursing home residents who received calcium and vitamin D compared with those receiving placebo.■ In another trial, high-dose intermittent vitamin D reduced nonvertebral fractures by nearly one third among ambulatory elderly persons.■ In older New England men and women, the combination of calcium citrate and 700 IU of vitamin D was shown to lessen by one third the risk for nonvertebral fractures.■ However, in a large population-based study with calcium and vitamin D, supplementation had no effect on nonvertebral fractures,■ although compliance and assessment of vitamin D levels were not sufficiently well documented to exclude an effect. Several recent meta-analyses suggest that 800 IU per day of vitamin D is needed to have fracture efficacy. Besides the potentially positive effects of vitamin D supplementation on the skeleton, particularly in older women, vitamin D may also enhance muscle strength and has been shown to reduce the risk for falling. Therefore, for most individuals with osteoporosis, 800 IU/day of vitamin D is sufficient to maintain adequate levels of 25-hydroxyvitamin D. However, in those patients with low bone mass and insufficient or deficient 25-hydroxyvitamin D levels (i.e., <20 ng/mL), administration of 50,000 IU of ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3) given once weekly is a safe and effective way to restore vitamin D levels to the normal range. Upper limits of

vitamin D supplementation are currently being reviewed to determine whether there is toxicity at higher doses.

Vitamin D analogues have been used in the treatment of osteoporosis since the early 1980s. However, this remains a controversial area. High doses of 1,25-dihydroxyvitamin D increase bone mass, but many patients develop hypercalciuria or hypercalcemia, or both. At doses of 0.5 µg/day, calcitriol reduced the rate of both vertebral and nonvertebral fractures, and it increased bone density in a very small trial. Other studies have found little benefit with a narrow therapeutic window, particularly in relation to renal function and hypercalcemia. Currently, vitamin D analogues are not recommended for the routine treatment of osteoporosis. A subset of patients with renal insufficiency (chronic kidney disease > 3) and high PTH levels may benefit from supplementation with calcitriol.

Physical Activity

Bedrest or immobility, particularly in elderly persons, can result in rapid bone loss. Moreover, the number of falls increases with age, and the number of falls that result in fractures also rises. A meta-analysis by the Cochrane Review Group demonstrated that muscle strengthening, balance retraining, home hazard assessment, withdrawal of psychotropic medications, and use of a multidisciplinary risk factor assessment program are beneficial in protecting against falls. An additional approach is to reduce loads applied to the hip during a fall by padding. Hip protectors have been shown to reduce the risk for hip fractures in at least one population, although compliance is generally poor. A more recent study failed to demonstrate the efficacy of these devices in older women in an assisted living facility. Regular physical activity, including aerobic, weight-bearing, and resistance exercises, is effective in increasing spine BMD and in strengthening muscle mass in postmenopausal women, but no large-scale studies have established whether these interventions reduce fracture risk.

Lifestyle

Other interventions, including smoking cessation and reduction of alcohol intake, should be considered within the framework of an individual's preventive health strategy. However, studies to date have been inconclusive in respect to understanding how changes in these lifestyles affect overall fracture risk.

Medical Therapy

Abundant evidence indicates that an aggressive intervention program can be successful in reducing fracture risk and in improving quality of life among postmenopausal women with preexisting osteoporosis. Several pharmacologic options are available, and these can be classified by their mechanism of action. The two major classes of osteoporosis drugs are (1) *antiresorptives* (i.e., agents that block bone resorption by inhibiting osteoclasts), and (2) *anabolics* (i.e., drugs that stimulate bone formation by primarily acting on osteoblasts).

Antiresorptive Agents

Antiresorptives inhibit bone resorption by suppressing osteoclast activity. Slowing the remodeling cycle allows bone formation to catch up to resorption, thereby enhancing matrix mineralization and stabilizing trabecular microarchitecture. The antiresorptives increase BMD and reduce fracture risk, but their efficacy varies.

Estrogen

Estrogen replacement therapy was long considered the cornerstone of therapy for postmenopausal women with osteoporosis. It works by slowing bone resorption through inhibition of cytokine signaling including RANKL from the osteoblast to the osteoclast, thereby increasing BMD. Estrogen replacement inhibits both cortical and trabecular bone loss, and BMD generally increases by 3 to 5% after 3 years.[6] There does not appear to be an additive effect from progesterone on bone mass in women also receiving estrogen. Conversely, progesterone is a necessary part of hormone replacement therapy in women with a uterus because it prevents the development of endometrial hyperplasia and carcinoma. In the WHI, estrogen and progesterone lowered hip fracture risk by one third.[7] Low-dose conjugated estrogens (0.3 or 0.45 mg/day) and ultralow-dose estradiol increase BMD and have been approved for the prevention of bone loss, but antifracture efficacy for these preparations has not been established. Discontinuation of estrogen results in measurable bone loss (3 to 5% in the first year), although whether that translates into a greater fracture risk is not clear.

Significant concern has been expressed about the nonskeletal risks associated with long-term estrogen and estrogen in combination with progesterone (Chapter 248). Particularly troublesome is the increased risk for breast cancer with the long-term use of estrogen and progesterone. In the WHI, there was a 26% increase in risk for invasive breast cancer over a 5.2-year period of follow-up.[7] Hence, estrogen replacement is contraindicated in any woman with a history of breast cancer; yearly mammograms are indicated in all women receiving hormone replacement therapy. Previous case-control and retrospective studies suggested that estrogen could reduce the risk for coronary artery disease; however, in the WHI, the risk for myocardial infarction or death from coronary artery disease was 29% higher in women receiving combination therapy.[7] Thromboembolic disease is also increased more than three-fold by hormone replacement therapy.[7] Hence, the use of estrogen or estrogen in combination with progestins for the prevention or treatment of osteoporosis has fallen dramatically. Moreover, the availability of newer and effective antiresorptive drugs for the treatment of osteoporosis has lessened enthusiasm for primary hormonal therapy in osteoporotic women.

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators such as tamoxifen and raloxifene also inhibit bone resorption by blocking cytokine release from the osteoblast. Both have been shown to reduce bone loss in postmenopausal women with breast cancer, but only raloxifene is approved by the U.S. Food and Drug Administration (FDA) for the prevention and treatment of osteoporosis.

Both these agents block the actions of estrogen on the breast but act like an estrogen agonist in bone; tamoxifen, but not raloxifene, has estrogen agonistic properties on the uterus and is associated with a greater risk for endometrial carcinoma with long-term use. Both agents have been associated with a reduction in new cases of breast cancer when they are administered as prophylaxis for high-risk patients.[8] Low-density lipoprotein cholesterol levels are also reduced in patients receiving these selective estrogen receptor modulators. Raloxifene increases spine BMD slightly (as does tamoxifen) and lowers the risk for vertebral fracture by 40%, although it has no effect on nonvertebral fracture risk.[9] Hot flashes, leg cramps, and a greater risk for deep venous thrombosis can occur with raloxifene therapy. The recommended dose of raloxifene is 60 mg once daily.

Tissue selectivity with these selective estrogen receptor modulators and others being investigated is a subject of great scientific interest. Raloxifene and estrogen both bind to the same region of the estrogen receptor, but they induce different conformational changes in that receptor. Coactivating and co-repressing proteins are recruited to the receptor-ligand complex, and it is thought that these transcription factors ultimately determine the activity of the nuclear complex. Because recruitment also depends on location, it is highly likely that significant tissue selectivity exists for these partners. Newer agents have been designed to facilitate particular complexes and rearrangements within the nucleus; these are being studied at both the preclinical and the clinical levels.

Bisphosphonates

The bisphosphonates are the most widely prescribed antiresorptives and are often considered first-line therapy for the treatment of severe postmenopausal osteoporosis. These drugs are carbon-substituted analogues of pyrophosphate that bind tightly to hydroxyapatite crystals. It is thought these agents directly suppress resorption by inhibiting osteoclast attachment and enhancing programmed cell death. The first-generation bisphosphonates include etidronate and clodronate. Neither is approved for the treatment of osteoporosis, although etidronate is widely used "off label" and in Europe. The dose of etidronate is 400 mg/day for 2 weeks every 3 months. The drug has few gastrointestinal side effects, and vertebral fracture risk reduction is significant with this agent. Alendronate and risedronate, two second-generation nitrogen-containing bisphosphonates, are effective in suppressing bone resorption and increasing BMD. In postmenopausal women with established osteoporosis, alendronate and risedronate reduced vertebral, hip, and nonvertebral fractures by nearly 50%, particularly during the first year of treatment.[10,11] Like other antiresorptive drugs, increases in BMD with alendronate or risedronate account for a small fraction of their antifracture efficacy. Hence, follow-up DXA measurements may significantly underestimate fracture risk reduction. Recent clinical trials have shown that these drugs can be safely administered for at least 7 years without adversely affecting bone strength. Moreover, discontinuation of alendronate after 5 years results in minimal bone loss over the ensuing 5 years. Both drugs have excellent safety profiles, although erosive esophagitis is a serious complication of all nitrogen-containing bisphosphonates. Once-weekly administration of alendronate has been shown to reduce the prevalence of drug-induced esophagitis, and currently both bisphosphonates are marketed as once-weekly treatments. Recently, the FDA approved the use of once-monthly risedronate (150 mg) for the treatment of osteoporosis.

Two new bisphosphonates have been approved by the U.S. FDA and have reached the market in the past 5 years: ibandronate and zoledronate. Ibandronate is given in a single monthly dose of 150 mg or intravenously (3 mg) every 3 months. It suppresses bone resorption and reduces the rate of spine fractures, but its efficacy in nonspine fractures is somewhat less than that of alendronate or residronate.[12,13] Compliance with the once-monthly regimen is higher than the weekly dosing, although long-term data are not encouraging. Zoledronate is also approved for the prevention and treatment of osteoporosis.[14] It is administered as a single intravenous infusion over 15 minutes (5 mg) once yearly. Large randomized controlled trials have unequivocally established its antifracture efficacy for hip, spine, and other nonspine fractures. Recently, the FDA approved the use of zoledronate for prevention of osteoporosis by administration of the drug once every 2 years. Both newer bisphosphonates can cause first-dose side effects, including joint pain, stiffness, and low-grade fevers. These do not persist with recurrent administration. However, the FDA has cautioned that zoledronic acid should be administered over 1 hour rather than 15 minutes to lessen any risk, albeit small, of renal damage.

Intravenous zoledronic acid is also approved for the treatment of hypercalcemia of malignancy (Chapter 186) and multiple myeloma, and as palliative therapy for metastatic disease.

Other bisphosphonates are available for off-label use or are being studied for the treatment of osteoporosis. Intravenous pamidronate has been available since the mid-1990s for the treatment of Paget's disease (Chapter 255) and malignant hypercalcemia (Chapter 186). It is currently also used to treat osteoporotic women who cannot tolerate oral bisphosphonates, although it has not been formally approved by the FDA for this indication, and its antifracture efficacy has not been established. The dose ranges from 30 to 90 mg given every 3 to 9 months. Acute and delayed-type hypersensitivity reactions can occur with this drug, and its use is contraindicated in patients who are vitamin D deficient because it can precipitously drop serum calcium.

In regard to the bisphosphonates, two rare side effects have been reported. Osteonecrosis of the jaw is a devastating condition associated with mandibular destruction following dental intervention (Chapter 256). It has been seen in patients taking bisphosphonates, particularly those receiving intravenous therapy who also have associated conditions such as multiple myeloma or metastatic breast cancer. Its true prevalence is unknown but is likely about 1 in 250,000 cases, and it is rare in women and men treated for osteoporosis who are otherwise healthy. Nevertheless, caution must be exercised in recommending dental surgery to patients taking a bisphosphonate. Subtrochanteric fracture is the other condition that may be associated with long-term bisphosphonate use. These midshaft fractures usually occur in middle-aged women taking an oral bisphosphonate for several years, frequently accompanied by treatment with glucocorticoids or use of an additional antiresorptive agent. The patient typically complains of leg pain before the fracture, and cortical thickening is noted in the subtrochanteric region on radiograph before the fracture. The true prevalence of this is unknown, but it is likely extremely uncommon, and the etiology is thought to be related to oversuppression of bone turnover. Treatment does not differ from any surgical management, although discontinuation of the bisphosphonate is recommended.

Calcitonin

Calcitonin is a 32–amino acid peptide normally produced by the thyroid C cells. Osteoclasts have calcitonin receptors, and calcitonin can rapidly inhibit bone resorption. Salmon calcitonin is more potent than human and is the preferred treatment choice. Nasal and subcutaneous calcitonin are both approved for the treatment of postmenopausal osteoporosis. However, the evidence favoring a strong effect from this hormone on either bone loss or fracture efficacy is lacking. In an RPCT of women with postmenopausal osteoporosis, 200 IU/day of nasal calcitonin reduced vertebral fracture incidence by one third.[15] However, methodologic flaws in that trial have limited enthusiasm for this agent as a primary treatment for osteoporosis. In at least one placebo-controlled study, nasal calcitonin reduced the pain associated with new spine fractures. The recommended dose of nasal calcitonin is 200 IU/day, and that of subcutaneous calcitonin is 100 IU/day. Side effects are uncommon with intranasal calcitonin and include nasal stuffiness and flushing. With subcutaneous administration, nausea is not infrequent.

Strontium Ranelate

Strontium ranelate is orally administered and stimulates calcium uptake in bone while it inhibits bone resorption. It is thought to have some anabolic activity, although the precise mechanism of action in the skeleton, where it is incorporated, is not known. In an RPCT of postmenopausal women with established disease, daily strontium reduced the risk for vertebral fractures by 40%.[16] However, a statistically significant effect on nonvertebral fractures was limited to a small subset of women in a post hoc analysis. This drug is approved by European regulatory agencies but not by the FDA.

Anabolic Agents

A new class of antiosteoporosis drugs was introduced in 2002. These are the so-called anabolics, agents that stimulate bone formation more than bone resorption. As such, these agents enhance bone remodeling and contrast sharply with the antiresorptives, which slow bone turnover. $PTH_{1\text{-}34}$ (teriparatide) was the first of this class of drugs to be approved by the FDA.

The prototypical anabolic drug was sodium fluoride, which saw widespread use in the 1970s and 1980s because of its ability to stimulate new bone formation. However, an RPCT in 1990 established that although there were dramatic increases in BMD, nonvertebral fracture risk actually increased. Unlike sodium fluoride, synthetic PTH ($PTH_{1\text{-}34}$) was approved by the FDA for the treatment of postmenopausal osteoporosis because it not only increases bone mass but also reduces fractures. In the largest RPCT using teriparatide in postmenopausal women with severe osteoporosis, 20 μg/day of PTH, administered subcutaneously, reduced spinal and nonvertebral fractures by more than 50% while it substantially increased (i.e., 8% per year) lumbar BMD.[17] Similar findings were noted in men with osteoporosis who were treated for 11 months. Unfortunately, the PTH trial in postmenopausal women was stopped after 20 months because of concerns related to the development of osteosarcoma in rats treated with high doses of $PTH_{1\text{-}34}$. However, retrospective studies have found no association between osteosarcoma and primary or secondary hyperparathyroidism, and only two cases of osteosarcoma in PTH-treated patients have been reported. More recently, recombinant human PTH ($PTH_{1\text{-}84}$) has shown similar benefits.[18] Currently, it is recommended that PTH therapy should be limited to those individuals with moderate to severe osteoporosis, and then taken only for 2 years.

Despite the appeal of using an anabolic with an antiresorptive, no evidence indicates that combinations of classes of drugs are additive or synergistic. Unlike the bisphosphonates, discontinuation of PTH can result in bone loss of 3 to 4% in the first year after PTH cessation. This post-treatment effect is prevented by adding an antiresorptive drug after PTH is stopped. In general, PTH is well tolerated, although nausea, flushing, hypotension, and mild but asymptomatic hypercalcemia (i.e., serum calcium < 11.0 mg/dL) can occur. Cost and compliance have been major limiting factors.

Vertebroplasty/Kyphoplasty

Vertebroplasty (percutaneous injection of cement into a collapsed vertebra to stabilize it) and kyphoplasty (use of a balloon to inflate the vertebral body prior to injection of the cement, in an attempt to restore the height and angle of the vertebral body) are widely used to treat the pain of vertebral compression fracture. Despite promising results for pain relief compared with standard care, benefits have not been seen when compared with a sham procedure.[19]

GLUCOCORTICOID-INDUCED OSTEOPOROSIS

The most common secondary cause of osteoporosis is glucocorticoid induced. This is often a result of pharmacologic doses of steroids used to treat inflammatory or autoimmune disorders. Generally, it is considered that glucocorticoids (Chapter 34) have a dose-dependent effect on the skeleton, such that longer duration and higher doses of steroids are most likely to cause bone loss and fractures. However, there clearly are subsets of individuals who are more or less sensitive to the skeletal effects of high doses of glucocorticoids. As a general clinical rule, those individuals with a cushingoid appearance and fat redistribution almost always have low bone mass or fractures, or both.

The effects of glucocorticoids on the skeleton are multifaceted and are particularly devastating because these agents cause uncoupling in the remodeling unit. Besides the indirect suppressive effects of glucocorticoids on the hypothalamic-gonadal axis, and inhibition of calcium absorption in the gut, high doses of steroids can stimulate osteoclastogenesis, increase RANKL production, and decrease OPG. This situation results in higher rates of bone resorption. Additionally, glucocorticoids also have a strong negative effect on bone formation by suppressing expression of IGF-I in bone cells and by shifting marrow stromal cells into the fat lineage and away from the osteoblast differentiation pathway. It is presumed that just as fat redistribution syndrome in the supraclavicular and mediastinal area is a clinical hallmark of Cushing's syndrome, enhanced adiposity in the bone marrow is a characteristic feature, almost certainly as a function of increased stromal cell differentiation into adipocytes. Bone strength is markedly compromised by the uncoupling in remodeling, and bone loss can be rapid over a short time period, particularly with high doses of glucocorticoids. Although there is no true dose-dependent effect on bone resorption, it is thought that prednisone doses as low as 5 mg/day may increase fracture risk. Indeed, in this syndrome, baseline BMD is not predictive of fractures and can often be normal even in the presence of ongoing resorption and recurrent fractures. Trabecular bone suffers the most in this syndrome, and spine DXA is the most sensitive indicator of bone loss. Markers of bone turnover are not helpful in the management of these patients.

Therapy for steroid-induced bone loss centers on treating the underlying disease or reducing the dose of glucocorticoids to the lowest possible regimen, or both. Barring that, several interventions have been shown to retard bone loss and prevent fractures. Adequate calcium and vitamin D intake is critical for every patient receiving glucocorticoids. However, these measures alone are not sufficient. Three bisphosphonates have been shown to have efficacy in glucocorticoid-induced osteoporosis—etidronate, alendronate,[20] and risedronate—and they are now considered the standard of care for this disease. These drugs are administered either weekly or cyclically to prevent bone loss and to reduce the risk for fractures. Some anecdotal data support the use of gonadal steroids in this condition, but clearly the bisphosphonates are superior. In a randomized trial, synthetic PTH (teriparatide, 20 mg daily subcutaneously for 18 months) significantly increased hip and spine bone mass density and reduced new vertebral fractures (from 7.2 to 3.4%), but not other fractures, compared with alendronate.[21] More studies are needed to establish its long-term efficacy in this disease, particularly

because secondary hyperparathyroidism is a frequent accompaniment of steroid-induced osteoporosis.

FUTURE DIRECTIONS

Denosumab, a synthetic RANKL antibody that works like OPG, prevents bone loss in women with severe disease and, in large randomized placebo-controlled trials, reduced hip, spine, and nonspine fractures when administered as a single subcutaneous injection (60 mg) once every 6 months. This drug is not associated with osteonecrosis of the jaw, but lower extremity cellulitis occurs three times more often with this therapy than with placebo. Currently, denosumab is not approved by the FDA. PTH-related protein (PTHrp), a peptide that is structurally similar to PTH, binds to the same receptor, is responsible for some cases of hypercalcemia of malignancy, and has significant anabolic properties when administered intermittently. It is not approved yet by the FDA for the treatment of osteoporosis.

OSTEOPOROSIS IN MEN

EPIDEMIOLOGY

Osteoporosis in men is now more frequently recognized. This may stem from greater awareness in respect to the clinical presentation, the role of bone density screening, and a better understanding of the pathogenesis of osteoporosis, particularly in older men. Thirty percent of all hip and vertebral fractures occur in men, and one in six men in later life will suffer a hip fracture.

CLINICAL MANIFESTATIONS

The clinical presentation is often different from that in women, especially in relation to the time to diagnosis after symptoms begin. Back pain with vertebral compression is the most common presenting complaint. Bone density measurements are less frequently obtained in men, but they are performed after symptoms occur, a far different situation than in postmenopausal women.

PATHOPHYSIOLOGY

Secondary causes of osteoporosis dominate this disease in men. Hypogonadism and hypercortisolemia are the major etiologic factors in male osteoporosis and must be considered regardless of the phenotypic presentation. However, certain other conditions, including gluten enteropathy, gastric resection or bypass, and ethanol abuse, are more common in men than women with osteoporosis. Hypercalciuria (with or without kidney stones) that is associated with secondary hyperparathyroidism occurs in men and is a frequent cause of low bone mass in young men. In contrast, anorexia in male patients is extremely rare, and the athlete's triad so characteristic of women runners (i.e., exercise, hypogonadism, and low bone mass) is infrequent, although not unheard of, in men.

Lack of androgens results in a skeletal deficit. Peak bone mass is clearly reduced in androgen-insufficient young male patients whether the condition results from idiopathic hypogonadotropic hypogonadism, Klinefelter's syndrome, or constitutional delayed puberty. The use of long-acting gonadotropin-releasing hormone analogues that block androgen production and are administered in the treatment of prostate cancer is also associated with significant bone loss and fractures in later life. Men with primary gonadal failure, hemochromatosis, hyperprolactinemic hypogonadism, and other disorders of the hypothalamus or pituitary often have very low bone mass. Androgens act by directly stimulating bone formation because osteoblasts have androgen receptors. However, testosterone probably also blocks bone resorption and can dampen the release of TNF, IL-6, and IL-1. Not surprisingly, estrogen also plays an important role in the male skeleton. Inhibition of aromatization of testosterone (i.e., aromatase P-450) to estrogen, whether caused by a genetic mutation or drugs, leads to significant bone loss. Investigators have also shown that men with low estradiol levels are at greater risk for osteoporosis. Thus, it appears that both estrogen and androgen are necessary for the development and maintenance of the male skeleton.

TREATMENT

Rx

Therapies for osteoporosis in male patients center on identifying any underlying cause and then treating with drugs that are also used in women. Hypogonadism can be effectively treated with androgen replacement, although caution must be used in elderly men because of the risk for prostate cancer. Hypercalciuria can be diminished by use of hydrochlorothiazide, which may also enhance bone density in men. Alendronate has been shown to prevent bone loss and to reduce fractures in men with idiopathic osteoporosis or osteoporosis resulting from androgen deficiency states.[22] PTH_{1-34} has also been approved for the treatment of male osteoporosis because it too can enhance bone density and prevent fractures. In a large randomized trial of men with limited prostate cancer taking gonadotropin-releasing agonists, denosumab reduced fractures and prevented bone loss. This agent, if approved by the FDA, may be the most appropriate therapy for a growing cohort of men receiving aggressive anticancer therapy. Selective androgen receptor modulators are under development and may offer a new approach to male osteoporosis.

OSTEOMALACIA AND RICKETS

ROBERT S. WEINSTEIN

DEFINITION

Rickets refers to impaired mineralization of the cartilaginous growth plate and abnormal endochondral bone formation and therefore cannot occur in adults after epiphyseal closure. *Osteomalacia,* literally meaning softening of bone, refers to defective or delayed mineralization of the organic matrix of bone, or osteoid, at the interface between calcified bone and osteoid, and may occur at any age. Both rickets and osteomalacia may be present in a growing child, but defective mineralization can cause only osteomalacia in adults; therefore, this chapter focuses on osteomalacia. Despite advances in our understanding of vitamin D metabolism and the increased sensitivity of measurements of serum 25-hydroxyvitamin D, osteomalacia remains a common but frequently overlooked disorder in the Western world. Optimal therapy requires precise identification of the etiology of the abnormal mineralization, which may present a problem because there are numerous causes (Table 252-1). However, once a correct diagnosis is made, therapy is usually gratifying and often spectacular. Early recognition of osteomalacia depends on familiarity with the typical clinical manifestations and settings. It is helpful to appreciate that the bone disease almost always manifests in the same manner regardless of the cause of the osteomalacia.

TABLE 252-1 CAUSES OF OSTEOMALACIA

VITAMIN D DEFICIENCY
Dietary deprivation and lack of sunlight exposure
VITAMIN D MALABSORPTION
Postgastrectomy Gastric bypass for obesity Gluten enteropathy Small bowel disease or resection Pancreatic insufficiency Cholestyramine therapy for cholestatic liver disease Laxative abuse

EPIDEMIOLOGY

About 20% of North American women receiving treatment for osteoporosis have 25-hydroxyvitamin D levels below 20 ng/mL (adequate values are greater than 30 ng/mL), and 8% have levels below 15 ng/mL, indicating that at the least, impaired bone mineralization could be a confounding factor in their osteoporosis treatment and, at worst, osteomalacia is the correct diagnosis (a defect in mineralization) rather than osteoporosis (a reduced amount of normally mineralized bone). Vitamin D deficiency is more common in elderly people, especially in nonaffluent elderly people during the winter and at higher latitudes. Vitamin D deficiency is also commonly found in medical inpatients and in postmenopausal women with acute hip fracture.

The prevalence of osteomalacia due to vitamin D deficiency varies with the referral source. The disorder is far more frequent when patients are referred from geriatricians, gastroenterologists (osteomalacia may be found in up to 30% of patients with gastric surgery or bypass for obesity), nursing homes, or orthopedists concerned about symmetrical or nonhealing fractures. The most common hypophosphatemic osteomalacia is the inherited disease X-linked hypophosphatemia, but affected adults infrequently present to internists and then only when troubled by severe bone pain or nonunion of fractures.

PATHOBIOLOGY

A review of normal bone remodeling and the mineralization of osteoid (bone matrix) serves as a background to understanding the abnormal mineralization characteristic of osteomalacia. Bone remodeling or turnover is carried out by teams of juxtaposed osteoclasts and osteoblasts, comprising temporary anatomic structures known as basic multicellular units (BMUs). In cortical bone, the BMUs drill tunnels or "cutting cones" through the compact tissue; while in spongy, cancellous bone, they gouge across the trabecular surface, forming serpiginous trenches. Bone turnover begins by conversion of a quiescent skeletal surface to a remodeling site, a process referred to as activation. Activation involves proliferation of new blood vessels needed to bring recruited osteoclast progenitors to the remodeling site and retraction of the flat, pavement-like bone-lining cells that cover the quiescent surfaces to expose the mineralized bone surface. The recruited cells become multinucleated osteoclasts, which attach to the newly exposed bone surface with a ring of contractile proteins sealing off a subosteoclastic resorption compartment. Lysosomal enzymes, hydrogen ions, and collagenase are secreted through the microvilli of the ruffled underside border of the osteoclasts, and these chemicals excavate a resorption cavity. The osteoclasts remove both the bone mineral and matrix. It is a misunderstanding to attribute to these cells or to metabolic acidosis the ability to remove only the mineral leaving behind demineralized osteoid. Demineralized bone in vivo is a misnomer. Demineralized or decalcified bone only occurs when bones are placed in acid (1 N HCl) or chelating solutions (ethylenediaminetetraacetate, or EDTA). Osteoclasts are motile cells, capable of resorbing more than just the cavity within which they are identified. After an osteoclast digs a cavity, it may detach from bone and move on to a new resorption site or die by apoptosis and be quickly removed by phagocytes. When the osteoclasts have moved on, osteoblasts assemble to reconstitute the previously resorbed cavity with new bone. In any established BMU, both events are happening at the same time; bone formation begins to occur while bone resorption advances.

Between the end of bone resorption and the beginning of bone formation is the reversal phase, when mononuclear phagocytes smooth out the jagged erosion bays. During this phase, the old bone is coated by a thin layer of cement substance, a collagen- and mineral-poor matrix rich in glycosaminoglycans, glycoproteins, and acid phosphatase, to which the new osteoblasts

attach. In adults, new osteoblasts assemble only at sites where osteoclasts have recently been eroding bone, a phenomenon referred to as coupling. The arrival of the osteoblasts in the right place at the right time and in sufficient numbers to reconstitute the cavity is referred to as remodeling balance and is likely due to proportional production of osteoblasts and osteoclasts in the bone marrow, release of osteoblast recruiting substances from the resorbed bone, and chemotaxis by the cement substances. As osteoblasts complete their bone matrix synthesis and move away from the cement line, they gradually flatten. Some osteoblasts become bone-lining cells, and some become osteocytes, but as many as 65% of the osteoblasts that originally assembled at the remodeling site die by apoptosis. It is the balance between cell proliferation and apoptosis that determines the amount of work performed by these cells.

Normally, up to 70% of the mineralization of the osteoid deposited by the osteoblasts starts within 4 to 12 days and proceeds at about 1 μm per day; but in osteomalacia, mineral deposition in the osteoid slows or stops completely, while the osteoblasts continue to make osteoid, which then accumulates in excessive amounts. Therefore, normal osteoid width is about 4 to 12 μm, but in osteomalacia, the osteoid width may become dramatically augmented. Depending on the extent of the delay in mineralization, overt osteomalacia may take many years to develop. In normal subjects, further mineralization proceeds slowly over months to years and at the cost of displacement of the water in the hydroxyapatite crystals resulting in increased brittleness and the eventual need for another round of remodeling. Even though a million BMUs are undergoing remodeling every day, bone mass in a healthy adult is preserved, owing to a remarkably tight balance between the amount of bone resorbed and formed during each cycle of remodeling. By this means, the adult skeleton is almost completely regenerated every 10 years.

Mineralization requires the availability of sufficient calcium and phosphorus at the remodeling site, the presence of a normal bone collagen matrix, the absence of inhibitors of mineralization, and an adequate amount of skeletal alkaline phosphatase activity. Defects in these requirements are the cause of most forms of osteomalacia. Deficiency of vitamin D per se has traditionally been incriminated as the cause of the osteomalacia, but today, considerable evidence indicates that the abnormal mineralization associated with vitamin D deficiency depends more on the deficiency of calcium and phosphorus than from the absence of a direct effect of vitamin D on bone cells. The primary function of vitamin D is to provide adequate levels of calcium and phosphorus by increasing their intestinal absorption. Chronic metabolic acidosis has also been identified as a cause of osteomalacia, but evidence suggests that the bone disease associated with chronic metabolic acidosis is primarily due to the associated hypophosphatemia.

CLINICAL MANIFESTATIONS

The clinical presentation of osteomalacia depends on three overlapping manifestations. Those due to the underlying disorder such as gastrointestinal disease or surgery (especially troublesome are gastric resection, stapling, or bypass for obesity and intestinal malabsorption); those due to hypocalcemia or hypophosphatemia; and those directly due to the bone disease. The most common symptoms and signs are bone pain, muscle weakness, and bone tenderness. The bone pain is usually nonspecific and poorly localized. Because of the paucity of findings, the pains are often attributed to rheumatism or neurosis. They may be worse at night and after sudden movements such as turning in bed or the change from sitting to standing. Most often, the pain is in the lower back, pelvis, and legs and is worse on weight bearing, resulting in a characteristic flat-footed, springless, waddling gait made worse by proximal muscle weakness. The gait has been referred to as "mother penguin's walk." Patients may complain that they can only climb stairs by pulling themselves up with the hand rail or rise from sitting in a chair or on the toilet by using their hands to push off. The decrease in strength is usually far greater than the degree of muscle wasting. Fasciculations are absent, and both reflexes and sensation remain normal. The bulbar, facial, and ocular muscles are always spared. However, muscle weakness is conspicuously absent when the osteomalacia is due to X-linked hypophosphatemia. Often, bone tenderness can be elicited by rib cage compression or pressing on the tibiae, wrists, pubic rami, or iliac crests. Hypocalcemia is usually mild to moderate but, rarely, can be severe enough to present with paresthesias, muscle cramps, a positive Chvostek's sign, or seizures. If the osteomalacia is mistaken for osteoporosis and treatment is started with a bisphosphonate, the patient may experience new-onset paresthesias, muscle cramps, and palpitations. This not uncommon scenario occurs because the antiresorptive treatment interferes with the compensatory secondary hyperparathyroidism and aggravates the hypocalcemia.

DIAGNOSIS

Biochemical changes depend on the stage of the disease and its etiology. In vitamin D deficiency, hypophosphatemia precedes and is more severe than the hypocalcemia because of the secondary hyperparathyroidism (Chapter 253) that almost invariably accompanies the disorder by the time that osteomalacia has occurred. In malabsorption, hypomagnesemia may contribute to the hypocalcemia, and hypoalbuminemia may lead to a spurious diagnosis of hypocalcemia. Increased serum alkaline phosphatase activity is classically associated with osteomalacia due to vitamin D deficiency but is not an early or reliable clue because some patients may have normal or borderline levels. The serum 25-hydroxyvitamin D levels are often less than 10 to 15 ng/mL. In contrast, serum 1,25-dihydroxyvitamin D levels are usually elevated owing to the concomitant hyperparathyroidism and do not contribute to the diagnosis of osteomalacia except in the rare abnormalities of vitamin D resistance (when 1,25-dihydroxyvitamin D levels may be extraordinarily high) or when 1-hydroxylation is defective (and 1,25-dihydroxyvitamin D levels are low). Quite a different pattern occurs with the inherited disease hypophosphatasia: serum 25-hydroxyvitamin D and calcium are normal, phosphorus is high normal or elevated, and alkaline phosphatase activity is below the normal range. Radiographic findings may be absent with early osteomalacia, and only blurred margins of the cancellous bone with thin cortices may be noted. The presence of bilateral, thin (2 to 3 mm), radiolucent bands known as pseudofractures (Fig. 252-1) found perpendicular to the periosteal surface in ribs, pubic and ischial rami, the neck of the femur, metatarsals, and below the glenoid fossa on the outer border of the scapulae are generally considered to be pathognomonic of osteomalacia, but this classic radiographic sign is infrequent today. Rarely, it may be seen in disorders lacking excessive osteoid. These pseudofractures (sometimes called Looser's zones or Milkman's fractures) show increased uptake on bone scans (Fig. 252-2) and may lead to an inappropriate search for a primary malignancy. Bone mineral density T-scores are often −3 or −4, with the radial diaphyseal density lower than that of the lumbar spine or total proximal femur.

Although characteristic clinical, radiographic, and biochemical findings may suggest osteomalacia, the absence of these findings cannot exclude the diagnosis. Quantitative histologic examination of undecalcified bone is, therefore, required to establish the unequivocal presence of osteomalacia (Fig. 252-3). Rigorous kinetic criteria for the histologic recognition of osteomalacia are necessary to preserve the traditional clinical, biochemical, and therapeutic connotations of the term. Therefore, a review of the quantitative bone histologic findings or histomorphometry in osteomalacia is useful. The histomorphometric diagnosis of osteomalacia requires the simultaneous presence of three findings: excessive osteoid (osteoid area greater than 10%;

FIGURE 252-1. Radiographic evidence of a pseudofracture of the femoral neck is suspicious for osteomalacia (*arrow*).

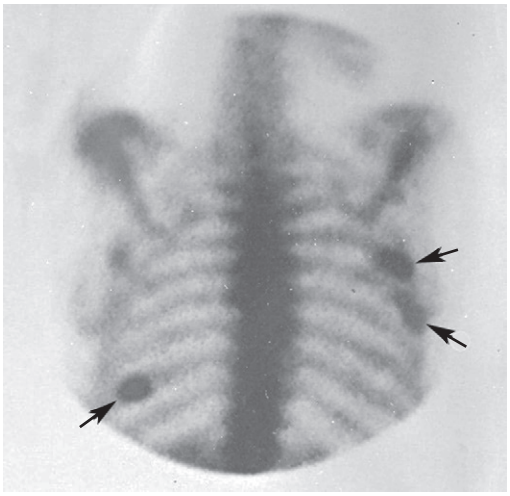

FIGURE 252-2. In osteomalacia, focal increased uptake of radionuclide on a bone scan may erroneously suggest metastatic disease (*arrows*).

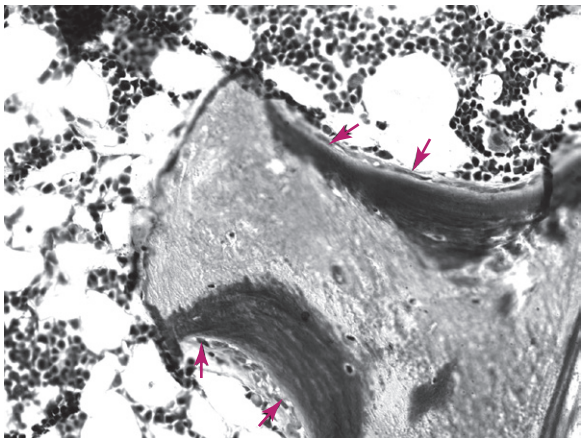

FIGURE 252-3. An undecalcified bone biopsy specimen shows the characteristic abundant osteoid and flattened osteoblasts (*arrows*) of osteomalacia. (Normally, mineralized bone appears gray and osteoid is black.)

normal is less than 4%), augmentation of the osteoid width (more than 15 μm; normal is 4 to 12 μm), and prolongation of the mineralization lag time (greater than 100 days; normal is 9 to 20 days), as determined by the osteoid width divided by the distance between and linear extent of double tetracycline labels observed in the bone after the patient receives two time-spaced courses of oral tetracycline. Tetracycline is deposited early in the course of hydroxyapatite crystal formation and generates bright stripes at the interface of mineralized bone and osteoid when viewed with fluorescent microscopy. If the two time-spaced courses of tetracycline (1 g/day for 3 days) are separated by a 14-day interval, the rate of mineralization (μm/day) can be calculated by measuring the average distance between the double labels divided by the number of days between the two courses. When the double labels are numerous and widely spaced, mineralization is intact, and excess osteoid must be due to increased bone turnover. A paucity of tetracycline labels that are narrowly spaced indicates that if excessive osteoid is present, it must be due to the delayed or ceased mineralization of osteomalacia.

Therefore, it follows that excessive osteoid can occur from two distinct mechanisms. Osteomalacia is the consequence of defective mineralization while osteoid production continues. However, osteoid will also accumulate with accelerated bone formation if the rate of osteoid deposition exceeds the rate of mineralization as occurs in states of increased bone turnover, such as hyperparathyroidism (Chapter 253), Paget's disease, or thyrotoxicosis. Although osteoblasts in osteomalacia are usually sparse and flattened, whereas they are numerous, plump, and cuboidal with high bone turnover, these two groups of disorders can be reliably distinguished only with the use of tetracycline markers. The treatment of increased bone turnover and of defective mineralization is completely different and that is why the three histomorphometric criteria are necessary. Additionally, evaluation of each of the criteria in isolation has limitations. Regarding the first requirement, a small increase in the osteoid area relative to the total bone area may occur in osteoporosis with a decrease in the amount of mineralized bone. In the second requirement, wide osteoid seams may be seen in some specimens obtained from patients with severe secondary hyperparathyroidism, such as those on maintenance hemodialysis therapy. In the third requirement, reduced mineral appositional rate and increased mineralization lag time are nonspecific indices of impaired matrix synthesis by osteoblasts, as is often found in patients with involutional osteoporosis. Only when all three requirements are fulfilled is the diagnosis of osteomalacia irrefutable.

Several presumed causes of osteomalacia (anticonvulsant drugs, metabolic acidosis without hypophosphatemia, pseudohypoparathyroidism, and chronic renal failure) have not fulfilled all of these requirements and primarily represent secondary hyperparathyroidism. Patients with the nephrotic syndrome lose albumin and vitamin D metabolites in the urine, but evidence indicates that serum ionized calcium and parathyroid hormone levels are normal and that metabolic bone disease in adults with the nephrotic syndrome is absent. Muscle weakness and bone pain are significantly more common in patients in whom the rigorous histologic diagnosis of osteomalacia has been proved. However, bone biopsy is not always necessary to be reasonably certain of the diagnosis. When biopsy is necessary, the local pathologist must be familiar with the processing of undecalcified bone specimens and plastic embedding; otherwise, the best solution is to refer the patient to a bone histomorphometry center for biopsy. This ensures satisfactory communication among the clinician, operator, and pathologist and is the best insurance against the incomplete, broken, fragmented, or accidentally decalcified bone specimens. Such referral may be indispensable in the evaluation of a patient with unusually painful disease or progressive loss of bone mineral density, particularly when the results of the physical examination, radiographs, and biochemical findings are ambiguous. Biopsy may also be indicated in patients with unexplained chronic hypophosphatemia.

The best approach is to avoid overlooking the diagnosis of osteomalacia by maintaining a high degree of suspicion in the typical clinical settings. This is especially important because osteomalacia can usually be successfully treated. An investigation for osteomalacia is indicated in elderly patients with bone pain and muscle weakness, in patients with gastric surgery and low bone mineral density or bone pain, and in patients with persistent hypophosphatemia. Unexplained elevations of the serum alkaline phosphatase activity are usually due to drugs (e.g., anticonvulsants, anabolic steroids, phenothiazines, or antibiotics) or Paget's disease of bone (Chapter 255) but rarely may be the only biochemical clue to osteomalacia in a patient with variable skeletal discomfort. Bilateral or slowly healing fractures also warrant an investigation for osteomalacia.

TREATMENT

Rx

Understanding the treatment of osteomalacia is facilitated by dividing the disease into four subgroups. The first subgroup is osteomalacia due to disorders of vitamin D absorption or metabolism; the second is osteomalacia due to chronic hypophosphatemia. Most patients with osteomalacia will be in these first two subgroups. The third subgroup includes osteomalacia caused by inhibitors of mineralization such as etidronate (the first oral bisphosphonate, now rarely used in North America); high doses of fluoride; and accumulation of a skeletal burden of aluminum from water used for dialysis or as a contaminant in solutions used for parenteral nutrition (now rarely seen), iron overload as in thalassemia, and cadmium or tenfovir, which induce the proximal tubular lesion of Fanconi's syndrome and cause osteomalacia due to the resultant hypophosphatemia. The fourth subgroup includes miscellaneous causes of osteomalacia that lack specific therapy but are fortunately quite rare. This last subgroup includes the variable forms of the heritable disorder hypophosphatasia, caused by a deficiency of the tissue-nonspecific (liver, bone, kidney) isoenzyme of alkaline phosphatase; axial osteomalacia, a sporadic osteosclerotic disorder primarily affecting middle-aged men and presenting with mild to moderate pain in the spine and pelvis (but without fractures), apparently from the production of an abnormal and poorly mineralized bone matrix by osteoblasts; and fibrogenesis imperfecta ossium, another sporadic disorder presenting with intractable bone pain and fractures mainly in middle-aged men and woman, apparently also due to production of an abnormal bone matrix by osteoblasts. In axial osteomalacia and fibrogenesis imperfecta ossium, serum calcium, phosphorus, and vitamin D levels are normal, but serum alkaline phosphatase activity may be increased. General measures for

this last subgroup include routine nutritional advice and avoidance of further bone loss due to postmenopausal or involutional osteoporosis. High-dose vitamin D therapy in these disorders has caused nephrocalcinosis, nephrolithiasis, and renal insufficiency and must be avoided.

Osteomalacia Due to Vitamin D Disorders

Iron deficiency anemia, hypocalcemia, weight loss, glossitis or rash, and bone discomfort in a patient with low bone mineral density point to celiac disease (Chapter 142), even without gastrointestinal symptoms. These signs suggest the need to test for antiendomysial immunoglobulin A antibodies. Cholestyramine therapy for cholestatic liver disease may increase malabsorption of vitamin D by binding bile salts. Laxative abuse may cause osteomalacia and severe resistance to vitamin D supplementation, including treatment with calcitriol. Advice on nutrition and sun exposure, discontinuation of offending drugs, adherence to a gluten-free diet, and pancreatic enzyme replacement may cure the mineralization defect in mild cases without the need for additional treatment.

Patients with severe disease usually require vitamin D and calcium supplementation. Replacement doses depend on the serum 25-hydroxyvitamin D level, as shown in Table 252-2. Because pharmacologic doses of any vitamin D preparation carry the risk for vitamin D intoxication, increases in the dose must be made carefully. The interval between increments in dosage should be at least the time required to reach maximal effects plus about 50%. However, experience with the doses given in Table 252-2 indicates that serum 25-hydroxyvitamin D levels rarely reach 80 to 100 ng/mL. Vitamin D intoxication is unlikely even with of levels of 100 to 110 ng/mL. The goal is to raise the serum 25-hydoxyvitamin D level well above 30 ng/mL and restore the elevated parathyroid hormone concentration to normal without hypercalcemia or hypercalciuria. Urinary calcium excretion should be monitored when treatment has normalized the serum calcium level. The urinary calcium-to-creatinine ratio (mg/mg) should be kept below 0.22. Approximately 1 to 1.5 g per day of oral elemental calcium is a reasonable initial dose. Frequent small doses (three times a day) are more effective and tolerable than fewer larger ones, and the absorbability of calcium supplements is enhanced with meals. Most patients do well with the calcium preparations used for osteoporosis, such as calcium carbonate (40% calcium as in Os-Cal or the equivalent) or calcium citrate (21% calcium as in Caltrate or the equivalent). Some patients who cannot tolerate calcium carbonate or citrate experience fewer adverse gastrointestinal symptoms with the use of the chocolate- or coffee-flavored formulations known as Viactiv (500 mg calcium per tablet). The vitamin D content of these calcium supplements is trivial in the treatment of osteomalacia.

In patients with malabsorption, vitamin D requirements may increase during periods of increased diarrhea, and calcitriol may be easier for these patients to absorb. Its rapid onset of action and disappearance after cessation add to the safety of treatment, albeit at far greater cost. Calcium, phosphorus, potassium, magnesium, multivitamins, and gonadal steroids may also be beneficial in patients with malabsorption. Some patients do not tolerate any form of oral vitamin D, and the parenteral ergocalciferol preparations in North America are ineffective. These patients can be improved, although not restored to normal, by the use of weekly tanning bed treatments to areas of their bodies not normally exposed to the sun, with an attempt to minimize solar-induced skin cancer. Calcitriol is the drug of choice in patients with the autosomal recessive disease vitamin D–dependent rickets type I, in which the 1α-hydoxylase enzyme necessary to convert 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D is deficient. In vitamin D–dependent rickets type II, another rare autosomal recessive disease presenting with alopecia, diminished target sensitivity to 1,25-dihydroxyvitamin D may require extraordinarily high doses of calcitriol. If oral treatment fails, nocturnal infusions of calcium and phosphorus have been successful, providing additional evidence that the osteomalacia is due to inadequate calcium and phosphorus rather than from the defect in vitamin D metabolism.

An increase in the serum alkaline phosphatase activity (the healing "flare") and a small increase in the serum and urine calcium levels are the earliest signs of effective treatment. Thereafter, the serum alkaline phosphatase activity level falls progressively as healing occurs. At the start of therapy, serum calcium levels should be measured at weekly intervals. If hypoalbuminemia is present, serum ionized calcium determinations are more useful. When therapy appears stabilized, biweekly or monthly intervals are usually sufficient for the first 3 or 4 months, but even with long-term therapy, measurements should be at least three times a year. In some patients with severe osteomalacia, bone pain and paresthesias may increase and the serum calcium levels decrease during the first few weeks of therapy. This is due to the increased skeletal avidity for mineral during healing and indicates the need for additional calcium supplementation.

Osteomalacia Due to Hypophosphatemia

Therapy of chronic hypophosphatemia is aimed at maintaining normal concentrations of serum phosphorus without inducing secondary hyperparathyroidism or nephrocalcinosis. This considerably difficult task requires divided doses of phosphorus supplements (1 to 3 g/day) and calcitriol (1 to 4 μg/day) to increase the absorption of phosphorus and calcium to prevent the increase in parathyroid hormone. If phosphorus-induced secondary hyperparathyroidism develops, the phosphorus supplements are rapidly excreted, and therapy not only is futile but also causes the additional bone disease of hyperparathyroidism (Chapter 253). Baseline and yearly renal ultrasound examinations are necessary to recognize early nephrocalcinosis or nephrolithiasis.

A rare form of acquired hypophosphatemic osteomalacia is called oncogenic osteomalacia. This disorder is associated with a variety of small, hard to find mesenchymal tumors that secrete phosphaturic proteins. Fibroblast growth factor 23 (FGF23) is the most frequently documented protein, but others are also incriminated. The muscle pain, weakness, fractures, and osteomalacia characteristic of this syndrome are due to hypophosphatemia made worse by inappropriately low levels of 1,25-dihydroxyvitamin D. Oncogenic osteomalacia is also treated with phosphorus supplementation and calcitriol until the offending tumor can be located and resected. Surgical correction of deformities should be postponed until medical management achieves persistently normal levels of calcium, phosphorus, and alkaline phosphatase activity. An exception to this rule is an acute fracture of the femoral neck. Prompt surgical repair may be essential to avoid osteonecrosis. In addition to the X-linked form of hypophosphatemia, adult hypophosphatemia may also occur sporadically, but a search for an offending mesenchymal tumor is still indicated. Antacid-induced hypophosphatemia due to the ingestion of large quantities of phosphate-binding antacids has become rare with the increased availability of proton pump inhibitors but still occurs occasionally.

PREVENTION

Advice about vitamin D supplementation should help to prevent osteomalacia caused by vitamin D deficiency, but this has proved to be difficult because routine supplements may be inadequate and compliance with nutritional supplements is poor. The optimal vitamin D supplementation dosage is not clear, but most bone and mineral problems are avoided by 50,000 units of ergocalciferol given once monthly. Notable exceptions occur in patients with celiac disease, gastric surgery, or bypass for obesity, who often require much larger amounts (see Table 252-2). In patients with osteomalacia due to hypophosphatemia, the need for phosphorus supplementation may be lifelong (Table 252-3). Exceptions occur in oncogenic osteomalacia when surgical removal of the tumor is accomplished.

TABLE 252-2 VITAMIN D PREPARATIONS FOR TREATMENT OF OSTEOMALACIA

	VITAMIN D_2 (ERGOCALCIFEROL)	CALCITRIOL [1,25(OH)$_2$D$_3$]
Trade name (generic name)	Drisdol (ergocalciferol)*	Rocaltrol (calcitriol)
Dosage form	Caps: 50,000 U = 1.25 mg	Caps: 0.25 and 0.50 μg
Dosage:		0.50-2.0 μg/day
If 25(OH)D = 20 to 30 ng/mL	50,000 once a week × 10 weeks† and once a month thereafter	
If 25(OH)D = 10 to 20 ng/mL	50,000 twice a week × 10 weeks† and twice a month thereafter	
If 25(OH)D = less than 10 ng/mL	50,000 three times a week × 10 weeks† and three times a month thereafter	
Dosage in resistant cases	Up to 50,000 units per day	5-20 μg/day
Time to reach maximal effects	4-10 weeks	3-7 days
Persistence of effects after cessation	6-30 weeks	3-7 days
Cost	$150/100 capsules of 50,000 units	$130/100 capsules of 0.25 μg $150/100 capsules of 0.5 μg

*The soft, gel capsule formulations are best because the hard, coated tablet preparations are unreliable.
†If not >30 ng/mL after 10 weeks, exclude malabsorption, gluten enteropathy, and noncompliance. Weekly tanning bed treatments may be used if oral vitamin therapy fails, or a switch to the more costly calcitriol may be necessary.
25(OH)D = 25-hydroxyvitamin D.

TABLE 252-3 PHOSPHATE PREPARATIONS FOR TREATMENT OF OSTEOMALACIA

PREPARATION	SODIUM CONTENT (mEq)	POTASSIUM CONTENT (mEq)	AMOUNT THAT CONTAINS 1 GRAM OF ELEMENTAL PHOSPHORUS
Neutra-Phos	28.5	28.5	4 unit dose caps*
Neutra-Phos-K	—	57.0	4 unit dose caps*
K-Phos Neutral	50.4	4.6	4 tabs
K-Phos Original	—	33.0	9 tabs

*Each unit dose cap is reconstituted with 75 mL of water, fruit juice, or cola. The unit dose cap contains the powder concentrate and is not to be swallowed undiluted.

PROGNOSIS

The response to appropriate treatment in most forms of osteomalacia is usually excellent. Improvements in bone pain and muscle weakness usually occur within 2 or 3 months and healing of skeletal lesions within 6 to 18 months. Depending on the quantity of excess osteoid, repeat bone mineral density determinations may show as much as 20% gains at the lumbar spine and total proximal femur. However, bone density at the radial diaphysis may not improve owing to the irreversible loss of cortical bone resulting from prolonged secondary hyperparathyroidism. Furthermore, if decreased bone volume is present in addition to excess osteoid, skeletal recovery may be incomplete, and the risk for fractures remains increased.

THE PARATHYROID GLANDS, HYPERCALCEMIA, AND HYPOCALCEMIA

JOHN J. WYSOLMERSKI AND KARL L. INSOGNA

CALCIUM AND CALCIUM METABOLISM

Calcium serves two principal physiologic functions. First, insoluble calcium salts (primarily hydroxyapatite) provide the structural characteristics that allow bones to protect internal organs, to bear weight, and to function as the levers on which muscles act during locomotion. Second, soluble calcium ions in the extracellular fluid (ECF) and cytosol are critical for myriad biochemical reactions, signaling cascades, and electrical systems that are necessary for life. An adult human contains about 1000 g of calcium, the majority of which (≈99%) is found in bone. Approximately 1% of total body calcium is contained within the ECF and soft tissues. Therefore, the skeleton is called on as a source of calcium when the ECF concentration falls, and it acts as a storehouse for excess calcium. Of the total circulating calcium, the ionized fraction is 50%; the remainder is bound to serum proteins, primarily albumin, and, to a lesser extent, is complexed with anions such as citrate or sulfate. Only the ionized fraction is physiologically important, and this component is regulated on a minute-to-minute basis. Although it is possible to measure ionized calcium, the specimen must usually be obtained anaerobically and analyzed promptly. Therefore, total serum calcium is often used as an indirect assessment of the ionized calcium fraction.

A complicated homeostatic system involving multiple organs and several hormones regulates both the calcium concentration of the ECF and the calcium content of the skeleton. The organs involved in the regulation of calcium metabolism are the parathyroid glands, kidneys, skeleton, and gut. The hormones include parathyroid hormone (PTH), vitamin D, and PTH-related protein (PTHrP). Abnormalities in these organs, the hormones, or their receptors can cause disturbances in calcium metabolism and lead to hypercalcemia or hypocalcemia. In this chapter, we review calcium homeostasis in humans and then discuss the most common causes of hypercalcemia and hypocalcemia.

Calcium Homeostasis

Parathyroid Glands and Parathyroid Hormone

The four parathyroid glands are located in the neck. The pair of glands located at the upper poles of the thyroid is derived from the fourth branchial pouch, whereas those located at the lower poles migrate downward from the third branchial pouch, along with the thymus gland. Extra parathyroids or parathyroid glands in aberrant locations are not uncommon, especially along the path of embryologic migration.

The parathyroid glands make PTH, an 84–amino acid protein. PTH is synthesized initially as a single-chain, pre-proparathyroid peptide. The 25-residue presequence is cleaved twice to generate the mature, 84–amino acid, full-length protein (PTH 1–84). Full-length PTH is the biologically active form of the hormone. It has a very short half-life (minutes) in the circulation and is degraded by the liver and kidney. This degradative process releases carboxy-terminal (C-terminal) fragments of PTH into the circulation. In addition, in response to hypercalcemia, proteases found within parathyroid secretory granules digest the amino-terminal portion of PTH, and these inactive C-terminal fragments are secreted. Therefore, the concentration of circulating inactive C-terminal species is a product of both parathyroid cell secretion and peripheral metabolism of full-length PTH. These fragments accumulate in the circulation in renal failure.

PTH secretion is regulated by the extracellular ionized calcium concentration. A steep inverse sigmoidal relationship exists between PTH secretion and calcium concentration, which can be defined by four parameters (Fig. 253-1). The steep part of this curve encompasses the physiologic range for extracellular calcium, over which small changes in the concentration of ionized calcium elicit large changes in the rate of PTH secretion.

For parathyroid cells to regulate PTH secretion, they must sense changes in extracellular calcium concentration. This is accomplished through a G protein–coupled receptor (GPCR) known as the *calcium-sensing receptor* (CaR). Calcium binding to the CaR activates downstream signaling pathways (primarily the induction of phospholipases and intracellular calcium transients). This process, in turn, suppresses PTH secretion. If calcium levels are persistently elevated, activation of this receptor also reduces PTH messenger RNA levels and inhibits parathyroid cell proliferation. In addition to parathyroid cells, the CaR is prominently expressed in the kidney, where it regulates calcium handling by the renal tubules. Hypercalcemia activates the CaR, suppressing renal calcium reabsorption. In this way, hypercalcemia directly promotes the excretion of calcium in the urine, and hypocalcemia directly enhances its reabsorption.

The actions of PTH are mediated by the type 1 PTH/PTHrP receptor (PTH1R). The calcium-regulating effects of the receptor appear to be primarily the result of activation of adenylyl cyclase. During usual conditions, this receptor is activated equally well by the amino-terminal portions of PTH and PTHrP (see later). The PTH1R is most abundant in bone and kidney, where it mediates the systemic functions of PTH. However, PTH1R is also expressed in many other cells in the body, where it serves as a PTHrP receptor. In this capacity, PTH1R has important functions during bone and mammary development and mediates many of PTHrP's effects on cellular proliferation, apoptosis, and differentiation (see later).

PTH exerts direct effects on kidney and bone cells and indirect effects on enterocytes. The integrated action of PTH on these organs results in an increase of ionized calcium. In the kidney, PTH has three principal effects.

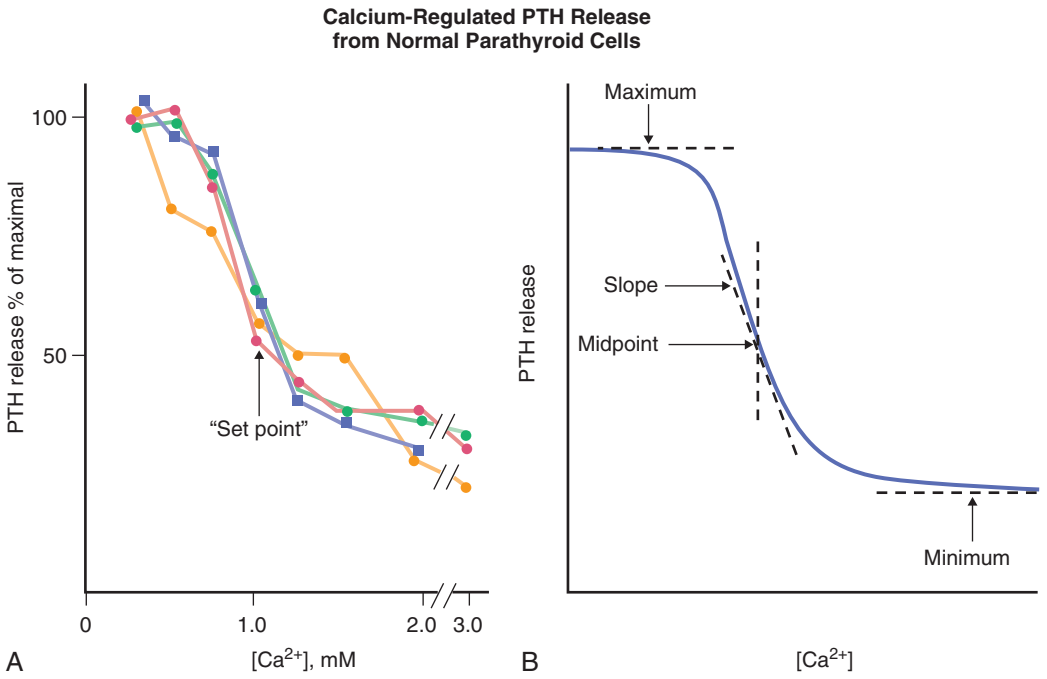

FIGURE 253-1. **Regulation of parathyroid hormone (PTH) secretion in response to changes in extracellular calcium. A,** PTH secretion by dispersed normal human parathyroid cells in culture in response to varying concentrations of extracellular calcium. **B,** The four-parameter model describing the inverse sigmoidal relationship between extracellular calcium and PTH secretion. Parameter 1 is the maximal secretory rate, parameter 2 is the slope of the curve at the midpoint, parameter 3 is the set point, and parameter 4 is the minimum secretory rate. (From Brenner BM, Stein H. Divalent ion homeostasis. *Contemp Issues Nephrol.* 1997;2:479-499.)

First, it acts on proximal tubular cells to inhibit the reabsorption of phosphate. Phosphate transport depends on the actions of sodium-phosphate cotransporters 2a and 2c (NPT2a, NPT2c), which are located in the luminal membranes of proximal tubular cells. PTH acts to inhibit phosphate reabsorption by causing NPT2a and NPT2c to be removed from the luminal membrane and degraded. Second, PTH stimulates the activity of renal 1α-hydroxylase in proximal tubular cells. This leads to the formation of biologically active $1,25(OH)_2$ vitamin D from its circulating precursor 25(OH) vitamin D. PTH also inhibits 24-hydroxylase, thus preventing the formation of the inactive metabolite $24,25(OH)_2$ vitamin D. Both these actions increase the circulating concentrations of $1,25(OH)_2$ vitamin D, an increase that stimulates intestinal calcium absorption. Finally, PTH acts to increase the reabsorption of calcium by the kidney. The majority of calcium is reclaimed from the glomerular filtrate in the proximal tubule through a PTH-independent paracellular process linked to the reabsorption of sodium. PTH helps promote some calcium reabsorption in the cortical thick ascending loop of Henle by increasing the net positive charge on the luminal side of the tubule, which enhances paracellular calcium and magnesium reabsorption. The distal tubule is the primary target of PTH's actions to promote calcium transport. In these cells, PTH leads to the insertion of calcium channels into the apical membrane of the cell and stimulates the activity of basolateral sodium-calcium exchangers. The net result is to stimulate directional, transcellular calcium transport from the tubule lumen, across the cell, and into the ECF.

In the skeleton, PTH activates bone turnover and liberates stored calcium. The immediate action of PTH is to stimulate the transport of calcium across bone lining cells from an easily mobilized pool of calcium at the surface of bone. A more delayed action of PTH is to increase the number and activity of bone-forming osteoblasts and bone-resorbing osteoclasts. PTH acts directly on cells within the osteoblast lineage. Overall, in vivo, PTH increases the size of the osteoblast precursor pool and increases the bone-forming activity of mature osteoblasts. PTH acts indirectly on osteoclasts. The hormone stimulates osteoblasts to release cytokines, such as colony-stimulating factor 1 and receptor activator of nuclear factor-κB (NF-κB) ligand (RANKL), which stimulate the formation of new osteoclasts and activate mature osteoclasts. PTH also inhibits osteoblast production of osteoprotegerin, a soluble decoy receptor for RANKL that inhibits osteoclast development. Through mechanisms that are still not entirely understood, persistent elevations of PTH increase osteoclast activity more than osteoblast activity, whereas intermittent elevations in PTH do the opposite, stimulating osteoblasts more than osteoclasts. As a result, continuous exposure to PTH causes net bone resorption, and intermittent exposure to PTH causes net bone formation.

Vitamin D

In response to ultraviolet light, keratinocytes in the epidermis convert 7-dehydrocholesterol, the immediate precursor of cholesterol, into vitamin D_3. Cutaneous production of vitamin D_3 is affected by a variety of factors such as latitude, season, use of sunscreen, concentration of melanin, and type of clothing, all of which vary the amount of ultraviolet light that penetrates the skin. Aging also reduces the ability of the skin to synthesize vitamin D. Most foods contain little vitamin D, although some is found in oily fish and in fish liver oils. In the United States, vitamin D is also found in fortified foods, including certain cereals, milk, and bread. Given these restrictions on its production and availability, vitamin D deficiency is very common in the winter months in elderly populations living at higher latitudes.

Vitamin D_3 produced in the skin is biologically inert and must be hydroxylated in two successive steps to become active. The first hydroxylation is performed in the liver by vitamin D 25-hydroxylase and generates 25-hydroxyvitamin D_3. This has little biologic activity, but it is metabolized by cells in the proximal renal tubule to form the active hormone $1,25(OH)_2$ vitamin D_3. The 25(OH)D-1α-hydroxylase (1α-hydroxylase) enzyme catalyzes this final hydroxylation step. PTH stimulates the activity of renal 1α-hydroxylase. This enzyme is also stimulated by phosphate and is inhibited by hypercalcemia. Although renal conversion of 25(OH)D to $1,25(OH)_2$ vitamin D is the reaction most relevant to calcium homeostasis, it is worth noting that this reaction occurs in other tissues and cells in the body, such as macrophages, where $1,25(OH)_2$ vitamin D may serve different roles.

Vitamin D is a steroid hormone that interacts with specific nuclear receptors to regulate gene expression. The vitamin D receptor is a member of the steroid hormone receptor family of ligand-binding transcription factors. It heterodimerizes with the retinoic acid X receptor, and, in the presence of $1,25(OH)_2$ vitamin D, the vitamin D receptor–retinoic acid X receptor complex binds to specific DNA recognition sequences within target genes. The main function of $1,25(OH)_2$ vitamin D is to support the circulating calcium concentration through two actions. The first is to stimulate calcium absorption from the gut lumen by enterocytes. The active vitamin D metabolite stimulates the expression of calcium channels within intestinal cells that allow calcium to enter the apical surface of the cell. It also enhances the production of proteins that shuttle calcium through the cytoplasm and stimulates the activity of calcium pumps that extrude calcium across the basolateral membrane of the cells. These functions enhance the transcellular transport of calcium across enterocytes. Vitamin D also enhances paracellular calcium absorption by the gut. In addition to calcium, vitamin D stimulates the absorption of phosphorus from the diet. The second important action of $1,25(OH)_2$ vitamin D in calcium homeostasis is to increase bone resorption by stimulating osteoblastic production of RANKL. This latter effect is

clinically important only when production of $1,25(OH)_2$ vitamin D is elevated to pathologic levels.

Parathyroid Hormone–Related Protein

PTHrP was discovered in the course of studies exploring the pathogenesis of humoral hypercalcemia of malignancy (see later). In humans, the gene is located on chromosome 12. The PTH and PTHrP genes share structural features that suggest they arose from a common ancestor. In particular, of the first 13 amino-terminal amino acids in each protein, 8 are identical; after this, the sequences of the two proteins diverge. The amino-terminal homology allows both PTH and PTHrP to bind to PTH1R with equal affinity and to activate the same signaling pathways. PTH is made only in the parathyroid glands, is secreted into the systemic circulation, and activates PTH1R in bone and kidney to regulate calcium metabolism. In contrast, PTHrP is made in a variety of cell types, is secreted locally, and acts in a paracrine or autocrine fashion to activate PTH1R on neighboring cells. Important sites of action include developing cartilage, bone, breast tissue, and various types of smooth muscle. During lactation, PTHrP is secreted by the breast into the circulation and acts like PTH to regulate systemic calcium metabolism.

Integrated Regulation of Calcium Metabolism

Hormones and organ systems coordinate to regulate the ECF ionized calcium concentration such that it is maintained within a very narrow physiologic range. As illustrated in Figure 253-2, if the calcium level falls below the physiologic range, PTH is rapidly secreted from the parathyroid glands and activates the release of calcium and phosphate from the skeleton. In the kidney, PTH increases the reabsorption of calcium from the urine while simultaneously inhibiting phosphate reabsorption to dispose of the phosphate released from the skeleton. This process prevents serum phosphate from rising, an action that would otherwise inhibit a rise in serum calcium by inducing the precipitation of calcium phosphate salts in soft tissues. In addition, alterations in CaR signaling within the kidney activate calcium reabsorption independent of changes in PTH. Combined, these actions return the calcium concentration back toward normal, thus inhibiting further PTH release. When hypocalcemia persists, PTH also stimulates the renal production of $1,25(OH)_2$ vitamin D, which increases intestinal calcium absorption. In the presence of hypercalcemia, PTH secretion is suppressed, and the various organs alter their calcium handling in an opposite fashion so circulating calcium levels fall. Data in animals suggest that CaR-mediated calcium excretion by renal tubules may be a particularly important defense against hypercalcemia.

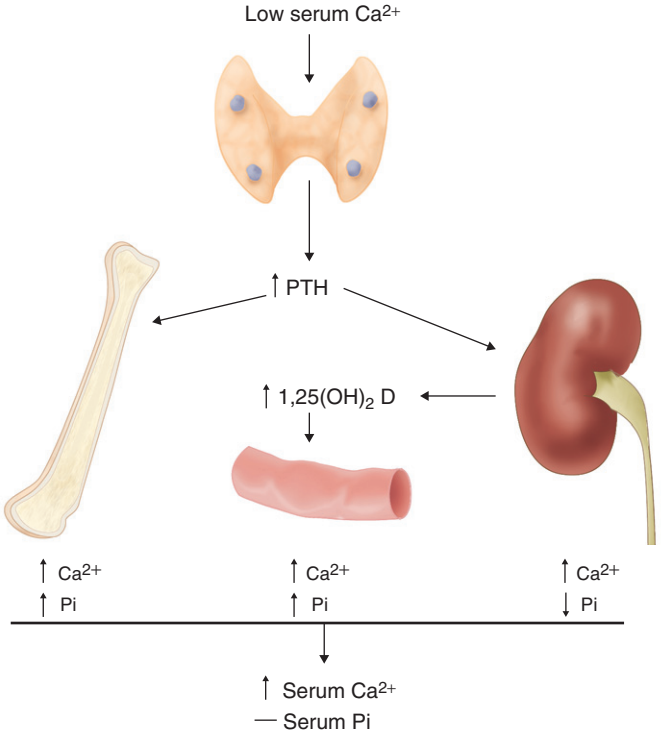

FIGURE 253-2. Homeostatic response to a fall in serum calcium (Ca^{2+}). Pi = inorganic phosphate; PTH = parathyroid hormone.

HYPERCALCEMIA

PATHOBIOLOGY

The long list of potential causes of hypercalcemia is provided in Table 253-1. However, most cases of hypercalcemia (>90%) are caused by either primary hyperparathyroidism or malignancy-associated hypercalcemia (MAHC). These two diseases, along with a few others, are discussed in detail. Several of the less common causes of hypercalcemia are worth noting briefly. First, abnormalities in serum proteins and severe thrombocytosis (platelet count >700,000) can cause pseudohypercalcemia, defined as elevations in total calcium without elevations in ionized calcium. Several endocrine disorders, including thyrotoxicosis, pheochromocytoma, adrenal insufficiency, and islet cell tumors of the pancreas, can manifest with mild to moderate hypercalcemia. An increasingly common cause of hypercalcemia is the milk-alkali syndrome. Patients with this disorder present with a triad of hypercalcemia, systemic alkalosis, and renal insufficiency associated with the ingestion of large amounts of calcium and absorbable alkali. The disorder was originally described in the 1930s as a complication of the treatment of peptic ulcer disease, but in its modern form, it is associated with the ingestion of calcium carbonate for the treatment or prevention of osteoporosis. In some patients, this syndrome can be precipitated by the daily intake of as little as 2 g of calcium. Immobilization uncouples bone turnover by inhibiting bone formation. Thus, in patients with elevated rates of bone resorption, immobilization can worsen or precipitate hypercalcemia. Patients at greatest risk include adolescents with physiologic elevations in bone turnover and patients with preexisting Paget's disease (Chapter 255) or subtle primary

Systemic lupus erythematosus
Breast hyperplasia

hyperparathyroidism. Finally, several medications other than calcium carbonate can cause hypercalcemia. The most commonly implicated drugs include thiazide diuretics, lithium carbonate, and vitamin D preparations. Several well-documented episodes of vitamin D intoxication have been caused by errors in the fortification of dairy products or the preparation of dietary supplements.

CLINICAL MANIFESTATIONS

Patients with mild hypercalcemia (<1 mg/dL above normal) are usually asymptomatic unless they have concomitant cerebral dysfunction. The likelihood of developing symptoms from hypercalcemia is related to both the degree of elevation in serum calcium and the rapidity with which the calcium level rises. When present, symptoms are caused by dehydration secondary to urinary losses of calcium, water, and other electrolytes and to an increase in membrane potential caused by the elevation in ECF ionized calcium concentration. Dehydration develops because an increase in the filtered load of calcium leads to variable degrees of hypercalciuria. Loss of calcium in the urine obligates the loss of anions and water. In addition, hypercalcemia causes nephrogenic diabetes insipidus because stimulation of the CaR in the collecting ducts of the kidney interferes with the trafficking of aquaporin water channels in response to vasopressin. Consequently, patients with hypercalcemia frequently report symptoms of polyuria and polydipsia. If significant dehydration ensues, hypercalcemia can worsen quickly because any impairment of glomerular filtration reduces the ability of the kidneys to excrete excess calcium. Patients with moderate to severe hypercalcemia often complain of nausea and vomiting, symptoms likely related to dehydration as well as to the effects of hypercalcemia on central nervous system function. Because hypercalcemia tends to hyperpolarize membranes, a range of neurologic and neuromuscular signs and symptoms can occur. Patients with mild hypercalcemia often complain of fatigue, depressed affect, and asthenia. With further increases in serum calcium, these complaints progress to impaired concentration and memory, difficulty with cognitive function, stupor, and coma. Muscle weakness can be seen, which occasionally progresses to flaccid paralysis if hypercalcemia becomes severe. Gastrointestinal motility is impaired; this commonly results in constipation and likely contributes to nausea and vomiting. Occasionally, pancreatitis can be the cause of abdominal pain in patients with hypercalcemia. Finally, cardiovascular function can be impaired, as manifested by bradycardia and sensitivity to the effects of digitalis. Electrocardiographic changes include shortening of the QT interval, varying degrees of atrioventricular block, and bradyarrhythmias and tachyarrhythmias.

DIAGNOSIS

As noted previously, most patients with hypercalcemia have either hyperparathyroidism or MAHC (Fig. 253-3). If the patient has hyperproteinemia or hypoproteinemia, or if the platelet count is markedly elevated, hypercalcemia should be confirmed by measuring the serum ionized calcium concentration. Otherwise, the first test should be a serum intact PTH level. Elevated PTH in the presence of hypercalcemia establishes the diagnosis of hyperparathyroidism. If PTH levels are suppressed and the patient has a known malignant disease, the diagnosis of MAHC is entertained. If the patient has a suppressed PTH level in the absence of a known malignant disease, the serum PTHrP level should be measured, and a careful screen for occult malignant disease should be performed. If the PTHrP level is normal in this setting, a careful history of prescription and over-the-counter medications should be taken, and laboratory tests to investigate other causes of hypercalcemia should be performed.

Primary Hyperparathyroidism

DEFINITION

Primary hyperparathyroidism is a disorder of calcium metabolism caused by the overproduction of PTH by the parathyroid glands. It is therefore characterized by simultaneous elevations in both circulating PTH and calcium levels.

EPIDEMIOLOGY

Historically, hyperparathyroidism was thought to be a rare disorder associated with severe complications. However, with the introduction of routine serum calcium measurements in the 1970s, it was recognized that many

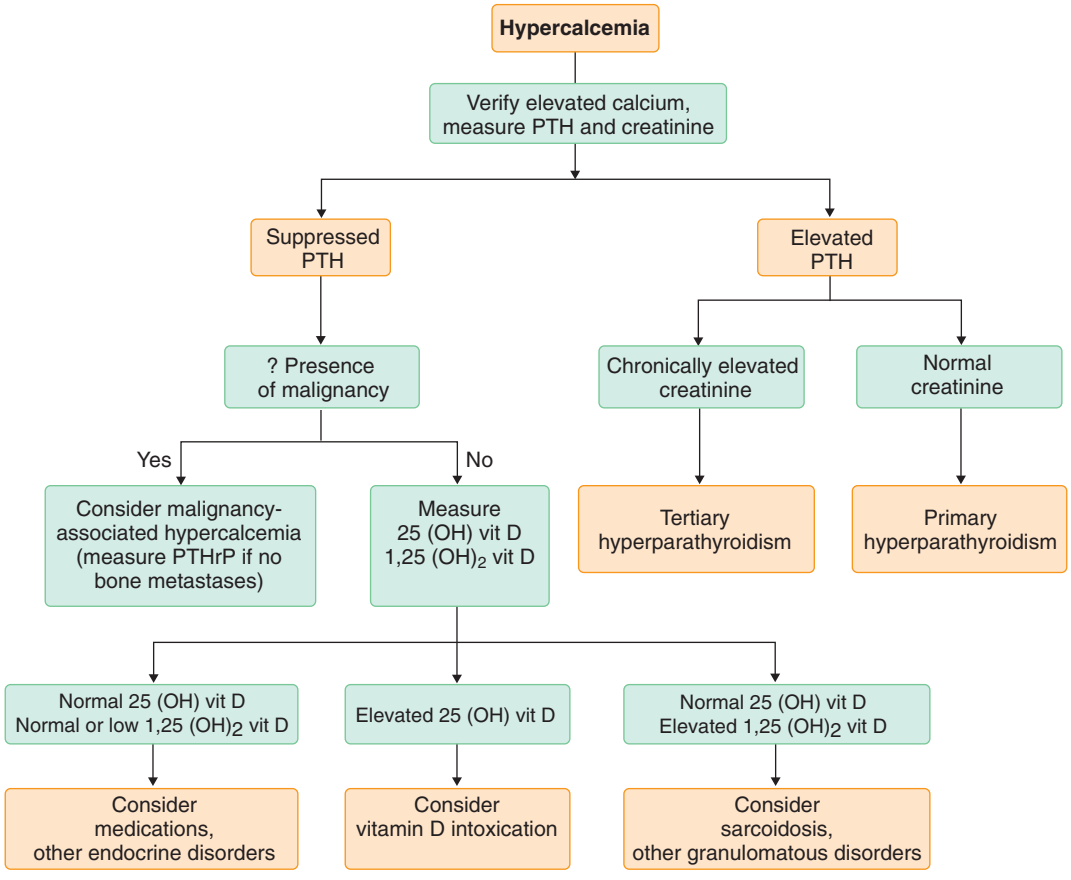

FIGURE 253-3. Algorithmic approach to the diagnosis of hypercalcemia. PTH = parathyroid hormone; PTHrP = PTH-related protein; vit = vitamin.

patients had milder forms of the disease. The incidence of hyperparathyroidism is currently estimated to be between 1 in 500 and 1 in 1000 persons. After age 50 years, women are more frequently affected than men; the female-to-male ratio in that age group is 3:1. Although hyperparathyroidism can manifest at any age, it is more common in older individuals, and the peak incidence is in the sixth decade. Typically, hyperparathyroidism occurs sporadically, but in a few patients it is part of a familial syndrome. Apart from these genetic disorders, the only other known risk factor is exposure to external neck irradiation during childhood.

PATHOBIOLOGY

In 80 to 85% of cases, hyperparathyroidism is caused by a solitary adenoma arising in one of the four parathyroid glands. These adenomas are benign, clonal neoplasms of parathyroid chief cells that tend to remain remarkably stable in size once they become clinically apparent. Although the molecular origins of parathyroid adenomas are only partly understood, these tumors presumably arise from somatic mutations in a single cell. Approximately 20 to 40% of adenomas have been reported to overexpress cyclin D1, a cell-cycle regulatory protein that can act as a dominant oncogene. An additional 25 to 30% of sporadic adenomas reportedly have somatic mutations in the multiple endocrine neoplasia 1 (*MEN1*; menin) tumor suppressor gene on chromosome 11 (Chapter 239). Approximately 15% of patients with hyperparathyroidism have diffuse enlargement of all four parathyroid glands caused by chief cell hyperplasia. The most common cause of four-gland hyperplasia is long-standing renal failure, which leads to chronic hypocalcemia, hyperphosphatemia, and low serum $1,25(OH)_2$ vitamin D levels, all of which stimulate parathyroid cell growth. This hyperplasia can eventually lead to hypercalcemia, so-called tertiary hyperparathyroidism. Most cases of inherited parathyroid hyperplasia result from one of the two MEN syndromes (Chapter 239). Hyperparathyroidism is a prominent feature of the MEN 1 syndrome (Chapter 239), which is caused by mutations in the menin gene, a tumor suppressor. In contrast, hyperparathyroidism associated with the MEN 2 syndrome (Chapters 239 and 254) is usually mild and occurs in fewer affected individuals. MEN 2 is caused by mutations in the *ret* proto-oncogene. Both syndromes have an autosomal dominant mode of inheritance. Hyperplasia in these syndromes can be asynchronous, with unequal enlargement of the individual glands over time, giving the misimpression of single-gland disease. Approximately 0.5% of all patients with hyperparathyroidism have parathyroid carcinoma. Typically, these patients have severe hypercalcemia and hyperparathyroidism that recurs following initial therapy. It can be very difficult to distinguish a parathyroid carcinoma from an adenoma by pathologic evaluation alone, but local tissue invasion, local lymph node involvement, and the presence of mitotic figures are clues to the diagnosis. Parathyroid carcinoma occurs with increased frequency in a rare genetic syndrome known as *hyperparathyroid jaw-tumor syndrome,* which is characterized by primary hyperparathyroidism in association with mesenchymal tumors of the mandible. This syndrome is caused by mutations in the gene encoding the tumor suppressor parafibromin; mutations in this gene may also cause a significant proportion of sporadic cases of parathyroid carcinoma.

CLINICAL MANIFESTATIONS

The presentation of hyperparathyroidism includes the characteristic symptoms of hypercalcemia combined with the variable occurrence of skeletal and renal complications. Hypercalcemia is caused by the chronic overproduction of PTH by the abnormal parathyroid cells. An important component of this abnormal secretion is a shift of the set point and slope of the calcium-PTH response curve; that is, adenoma cells become less sensitive to calcium's ability to suppress PTH production. Parathyroid adenomas still respond to calcium, but only at higher ambient levels of the ion, resulting in the establishment of a new equilibrium at abnormally high levels of calcium and PTH.

The most common complication of hyperparathyroidism besides hypercalcemia is nephrolithiasis. Approximately 20% of patients present with kidney stones. Nephrocalcinosis, which is the diffuse deposition of calcium phosphate complexes in the renal parenchyma, is seen less commonly. The most common stone type is calcium oxalate. However, stones of mixed chemical composition (calcium oxalate and calcium phosphate) are often observed. The risk factors for stone disease in patients with hyperparathyroidism are hypercalciuria (calcium excretion >4 mg/kg lean body weight over 24 hours) and a tendency to waste bicarbonate, which leads to a relatively alkaline urine. Precipitation of calcium phosphate is favored in an alkaline urine. Whether mild hyperparathyroidism directly impairs renal function is unclear. In the majority of patients with this disease followed conservatively, renal function remains stable.

The classic skeletal presentation of hyperparathyroidism is osteitis fibrosa cystica, which is defined as the combination of subperiosteal bone resorption, especially in the distal phalanges and skull; bone cysts; brown tumors of the long bones; osteoporosis; and fractures. This form of bone disease is now uncommon, occurring in less than 5% of patients. However, more than 50% of otherwise asymptomatic patients with hyperparathyroidism eventually develop progressive bone loss and are at risk for osteoporosis. Thus, bone mineral density should be measured in all patients with hyperparathyroidism. Cortical bone is more sensitive to the effects of hyperparathyroidism, so bone mineral density in the distal forearm and hip is typically more severely affected than is bone mineral density in the spine.

Patients with severe hyperparathyroidism can develop muscle weakness and myopathy. Patients with mild disease often complain of weakness, fatigue, listlessness, and trouble concentrating. However, the specificity and origin of these symptoms are debated. Occasionally, patients with hyperparathyroidism develop acute or subacute monarticular inflammatory arthritis resulting from calcium pyrophosphate dihydrate crystal arthropathy. Finally, some reports suggest that patients with hyperparathyroidism have excess body fat, are insulin resistant, and suffer from an increased incidence of cardiovascular events. Serum levels of the inflammatory cytokine interleukin-6 (IL-6), which has been linked to insulin resistance and adverse cardiac outcomes, are elevated in patients with hyperparathyroidism. Thus, it is possible that IL-6 provides a pathogenic link between hyperparathyroidism and these complications.

DIAGNOSIS

The diagnosis of hyperparathyroidism is made by documenting simultaneous elevations in the circulating levels of calcium and PTH in a patient with normal renal function. If abnormalities of serum proteins are noted, it may be necessary to measure ionized calcium to be certain that hypercalcemia is present. Again, C-terminal fragments of PTH are excreted by the kidney and may accumulate in renal failure. Historically, this was a problem in assays that used antisera directed at the mid-region or C-terminal portions of PTH and therefore gave falsely elevated results in patients with renal insufficiency. Newer, "biointact" PTH assays avoid this problem and should be used to measure PTH in any patient with abnormal renal function. Patients with hyperparathyroidism also may have slightly low or low-normal serum phosphorus concentrations and mild hyperchloremic metabolic acidosis. Alkaline phosphatase levels may be elevated in patients with overt bone disease.

Once a diagnosis of hyperparathyroidism is made, patients should be screened for end-organ complications. Renal ultrasonography or spiral computed tomography (CT) scans can be used to determine whether the patient has kidney stones. Bone mineral density should be measured to detect skeletal disease, preferably using dual-energy x-ray absorptiometry, at the spine, hip, and wrist. A 24-hour urine collection should be performed to determine whether hypercalciuria is present. Hyperparathyroid myopathy can be diagnosed by electromyography.

TREATMENT

Rx

Surgery is the only curative treatment for hyperparathyroidism. Traditionally, this involved bilateral neck exploration, during which the surgeon identified all four parathyroid glands before resecting the abnormal gland. However, minimally invasive parathyroidectomy has been supplanting traditional neck exploration in referral centers. This requires preoperative localization of the offending adenoma. Technetium-99m-sestamibi scans, ultrasonography, four-dimensional CT scans, and magnetic resonance imaging can all be used as preoperative localization studies; we prefer the first two. If parathyroid hyperplasia is suspected, a minimally invasive approach is not appropriate because the surgeon must remove either three and a half parathyroid glands or all four glands, with autotransplantation of some parathyroid tissue to the forearm. Complications of parathyroid surgery include damage to the recurrent laryngeal nerve and permanent hypoparathyroidism. Activity of the unaffected parathyroid glands is suppressed by the hypercalcemia associated with hyperparathyroidism, and the remaining glands take several days to recover normal secretory activity after removal of an adenoma. This can result in postoperative hypocalcemia in the first 24 to 48 hours. If significant bone disease is present, the influx of calcium into the skeleton as it heals following parathyroid adenomectomy can lengthen the duration and increase the severity of hypocalcemia. This phenomenon is known as the *hungry bones syndrome.* Operative and postoperative complications are much less frequent when parathyroidectomy

is performed by an experienced surgeon. Therefore, patients should be referred to centers that perform this operation frequently.

Many patients with mild hyperparathyroidism are asymptomatic and have no evidence of end-organ damage. In addition, many patients with mild forms of the disease do not develop more severe disease over time. Therefore, not all patients necessarily benefit from surgery. However, concern lingers over the possibility of excess vascular disease in these patients, as well as the subtle neurocognitive effects ascribed to hyperparathyroidism in some studies. In addition, the most recent studies found that up to 59% of initially asymptomatic patients developed a greater than 10% decline in bone mineral density at one or more sites over a 15-year period of observation. Given the ongoing uncertainty about this topic, a group of international experts met for the third time in 2008 to review and update guidelines for parathyroidectomy first formulated by a National Institutes of Health consensus conference in 1990. Table 253-2 lists the criteria for surgery in otherwise asymptomatic patients, and Table 253-3 provides the guidelines for managing nonsurgical patients as suggested by the 2008 international workshop. These guidelines are not rigid, and each patient must be approached with his or her unique circumstances in mind. Studies have demonstrated that most patients who do not meet the criteria for surgery remain stable from the standpoint of biochemical parameters, although many patients develop progressive cortical bone loss after 10 to 15 years of follow-up. Up to 37% of asymptomatic patients eventually develop signs of progressive disease. Therefore, patients who do not undergo surgical treatment should have annual measurements of serum calcium and serum creatinine and bone density measurements every year or every other year. If patients demonstrate worsening of hypercalcemia, deterioration of renal function, or progressive bone loss, they should be referred for surgery.

Medical management of hypercalcemia is discussed further in the Treatment section for Hypercalcemia of Malignancy. Several adjunct medical therapies exist for patients who meet the criteria for surgery but either decline parathyroidectomy or are poor operative candidates. Maintenance of hydration and physical activity are important in all patients. Bisphosphonates and estrogen replacement therapy have been shown to prevent and even reverse, to a limited extent, low bone mass in patients with hyperparathyroidism. Finally, cinacalcet can lower serum calcium levels in patients with primary hyperparathyroidism. This drug is an allosteric activator of CaR and directly inhibits PTH release by parathyroid adenomas. Cinacalcet showed good efficacy in controlling serum calcium in a 1-year randomized clinical trial in patients with this disease. Normalization of serum calcium continued for up to 5 years of therapy in an open-label extension of this trial.[1] However, cinacalcet does not normalize PTH levels or prevent bone loss, so its role in the long-term management of primary hyperparathyroidism remains uncertain.

Hypercalcemia of Malignancy

DEFINITION

The most common cause of elevated calcium levels in hospitalized patients is MAHC. MAHC has two pathophysiologic subgroups: humoral hypercalcemia of malignancy (HHM), which is caused by tumor cell secretion of a bone-resorbing factor (usually PTHrP) into the systemic circulation; and local osteolytic hypercalcemia (LOH), which is caused by localized bone resorption surrounding tumor cells within the skeleton. HHM is also discussed in Chapter 186.

TABLE 253-2 GUIDELINES FOR PARATHYROID SURGERY IN ASYMPTOMATIC PRIMARY HYPERPARATHYROIDISM: THIRD INTERNATIONAL WORKSHOP, 2008

Serum calcium >1.0 mg/dL above upper limit of normal
Reduction of creatinine clearance to <60 mL/min
Bone mineral density T-score <−2.5 at any site and/or previous fragility fracture
Age <50 yr

TABLE 253-3 GUIDELINES FOR MONITORING PATIENTS WITH ASYMPTOMATIC HYPERPARATHYROIDISM NOT MEETING CRITERIA FOR SURGERY: THIRD INTERNATIONAL WORKSHOP, 2008

Measurement of serum calcium annually
Measurement of serum creatinine annually
Measurement of bone density at spine, hip, and forearm every 1-2 yr

EPIDEMIOLOGY

Hypercalcemia, a frequent complication of cancer, occurs in up to 20 to 30% of patients during the course of their malignant disease. MAHC is usually a manifestation of advanced disease, and investigators have estimated that patients with MAHC have a 50% 30-day mortality. HHM is classically associated with squamous cell tumors of the lung, head and neck, esophagus, and cervix; urothelial malignant diseases (both renal cell and transitional cell); and breast cancers. However, almost every tumor type has been reported to secrete PTHrP and to cause HHM. LOH is most frequently diagnosed in patients with multiple myeloma or breast cancer.

PATHOBIOLOGY

The principal cause of hypercalcemia in MAHC is increased bone resorption. In HHM, patients have a generalized increase in osteoclast number and activity, whereas in LOH, osteoclast number and activity are increased only in the vicinity of skeletal metastases. In both instances, hypercalcemia develops when the efflux of calcium from the skeleton exceeds the kidneys' ability to excrete the excess calcium that enters the ECF. Patients with MAHC often suffer from nausea and anorexia and have hypercalcemia-induced polyuria. Therefore, dehydration is an important component of the presentation of all patients with MAHC.

In most cases, HHM is caused by the secretion of PTHrP into the systemic circulation by tumor cells. As noted earlier, PTH and PTHrP bind and activate PTH1R with equal affinity. Thus, when PTHrP gains access to the systemic circulation, it activates the PTH1R in the bone and stimulates bone resorption throughout the skeleton, as occurs in hyperparathyroidism. However, in contradistinction to patients with hyperparathyroidism, patients with HHM have suppressed bone formation. Because no compensatory increase in bone formation occurs, patients with HHM tend to be more severely hypercalcemic than are patients with hyperparathyroidism. Another important biochemical difference between these two diseases is that in HHM, $1,25(OH)_2$ vitamin D levels are either low-normal or low, so intestinal calcium absorption is not increased. Therefore, bone is the main and often the sole source of the excess calcium in this disease.

In LOH, tumor cells within the skeleton secrete various cytokines into the local microenvironment, which recruit new osteoclasts into the area surrounding the tumor cells. This process leads to osteolysis, which releases growth factors from the bone matrix that stimulate the growth of the adjacent tumor cells. This pernicious positive feedback loop sustains the pathologic bone resorption, leads to expansion of the bone metastasis, and can ultimately result in local pain and pathologic fracture. Once the size and number of metastases reach a point at which the amount of calcium released from the skeleton exceeds the kidneys' ability to excrete it, systemic hypercalcemia ensues. Much research has been directed at elucidating the nature of the osteoclast-activating factors secreted by bone metastases. In the case of multiple myeloma, several cytokines, including MIP-1α, transforming growth factor-α, IL-1, IL-3, IL-6, and CD47, have been implicated. More recent work has suggested that myeloma cells also secrete Dickkopf 1 (DKK-1), an inhibitor of the Wnt signaling pathway that suppresses osteoblast activity and bone formation. In the case of breast cancer, local production of PTHrP, IL-8, and IL-11 may be important in mediating osteolysis.

DIAGNOSIS

Patients with HHM typically present with moderate to severe elevations in serum calcium levels, low to low-normal levels of serum phosphorus, low levels of $1,25(OH)_2$ vitamin D, suppressed levels of PTH, and elevated circulating levels of PTHrP. These patients, by definition, have no (or only a few) skeletal metastases. In contrast, patients with LOH have many skeletal metastases. They have moderate to severe hypercalcemia, but they do not have elevations in PTHrP; they also have normal serum phosphorus concentrations. Because MAHC is a late manifestation of malignant disease, the offending tumor is usually clinically obvious, and detailed laboratory investigations are not needed. However, because hyperparathyroidism is common in the general population, it should be ruled out by measuring PTH levels in all hypercalcemic patients, even those with cancer. In patients with suspected HHM, documentation of elevated PTHrP levels confirms the diagnosis. This approach is not needed in all cases, but it can be helpful in patients with unusual tumor types and for the rare occurrence of HHM in association with benign tumors.

TREATMENT

Rx

Rehydration is the first step in the acute treatment of MAHC. This often requires the infusion of isotonic saline at rates of 200 to 300 mL/hour, and it should be accompanied by close monitoring of electrolytes and cardiovascular status. Once volume depletion is corrected, treatment with loop diuretics can be initiated to induce natriuresis, which increases renal calcium excretion. Rehydration and forced saline diuresis can result in a lowering of the serum calcium on the order of 1 to 1.5 mg/dL. The only cure for MAHC is successful treatment of the underlying malignant disease; hypercalcemia resolves with successful surgery or chemotherapy. If the tumor cannot be successfully treated, pharmacologic therapy can be used to lower calcium levels transiently. Because the principal cause of MAHC is increased bone resorption, antiresorptive drugs have the greatest efficacy in this condition. Calcitonin is the most rapidly acting antiresorptive agent. It can be given in doses of 4 to 8 IU/kg subcutaneously or intramuscularly every 6 to 12 hours. This treatment can lower serum calcium levels by 1 to 2 mg/dL within several hours, but tachyphylaxis to calcitonin occurs within 24 to 48 hours. Bisphosphonates are now the standard treatment for MAHC. Pamidronate was once the most commonly used medication for this purpose. The intravenous infusion of 60 or 90 mg pamidronate begins to lower serum calcium after 24 to 72 hours, and nadir calcium levels are reached within 5 to 6 days. Up to 70% of patients experience a normalization of calcium levels that can last up to 18 days. More recently, zoledronate has become the treatment of choice. Intravenous infusions of 4 to 8 mg zoledronate result in the normalization of calcium within 3 to 5 days in approximately 90% of patients, with a duration of response up to 32 days. In a head-to-head trial, zoledronate resulted in more rapid and more durable remission of hypercalcemia in patients with MAHC than did pamidronate. The use of a humanized, neutralizing monoclonal antibody to RANKL (denosumab) for the treatment of MAHC is currently under investigation. Dialysis against a calcium-free bath can be useful in patients with MAHC and renal failure or in patients who cannot tolerate bisphosphonates.

TABLE 253-4 CAUSES OF HYPOCALCEMIA

HYPOCALCEMIA RESULTING FROM REDUCED OR ABSENT PTH SECRETION
Surgical damage or destruction of parathyroid glands
Infiltrative diseases and deposition of heavy metals
High-dose radiation
Failure of organogenesis: DiGeorge sequence
Idiopathic hypoparathyroidism
Molecular abnormalities in PTH gene (loss-of-function mutations)
Molecular abnormalities in calcium-sensing receptor gene (gain-of-function mutations)
Autoimmune polyglandular syndrome type 1
Functional defects in PTH secretion
HYPOCALCEMIA RESULTING FROM RESISTANCE TO THE ACTIONS OF PTH
Pseudohypoparathyroidism
Hypomagnesemia
HYPOCALCEMIA IN THE SETTING OF NORMAL OR INCREASED SERUM PTH LEVELS AND NORMAL PTH RECEPTOR FUNCTION
Hypocalcemia induced by hyperphosphatemia
Nutritional vitamin D deficiency
Vitamin D malabsorption
Loss-of-function mutations in 1α-hydroxylase enzyme
Hereditary resistance to $1,25(OH)_2$ vitamin D
Hypocalcemia resulting from accelerated skeletal mineralization (hungry bones syndrome)
Medical illness (sepsis)
Medications

PTH = parathyroid hormone.

HYPOCALCEMIA

DEFINITION

Hypocalcemia is defined as an abnormally low serum concentration of ionized calcium.

PATHOBIOLOGY

Hypocalcemia can be caused by abnormalities of PTH availability, result from PTH resistance due to PTH receptor or postreceptor defects, or occur in the setting of normal or increased PTH activity and normal PTH receptor function. A full listing of the causes of hypocalcemia is given in Table 253-4. Selected disorders are discussed in the following subsections.

Hypocalcemia Resulting from Abnormalities of Parathyroid Hormone Availability

Various congenital or acquired disorders can lead to developmental failure of the parathyroid glands, failure of functional hormone production, or destruction of the glands. These disorders all manifest as hypocalcemia, usually with attendant hyperphosphatemia and undetectable or inappropriately low levels of circulating PTH.

Destruction of the Parathyroid Glands

Surgical destruction of the parathyroid glands is the most common cause of hypoparathyroidism. Given the close anatomic relationship of the parathyroid glands with the thyroid, complete or near-complete extirpation of the thyroid gland (Chapter 233) for the management of either Graves' disease or thyroid cancer can be complicated by the destruction or vascular compromise of parathyroid tissue and varying degrees of hypoparathyroidism. Aggressive surgical treatment of head and neck cancer can also cause parathyroid damage. Permanent destruction of the parathyroid glands should be a rare complication of neck surgery; for experienced surgeons, it occurs with a frequency of less than 10%. More common is transient parathyroid dysfunction—so-called stunned parathyroids—which can cause a decline in total serum calcium of 1 mg/dL in the first 24 to 48 hours postoperatively. The presumed cause is temporary vascular compromise or mechanical damage to the glands.

Infiltrative diseases, granulomatous diseases, metastases to the parathyroids, and deposition of heavy metals are all uncommon but recognized causes of parathyroid destruction and hypoparathyroidism. Although the parathyroid glands are quite resistant to radiation, hypoparathyroidism following radioactive iodine treatment for hyperthyroidism has been described.

Hypomagnesemia

Magnesium is an important cofactor for PTH secretion; it is apparently required for the release of stored hormone from secretory granules. In severe cases of hypomagnesemia (i.e., serum levels <1 mg/dL), suppressed parathyroid secretion can occur. This is most often seen in chronic gastrointestinal disease; in nutritional deficiency, especially alcoholism; or with *cis*-platinum therapy. Resistance to the actions of PTH at the level of bone and kidney may also contribute to the hypocalcemia seen with magnesium deficiency. Replenishment of magnesium stores promptly restores parathyroid function to normal.

Idiopathic Hypoparathyroidism

Isolated failure of parathyroid gland development is a rare genetic cause of hypoparathyroidism. Molecular abnormalities in PTH biosynthesis can cause genetic absence of the hormone in the presence of apparently normal parathyroid glands. In addition, activating mutations in the CaR can lead to inappropriate suppression of PTH secretion, a condition referred to as *autosomal dominant familial hypocalcemia.* In affected individuals, the mutant receptor constitutively signals and leads to the continuous suppression of PTH secretion, despite hypocalcemia.

Autoimmune Polyglandular Syndrome Type 1

This autoimmune disorder is characterized by the early development of hypoparathyroidism in association with Addison's disease and mucocutaneous candidiasis. Most affected individuals manifest hypocalcemia by age 10 years. In addition to Addison's disease, one third of these patients develop other endocrine disorders such as diabetes mellitus, pernicious anemia, or premature ovarian failure. This disorder is now known to be caused by mutations in the gene encoding an autoimmune regulatory protein (AIRE).

Autoimmune Hypoparathyroidism Caused by Antibodies to the Calcium-Sensing Receptor

Following cloning of the CaR, a few cases have been reported in which the presence of antibodies to the CaR appeared to cause hypoparathyroidism. In this situation, the antibody is thought to directly activate the CaR, thereby suppressing parathyroid secretion. These cases are rare. Although antibodies

to the CaR have also been reported with variable and usually low frequency in autoimmune polyglandular syndrome type 1, it remains unclear what role, if any, these antibodies play in the pathogenesis of the hypoparathyroidism seen in that disorder.

Hypocalcemia Resulting from Resistance to the Actions of Parathyroid Hormone

Pseudohypoparathyroidism

Peripheral tissue resistance to PTH was classically termed *pseudohypoparathyroidism* (PHP). The characteristic biochemical manifestations of PHP are hypocalcemia and hyperphosphatemia, just as in parathyroprivic hypoparathyroidism; however, circulating levels of PTH are elevated, rather than low or undetectable. The renal tubule is the primary site of PTH resistance, although variable degrees of skeletal resistance have also been reported. When the skeleton retains sensitivity to PTH, lesions characteristic of hyperparathyroidism, including osteitis fibrosa cystica, can develop. PTH stimulates renal cyclic adenosine monophosphate (cAMP) production, and levels of cAMP increase in the urine following administration of the hormone. A direct correlation has been demonstrated between the degree of PTH resistance (as assessed by the magnitude of the change in cAMP excretion or renal phosphate threshold) and the ambient circulating PTH level.

The renal cAMP response is the basis of a diagnostic test that allows the partial classification of this heterogeneous group of disorders. Individuals with PHP who demonstrate a blunted urinary cAMP response have type I PHP. Those who generate a normal cAMP response have type II PHP.

PHP type I has been further characterized as types Ia, Ib, and Ic. Type Ia describes those individuals with the Albright's hereditary osteodystrophy phenotype, defined by short stature and large frame, broad facies, and shortened fourth metacarpals (Fig. 253-4). Soft tissue calcifications and multiple endocrine abnormalities are often present. These individuals frequently have a mutation in the α-subunit of the stimulatory guanine nucleotide binding regulatory protein G_s. This regulatory protein couples membrane receptors to adenylate cyclase, thereby regulating receptor-dependent cAMP production. The presence of G_s in various cell types accounts for the generalized hormone resistance that may occur. Affected patients often have elevated thyrotropin levels with a compensated euthyroid state. Variable degrees of gonadotropin, antidiuretic hormone, adrenocorticotropic hormone, and glucagon resistance have been described. Patients with type Ib PHP have only PTH resistance, without the Albright's hereditary osteodystrophy phenotype. It has been suggested that this phenotype may result from abnormalities in the tissue-specific imprinting of the G_s α gene, such that $G_{s\alpha}$ function is specifically lost in the kidney but retained in other tissues. Patients without a mutation in $G_{s\alpha}$ but with associated hormonal abnormalities and/or Albright's hereditary osteodystrophy have been classified as having type Ic PHP. The catalytic subunit of adenylate cyclase is a possible site for the defect in this latter condition.

Type II PHP appears to result from a variety of defects distal to cAMP generation in the intracellular PTH signaling cascade. No distinct phenotype exists, although various autoimmune findings have been described in some patients. Other investigators have suggested that a circulating PTH inhibitor may play a role in the pathogenesis of PHP, indicating that this inhibitor may be generated by parathyroid tissue itself. Resistance to PTH has also been described in hypomagnesemia, as noted earlier.

Hypocalcemia in the Setting of Normal or Increased Parathyroid Hormone Activity and Normal Receptor Function

Despite normal PTH function and downstream signaling from its receptor, hypocalcemia can still result from disturbances in skeletal homeostasis, vitamin D metabolism, and a variety of medical illnesses.
